CHAPTER 137

Lung Cancer

DEBORAH A. FRIEZE AND VAL R. ADAMS

KEY CONCEPTS

1. Lung cancer is the leading cause of cancer deaths in both men and women in the United States. The overall 5-year survival rate for all types of lung cancer is approximately 15%.
2. Cigarette smoking is responsible for most lung cancers. Smoking cessation should be encouraged, particularly in those receiving curative treatment (i.e., stages I to IIIA non–small cell lung cancer and limited-stage small cell lung cancer).
3. Non–small cell lung cancer (NSCLC) is diagnosed in most (~80%) lung cancer patients. NSCLC typically has a slower growth rate and doubling time than small cell lung cancer (SCLC).
4. No screening test is currently recommended to identify lung cancer. However, several studies are evaluating different methods of screening in an attempt to diagnose lung cancer at an earlier stage, when it should be more curable.
5. Treatment decisions are guided by the stage of disease, which is characterized by tumor size and spread. Patient-specific factors (i.e., performance status, co-morbid conditions, etc.) must also be considered when developing a treatment plan.
6. The treatment goals in lung cancer are cure (early-stage disease), prolongation of survival, and maintenance or improvement of quality of life through alleviation of symptoms.
7. Early-stage lung cancer has the highest cure rates when surgical resection of the tumor is used with or without chemotherapy for NSCLC and chemoradiotherapy for SCLC.
8. Advanced-stage lung cancer is primarily treated with systemic therapy. Doublet chemotherapy regimens are superior in response to single-agent regimens and should be used when the patient can tolerate the associated toxicity. Platinum-containing doublets are first-line treatment in most cases of NSCLC and SCLC.
9. Optimal patient care needs to include prevention and treatment of adverse events from chemotherapy. Adverse events may cause delays in chemotherapy administration, increase morbidity, and contribute to treatment failure.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Lung cancer is a major cause of morbidity and mortality. It has reached epidemic proportions in many industrialized countries and is the most frequently fatal malignancy in the world. It is estimated that 222,520 new cases of lung cancer were diagnosed in the United States in 2010.[1] Despite major advances in the understanding and management of lung cancer, the overall 5-year survival rate for all types of lung cancer remains a dismal 15%. In the United States, lung cancer is estimated to account for approximately 15% of all newly diagnosed cancer in adults.[2] 1 It remains the leading cause of cancer death in both adult men and women, with about 157,300 deaths in 2010.[1] The incidence and death rate caused by lung cancer are declining in men, but the incidence recently plateaued and mortality continues to increase in women. Since 1987, lung cancer has surpassed breast cancer as the primary cause of cancer death in American women. In comparison to whites, the incidence of lung cancer is greater in African Americans, and the mortality rate is greater in African American men, but lower in African American women.[1]

The incidence of lung cancer increases with age, with peak age of diagnosis being between 55 and 65 years.[1] Among patients 40 years of age and older, the likelihood that a solitary pulmonary nodule seen on chest radiography is carcinoma is high, and this probability increases proportionately with age. Patients with lung cancer may undergo surgery, chemotherapy, radiation, or multimodality therapy, depending on the histological type of the tumor, its size and location, and the presence of metastases at diagnosis. Two leading oncology groups representing leading clinicians in the United States have published clinical practice guidelines for the treatment of lung cancer. The National Comprehensive Cancer Network (NCCN) has developed consensus-based guidelines that provide recommendations regarding the screening, staging, and treatment of both small cell lung cancer (SCLC) and non–small cell lung cancer (NSCLC).[3,4] The American Society of Clinical Oncology first published evidence-based guidelines regarding the staging and treatment of NSCLC in 1997, which were subsequently updated in 2003; they updated the stage IV NSCLC guideline in 2009.[5] In addition, the Agency for Healthcare Research and Quality has published an evidence report regarding the management of SCLC.[6] The American College of Chest Physicians (ACCP) also recently published evidence-based clinical practice guidelines.[7]

ETIOLOGY

Lung carcinomas arise from normal bronchial epithelial cells that have acquired multiple genetic lesions and are capable of expressing a variety of phenotypes.[2] Recently, significant advances have been made in understanding the molecular genetic changes involved in lung cancer pathogenesis.[2] A large variety of molecular lesions result in abrogation of key cellular regulatory and growth control pathways. Activation of a proto-oncogene, inhibition or mutation

of tumor suppressor genes, and production of autocrine (self-stimulatory) growth factors contribute to cellular proliferation and malignant transformation.[2] Many of the autocrine loops and proto-oncogene and tumor suppressor gene changes are common to both SCLC and NSCLC, but certain mutations are found more frequently in each subtype of lung cancer. These unique tumor characteristics may offer more targeted interventions to prevent or treat lung cancer. For example, of the autocrine loops, SCLC frequently overexpresses c-KIT, whereas NSCLC frequently overexpresses epidermal growth factor receptor (EGFR).[2,8] EGFR inhibitors, such as erlotinib, are used clinically to treat NSCLC (see Human Epidermal Growth Factor Receptor Inhibitors) and offer a potential method of lung cancer chemoprevention. Properly designed clinical trials are necessary, however, as demonstrated by the lack of efficacy of imatinib in the treatment of SCLC. Although imatinib inhibits c-KIT kinase in several SCLC lines, no responses occurred in patients with SCLC overexpressing c-KIT.[9]

2 Smoking is a major cause of lung cancer, with approximately 80% of lung cancer deaths in the United States directly attributed to tobacco use. Tobacco smoke contains many substances, including tumor promoters, carcinogens, and co-carcinogens.[2,10] Many of these carcinogens cause lung tumors in laboratory animals or humans and are likely to be involved in induction of lung cancer. Most cases of NSCLC and SCLC are caused by cigarette smoking, although cigars and pipes are also carcinogenic.[2,10] Smoking cessation is associated with a gradual decrease in the risk, but more than 5 years is necessary before an appreciable decline in risk occurs.[2,10] Although smoking cessation substantially reduces the risk of lung cancer, the risk is never lowered to that of a nonsmoker. Because of the public health implications, the United States has several, mainly state-led, tobacco control efforts, including antismoking campaigns, increased tobacco taxes, and smoke-free areas in many public areas. Continued efforts are needed as the prevalence of cigarette smoking has slowly decreased but was estimated to be approximately 18% in 2008.[11] The association between environmental tobacco smoke (ETS, also referred to as passive smoking) and lung cancer risk in nonsmokers in not as clear. Most studies have consistently found that spouses of smokers have higher rates of lung cancer than spouses of nonsmokers (~25% higher risk). Additionally, data from workplace exposure to environmental smoke seems to increase the risk of lung cancer by ~17%. The current estimates are that ETS contributes to approximately 3,000 lung cancers annually. Although many of these studies have flaws, the data seem consistent and seem to indicate a dose–risk relationship, with no safe level of exposure.[12]

Although most cases of lung cancer are attributable to cigarette smoking, less than 20% of smokers develop lung cancer, which suggests that other risk factors are relevant. An increased risk of lung cancer has been associated with exposure to other environmental respiratory carcinogens (e.g., asbestos, benzene). Genetic risk factors are also important, with an increased risk of lung cancer observed in those with first-degree relatives diagnosed with the disease. Lung cancer risk is associated with polymorphisms that affect the expression and/or function of enzymes regulating metabolism of tobacco carcinogens, DNA repair, or inflammation. Patients with a history of chronic obstructive airway disease and adults with asthma are at an increased risk for lung cancer.[1,2,7,12] Gathering data to better identify which patients are at highest risk of developing lung cancer will be key for new lung cancer screening trials and in chemoprevention trials.

HISTOLOGIC CLASSIFICATION

Before treatment begins, it is critical that an experienced lung cancer pathologist reviews the pathological material because of the different treatment regimens for NSCLC and SCLC. 3 NSCLC is diagnosed in most (80%) lung cancer patients. NSCLC typically has a slower growth rate and doubling time than SCLC. The World Health Organization Classification of Lung Cancer is widely accepted (Table 137–1). In the most recent update of this classification, adenocarcinoma was further subclassified, the definition of bronchioalveolar carcinoma was restricted to noninvasive tumors, and large cell neuroendocrine carcinoma was recognized histologically as a high-grade NSCLC.[2,4]

Four major cell types of carcinomas (squamous cell, adenocarcinoma, large cell, and small cell) account for more than 90% of all lung tumors. Because squamous cell, adenocarcinoma, and large cell carcinomas have a similar overall prognosis and treatment strategy, they are frequently grouped together and referred to as NSCLC. Historically, NSCLC's treatment regimens did not differ between histology, but clinical trials with newer agents have shown differences in efficacy and toxicity with regard to histology. Consequently, knowledge concerning the histology is essential in optimizing drug therapy.[2,4]

TABLE 137-1 The World Health Organization/International Association for the Study of Lung Cancer Histologic Classification of Non-Small Cell Lung Carcinomas

1. Squamous cell carcinoma
   - Papillary
   - Clear cell
   - Small cell
   - Basaloid
2. Adenocarcinoma
   - Acinar
   - Papillary
   - Bronchioloalveolar carcinoma
     - Nonmucinous
     - Mucinous
     - Mixed mucinous and nonmucinous or indeterminate cell type
   - Solid adenocarcinoma with mucin
   - Adenocarcinoma with mixed subtypes
   - Variants
     - Well-differentiated fetal adenocarcinoma
     - Mucinous (colloid) adenocarcinoma
     - Mucinous cystadenocarcinoma
     - Signet ring adenocarcinoma
     - Clear cell adenocarcinoma
3. Large cell carcinoma
   - Variants
     - Large cell neuroendocrine carcinoma
     - Combined large cell neuroendocrine carcinoma
     - Basaloid carcinoma
     - Lymphoepithelioma-like carcinoma
     - Clear cell carcinoma
     - Large cell carcinoma with rhabdoid phenotype
4. Adenosquamous carcinoma
5. Carcinomas with pleomorphic, sarcomatoid, or sarcomatous elements
   - Carcinomas with spindle and/or giant cells
   - Spindle cell carcinoma
   - Giant cell carcinoma
   - Carcinosarcoma
   - Pulmonary blastoma
6. Carcinoid tumor
   - Typical carcinoid
   - Atypical carcinoid
7. Carcinomas of salivary gland type
   - Mucoepidermoid carcinoma
   - Adenoid cystic carcinoma
   - Others
8. Unclassified carcinoma

Adapted from references 13 and 14.

Squamous cell carcinoma was once the most common histology but is now estimated to constitute less than 30% of all lung cancers. Squamous cell carcinomas have a much higher incidence in smokers and among males and appear to have a strong dose-response relationship to tobacco exposure. The majority of these tumors occur centrally, but the incidence of peripheral presentation is increasing. Although they can grow rapidly, most squamous cell carcinomas tend to be slow growing and confined to the lungs (especially early in the disease course). Such tumors may eventually metastasize to the hilar and mediastinal lymph nodes, liver, adrenal glands, kidneys, bone, and gastrointestinal tract.[2,4]

Adenocarcinoma accounts for about one-half of lung cancers and is increasing in frequency. As outlined in Table 137–1, there are several subclassifications of adenocarcinoma, and mixed histologies predominate. The importance of these subtypes to treatment is currently limited, but newer targeted therapies may work best in certain subtypes, thus allowing more individualized treatment selection. For example, erlotinib is generally effective in adenocarcinoma, but it appears to be most effective in patients with the bronchioloalveolar subtype of adenocarcinoma. Adenocarcinoma is the most common subtype in nonsmoking lung cancer patients. Patients with adenocarcinoma can present with a single nodule, multifocal nodules, or rapidly progressing, bilateral, diffuse processes. This histology is likely to metastasize at an early stage (often before the diagnosis of the primary tumor) and spread widely to distant sites, including the contralateral lung, liver, bone, adrenal glands, kidneys, and central nervous system. As a result, adenocarcinoma has a worse prognosis than squamous cell carcinoma; however, the prognosis is similar when controlled for stage.[2,4]

Large cell carcinomas are undifferentiated epithelial tumors, which are often a diagnosis of exclusion. These tumors tend to be large and bulky tumors arising in the periphery of the lung, have a propensity to metastasize in a pattern quite similar to adenocarcinomas, and are associated with a similar poor prognosis.[2,4]

Small cell carcinomas account for approximately 15% of all lung tumors. Nearly all SCLCs are immunoreactive for keratin, epithelial membrane antigen, and thyroid transcription factor 1, and many stain positively for markers of neuroendocrine differentiation. They are distinguished by a proliferation of neoplastic cells with round to oval nuclei. These tumors occur in both the major bronchi and the periphery of the lung. SCLC is a very aggressive and rapidly growing tumor, with approximately 60% to 70% of patients initially presenting with disseminated disease outside of the hemithorax. These tumors commonly express neuroendocrine differentiation, which may account for some of the paraneoplastic syndromes frequently associated with this disease. SCLC secretes gastrin-releasing peptide that acts as an autocrine growth factor. Secretion of other peptide hormones, cytogenetic abnormalities, and amplification and increased expression of oncogenes are also common. This disease has a propensity to metastasize to the lymph nodes, opposite lung, liver, adrenal glands and other endocrine organs, bone, bone marrow, and central nervous system.[2,3]

Lung can exhibit more than one histological cell type (e.g., adenosquamous), which may impact therapy. Occasionally, patients can also have multiple lung nodules arising in different lobes or the contralateral lung. They can be the same or different histology. This is referred to as synchronous tumors, and the nodules may be of similar or different cell types. This usually worsens the patient's overall prognosis.

CLINICAL PRESENTATION

At the time of diagnosis, 16% of lung cancers are localized, 25% have regional spread, and 51% have distant metastases (the remaining were not staged).[1] Location and extent of the tumor determine the presenting signs and symptoms. A lesion in the central portion of the bronchial tree is more likely to cause symptoms at an earlier stage as compared with a lesion in the periphery of the lung, which may remain asymptomatic until the lesion is large or has spread to other areas. The most common initial signs and symptoms include cough, dyspnea, and chest pain or discomfort, with or without hemoptysis.[2] Unfortunately, many patients with lung cancer also have chronic pulmonary and/or cardiovascular diseases (usually related to smoking), and such symptoms may go unnoticed or be attributed to the concomitant disease. Many patients also exhibit systemic symptoms of malignancy such as anorexia, weight loss, and fatigue. Disseminated disease can cause extrapulmonary signs and symptoms such as neurological deficits resulting from CNS metastases, bone pain or pathological fractures secondary to bone metastases, or liver dysfunction resulting from tumor involvement in the liver.[2]

CLINICAL PRESENTATION OF LUNG CANCER

Local Signs and Symptoms Associated with Primary Tumor or Regional Spread within the Thorax

- Cough
- Hemoptysis
- Dyspnea
- Rust-streaked or purulent sputum
- Chest, shoulder, or arm pain
- Wheeze and stridor
- Superior vena cava obstruction
- Pleural effusion or pneumonitis
- Dysphagia (secondary to esophageal compression)
- Hoarseness (secondary to laryngeal nerve paralysis)
- Horner's syndrome
- Phrenic nerve paralysis
- Pericardial effusion/tamponade
- Tracheal obstruction

Extrapulmonary Signs and Symptoms Associated with Metastatic Involvement

- Bone pain and/or pathologic fractures
- Liver dysfunction
- Neurologic deficits
- Spinal cord compression

Paraneoplastic Syndromes

- Weight loss
- Cushing's syndrome
- Hypercalcemia (most commonly in squamous cell lung cancer)
- Syndrome of inappropriate secretion of antidiuretic hormone (most commonly in SCLC)
- Pulmonary hypertrophic osteoarthropathy
- Clubbing
- Anemia
- Eaton-Lambert's myasthenic syndrome
- Hypercoagulable state

Paraneoplastic syndromes are signs and symptoms that occur at sites away from the primary tumor or its metastases and are not associated with direct tumor involvement. They may be caused

by the production of biologically active substances (e.g., peptide hormones) or antibodies, or by other undefined mechanisms. Paraneoplastic syndromes occur more frequently with lung cancer than with any other tumor, and more frequently with SCLC than with NSCLC. These syndromes may be the first signs of a tumor and may prompt the search for an underlying malignancy.[2]

SCREENING AND PREVENTION

4 Most lung cancer patients are diagnosed with advanced disease, which is a key factor in the poor prognosis associated with this disease. Surgery (NSCLC) and radiation (SCLC) are the most effective treatment modalities, which generally limits curative intent to patients diagnosed at an early clinical stage.[2–4] Therefore, it is important to diagnose lung cancer earlier through screening and identify early signs and symptoms. Several screening techniques, including computed tomography (CT) and positron emission tomography (PET) scanning, are being investigated to detect lung cancer at an earlier stage.[13] However, screening is not part of the current recommendations. The current approach is based on diagnosing lung cancer in patients who present with signs and symptoms. Patients interested in screening should be enrolled in a clinical trial.

The term *chemoprevention* refers to the use of prophylactic medications to prevent the development of cancer. Many studies of potential chemopreventive agents, including nonsteroidal anti-inflammatory drugs (NSAIDs), retinoids, inhaled glucocorticoids, vitamin E, selenium, and green tea extracts, have been conducted, but none have been successful.[14] Large randomized clinical trials have evaluated β-carotene as a lung cancer chemopreventive agent in high-risk patients (older smokers). Rather than prevent lung cancer, the trials clearly show that older people who smoke have a higher risk of developing and dying of lung cancer if they take a β-carotene supplement. Nonsmokers do not appear to have an altered risk of lung cancer with β-carotene consumption.[8] The impact of selenium and/or vitamin E supplementation was evaluated in older men as part of a large prostate cancer prevention study (SELECT trial).[15] Unfortunately, no benefit was seen with selenium or vitamin E supplementation.[8,15]

Since screening and chemoprevention trials have not yet proven to provide a survival benefit, the current recommendation is to avoid smoking and maintain a healthy diet with high amounts of fruits and vegetables.[16]

DIAGNOSIS

A patient suspected of have lung cancer should undergo a diagnostic evaluation. Diagnosis of lung cancer requires both visualization of the cancerous lesion and tissue sampling for pathological assessment. All patients must have a thorough history and physical examination with emphasis on detecting signs and symptoms of the primary tumor, regional spread of the tumor, distant metastases, and paraneoplastic syndromes. The patient's performance status should be assessed to determine whether or not a patient may be able to tolerate surgery and/or chemotherapy.[2–4]

Visualization of the suspected tumor provides the clinician with the information necessary to choose the most appropriate sampling technique. Chest radiographs, endobronchial ultrasound, CT scans, and PET scans are among the most valuable diagnostic tests.[17] Chest radiography is the primary method of lung cancer detection and may also be used to measure tumor size, establish gross lymph node enlargement, and detect other tumor-related findings, such as pleural effusion, lobar collapse, and metastatic bone involvement of ribs, spine, and shoulders. In addition, CT may be helpful in the evaluation of parenchymal lung abnormalities, detection of masses only suspected on the chest radiography, and assessment of mediastinal and hilar lymph nodes. PET scans are more accurate than CT scans in distinguishing malignant from benign lesions, detecting mediastinal lymph node metastases, and identifying metastatic spread. Most recently, the use of integrated CT-PET technology has been reported to improve the diagnostic accuracy in the staging of NSCLC over either CT or PET technology alone.[18]

Once the tumor has been located, pathological examination of tumor tissue is necessary to establish the diagnosis of lung cancer. Tissue is typically obtained through the least invasive method likely to result in an adequate sample; methods include sputum cytology, tumor biopsy by bronchoscopy, mediastinoscopy, percutaneous needle biopsy, or open-lung biopsy. The tissue sample not only confirms malignancy but is also necessary to determine the histology (i.e., squamous cell, adenocarcinoma, large cell, or small cell). Once the diagnosis is established, additional radiologic tests may be required to evaluate lymph nodes and potential metastatic sites for accurate staging. Surgical candidates will have additional sampling of their mediastinal nodes to determine those with stage IIIB (N_3) disease (Table 137–2).[2–4,18]

STAGING

5 Once the diagnosis of lung cancer is confirmed, the extent of disease must be determined to estimate prognosis and guide therapy. For NSCLC, tumor growth and spread are staged with the American Joint Committee on Cancer (AJCC) tumor, node, and metastasis (TNM) staging system. Small cell lung cancer is typically staged with the Veterans Administration Lung Cancer Study Group method.[2–4,18]

NON–SMALL CELL LUNG CANCER

Clinical staging of NSCLC with the TNM system evaluates the size of the tumor, extent of nodal involvement, and presence of metastatic sites. The TNM criteria have recently been updated,[19] and went into effect in January 2010.[4] The combination of these three evaluations determines the stage. Clinical stages and associated survival rates are described in Table 137–2. For comparison of various therapeutic modalities, a simpler stage grouping system is used in which stage I refers to tumors confined to the lung without lymphatic spread; stage II refers to large tumors with ipsilateral peribronchial or hilar lymph node involvement; stage III includes other lymph node and regional involvement; and stage IV includes tumor with distant metastases. Local disease is associated with the highest cure and survival rates, whereas those with advanced disease have less than a 10% 5-year survival rate.

SMALL CELL LUNG CANCER

The most commonly used system of staging SCLC was developed originally by the Veterans Administration Lung Cancer Study Group. This system categorizes SCLC into two stages: limited and extensive disease. When evidence of the tumor is confined to a single hemithorax and can be encompassed by a single radiation port, the disease is considered limited. Any progression beyond this point is extensive disease. Approximately 60% to 70% of patients initially present with extensive stage disease. The initial pretreatment evaluation of an SCLC patient should include a medical history, a clinical examination, and laboratory survey, as well as a CT scan of the chest, abdomen, and head. Typically the approach is to identify tumor spread that would demonstrate extensive stage, at which time the workup can stop. For patients without extrathoracic disease identified by these tests, a bone scan and bone marrow biopsy should be performed to confirm limited-stage disease.[2,3]

TABLE 137-2 Tumor (T), Node (N), Metastasis (M) Staging for Non-Small Cell Lung Cancer

Primary Tumor	Description
T_1	Tumor ≤3 cm diameter, surrounded by lung or visceral pleura, without invasion more proximal than lobar bronchus
T_{1a}	Tumor ≤2 cm in diameter
T_{1b}	Tumor >2 cm but ≤3 cm in diameter
T_2	Tumor >3 cm but ≤7 cm, or tumor with any of the following features: – Involves main bronchus, ≥2 cm distal to carina – Invades visceral pleura – Associated with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung
T_{2a}	Tumor >3 cm but ≤5 cm
T_{2b}	Tumor >5 cm but ≤7 cm
T_3	Tumor >7 cm or any of the following: – Directly invades any of the following: chest wall, diaphragm, phrenic nerve, mediastinal pleura, parietal pericardium, main bronchus <2 cm from carina (without involvement of carina) – Atelectasis or obstructive pneumonitis of the entire lung – Separate tumor nodules in the same lobe
T_4	Tumor of any size that invades the mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, carina, or with separate tumor nodules in a different ipsilateral lobe
Regional lymph nodes (N)	
N_0	No regional lymph node metastases
N_1	Metastasis in ipsilateral peribronchial and/or ipsilateral hilar lymph nodes and intrapulmonary nodes, including involvement by direct extension
N_2	Metastasis in ipsilateral mediastinal and/or subcarinal lymph node(s)
N_3	Metastasis in contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s).
Distant metastasis (M)	
M_0	No distant metastasis
M_1	Distant metastasis
M_{1a}	Separate tumor nodule(s) in a contralateral lobe; tumor with pleural nodules or malignant pleural or pericardial effusion
M_{1b}	Distant metastasis

Stage	T	N	M	5 Yr Survival
Stage IA:	T_{1a}-T_{1b}	N_0	M_0	73%
Stage IB:	T_{2a}	N_0	M_0	58%
Stage IIA:	T_{1a}, T_{1b}, T_{2a}	N_1	M_0	46%
	T_{2b}	N_0	M_0	
Stage IIB:	T_{2b}	N_1	M_0	36%
	T_3	N_0	M_0	
	T_{1a}, T_{1b}, T_{2a}, T_{2b}	N_2	M_0	
Stage IIIA:	T_3	N_1,N_2	M_0	24%
	T_4	N_0,N_1	M_0	
Stage IIIB:	T_4	N_2	M_0	9%
	Any T	N_3	M_0	
Stage IV:	Any T	Any N	M_{1a} or M_{1b}	13%

TREATMENT

6 The treatment of lung cancer depends on tumor histology, stage of disease, and patient characteristics such as age, history, and performance status.[2] These aspects must be assessed before appropriate treatment can be recommended. In the development of a patient care plan, keep in mind the ultimate goals of therapy. In patients with early-stage disease, a definitive cure is the primary goal of treatment, although this end point is not always met. Additional goals of treating lung cancer patients include prolongation of survival and improvement of quality of life through alleviation of symptoms. The goals of treatment must be considered when selecting a therapeutic plan. Delivering a treatment that may prolong survival by a few months but at the expense of toxicity that significantly decreases patient quality of life may not be the best approach. Treatment decisions must include both the healthcare team and an informed and well-counseled patient.

NON–SMALL CELL LUNG CANCER

If left untreated, most patients with NSCLC will die within 1 year of diagnosis. Surgery, radiation therapy, and systemic therapy with cytotoxic chemotherapy or targeted therapies are all used in the management of NSCLC patients. The applications of these treatment modalities are determined by stage and other patient-specific factors (e.g., age, performance status).[2,4] A list of commonly used chemotherapy regimens including doses and schedules can be seen in Table 137–3.[4,5]

Local Disease (Stages 1A, 1B, and IIA)

7 Local disease is associated with a favorable prognosis, and the goal of therapy is cure. Surgery is the mainstay of treatment and may be used alone or in some situations with radiation and/or chemotherapy. Patients who have comorbid conditions preventing them from being surgical candidates can be treated with radiation in place of surgery with curative intent, although the cure rates are lower. Stage IA tumors are treated with surgery alone; adjuvant therapy has not been studied adequately to know if it is beneficial. If surgical margins are positive, re-resection is recommended, alternatively patients may receive radiotherapy with or without chemotherapy.[2,4,5]

CLINICAL CONTROVERSY

The benefit of adjuvant cytotoxic chemotherapy for patients with stage I NSCLC is unclear. Adjuvant cytotoxic chemotherapy improves overall survival in patients with later stages (i.e., stage II to IIIA) NSCLC. However, limited numbers of patients with stage IA are enrolled in these trials, and the data do not suggest a survival benefit. Additional clinical trials are needed to clarify the role of adjuvant chemotherapy for patients with stage IA NSCLC.

Stage IB, IIA, and IIB disease is primarily treated with surgery, which should be followed by adjuvant chemotherapy. Although trials evaluated patients with stage IB tumors (Table 137–4), the benefit in this subset of patients is unclear. A recent guideline recommends that patients with IB tumors and high-risk features (poorly differentiated tumors, vascular invasion, wedge resection, minimal margins, tumors > 4 cm, or visceral pleural involvement) should receive chemotherapy. Patients who have positive or questionable margins may receive radiation therapy, which is typically administered with the adjuvant chemotherapy. The adjuvant treatment regimen of choice is not clear, but the positive clinical trials used platinum-based regimens, with arguably the best data coming from cisplatin-vinorelbine (Table 137–4).[4,20–26] The benefit in terms of 5-year overall survival in large randomized trials ranges from

TABLE 137-3 Common Chemotherapy Regimens Used to Treat Lung Cancer

Non-small cell lung cancer[3]	
Carboplatin/Paclitaxel/Bevacizumab	Carboplatin AUC 6 IV mg/mL/min on day 1 Paclitaxel 200 mg/m2 IV on day 1 Bevacizumab 15 mg/kg IV on day 1 Repeat cycle every 3 weeks – Continue bevacizumab until progression
Carboplatin/Pemetrexed	Carboplatin AUC 5 mg/mL/min IV day 1 Pemetrexed 500 mg/m^2 IV day 1 Repeat cycle every 3 weeks
Cetuximab/cisplatin/vinorelbine	Cetuximab 400 mg/m^2 IV 1st dose day 1, then 250 mg/m^2 IV weekly Cisplatin 80 mg/m^2 IV on day 1 Vinorelbine 25 mg/m^2 IV on day 1 and day 8 Repeat cycle every 3 weeks
Cisplatin/paclitaxel (CP)	Cisplatin 75 mg/m^2 IV day 1 Paclitaxel 175 mg/m^2 over 24 hours IV day 1 repeat cycle every 21 days[42] *or* Cisplatin 80 mg/m^2 IV day 1 Paclitaxel 175 mg/m^2 IV over 3 hours day 1 repeat cycle every 21 days[87]
Gemcitabine/cisplatin (GC)	Gemcitabine 1,000 mg/m^2 IV days 1, 8, 15 Cisplatin 100 mg/m^2 IV day 1 repeat cycle every 28 days[42]
Gemcitabine/cisplatin (GCq21)	Gemcitabine 1,200 mg/m^2 days 1 and 8 Cisplatin 80 mg/m^2 IV day 1 repeat cycle every 21 days[88] *or* Gemcitabine 1,250 mg/m^2 days 1 and 8 Cisplatin 80 mg/m^2 IV day 1 repeat cycle every 21 days[87]
Docetaxel/cisplatin (DC)	Docetaxel 75 mg/m^2 IV day 1 Cisplatin 75 mg/m^2 IV day 1 repeat cycle every 21 days[42]
Paclitaxel/carboplatin (PCb)	Paclitaxel 225 mg/m^2 over 3 hours IV day 1 Carboplatin AUC 6 mcg*h/mL IV day 1 repeat cycle every 21 days[42,43] *or* Paclitaxel 175 mg/m^2 IV over 3 hours day 1 Carboplatin AUC 6 mcg*h/mL IV day 1 repeat cycle every 21 days for 6 cycles[89]
Vinorelbine/cisplatin (VC)	Vinorelbine 25 mg/m^2 IV weekly Cisplatin 100 mg/m^2 IV day 1 repeat cycle every 28 days[43] *or* Vinorelbine 30 mg/m^2 IV days 1 and 8 Cisplatin 80 mg/m^2 IV day 1 repeat cycle every 21 days[88]
Etoposide/cisplatin (EP)	Etoposide 100 mg/m^2 IV days 1, 2, and 3 Cisplatin 100 mg/m^2 IV day 1 repeat cycle every 28 days[32]
Vinorelbine/gemcitabine (VG)	Vinorelbine 25 mg/m^2 IV days 1 and 8 Gemcitabine 1,000 mg/m^2 days 1 and 8 Repeat cycle every 21 days[88,90]
Paclitaxel/gemcitabine (PG)	Paclitaxel 175 mg/m^2 IV over 3 hours day 1 Gemcitabine 1,250 mg/m^2 days 1 and 8 repeat cycle every 21 days[87]
Gemcitabine/docetaxel (GD)	Gemcitabine 1,000 mg/m^2 IV days 1 and 8 Docetaxel 100 mg/m^2 IV day 8 repeat cycle every 21 days[91]
Paclitaxel/vinorelbine (PV)	Paclitaxel 135 mg/m^2 IV day 1 Vinorelbine 25 mg/m^2 IV day 1 repeat cycle every 14 days for 9 cycles[89]
Small cell lung cancer[4]	
Etoposide/cisplatin (EP)	Cisplatin 80 mg/m^2 IV day 1 Etoposide 100 mg/m^2 IV days 1, 2, and 3 repeat cycle every 3 weeks[83,92] *or* Cisplatin 60 mg/m^2 IV day 1 Etoposide 120 mg/m^2 IV days 1, 2, and 3 repeat cycle every 3 weeks[84]
Cisplatin/irinotecan (IP)	Cisplatin 60 mg/m^2 IV day 1 Irinotecan 60 mg/m^2 IV days 1, 8, and 15 repeat cycle every 4 weeks[83,92] *or* Cisplatin 30 mg/m^2 IV day 1 Irinotecan 65 mg/m^2 IV days 1 and 8 repeat cycle every 3 weeks[84]

TABLE 137-4 Adjuvant Chemotherapy for Early Stage Lung Cancer

Trial	Stage	Number of Participants	Treatment Arms	Number of Cycles	Postoperative Radiotherapy	5-Year Survival	*P* Value
BLT[23,25]	I–IV	381	Observation		Per individual institutional policy	60% (2-year)	0.90
			Cisplatin plus vindesine; mitomycin/ifosfamide; mitomycin/vinblastine; or vinorelbine	3		74% (2-year)	
IALT[20]	I–III	1,867	Observation		Per individual institutional policy	40.4%	0.03
			Cisplatin-based doublet (etoposide, vindesine, vinorelbine, vinblastine)			44.5%	
ALPI[23,25]	I–IIIA	1,209	Observation		Per individual institutional policy	No difference in overall survival	0.585
			Cisplatin, mitomycin, and vindesine	3			
ANITA[21]	I–IIIA	840	Observation		Per individual institutional policy	43%	0.017
			Vinorelbine/cisplatin	4		51%	
JBR.10[26]	IB–II	482	Observation		None	54%	0.002
			Vinorelbine/cisplatin	4		69%	
CALGB 9633[27]	IB	344	Observation		None	57%	0.32
			Paclitaxel/carboplatin	4		60%	

ALPI, Adjuvant Lung Cancer Project Italy; ANITA, Adjuvant Novelbine International Trialist Association; BLT, Big Lung Trial; CALGB, Cancer and Leukemia Group B; IALT, International Adjuvant Lung Cancer Trial; JBR.10, National Cancer Institute of Canada JBR10.10.

no benefit to 15%, with a recent systematic review reporting an absolute difference of 5%.[2,4,27] Adjuvant radiation should be avoided in patients who have clean margins, because it appears to have a detrimental effect.[2,4,22,28]

Locally Advanced Disease (Stages IIB and IIIA)

7 Patients with more advanced local disease should still be considered for surgery.[2,4] Adjuvant chemotherapy (Table 137–4) has become the standard and appears to improve overall survival.[20,27] In some situations, chemotherapy with concurrent radiotherapy can be used prior to surgery.[2,4] Although small studies have shown a survival benefit with neoadjuvant treatment, large definitive studies have not been performed. Consequently, this practice is not standardized and varies from institution to institution. Nonresectable locally advanced disease may be treated with both an active platinum-containing regimen and radiotherapy. Responding patients may then become surgical candidates. Patients who are not surgical candidates should be treated with concurrent chemotherapy and radiation. Adjuvant radiotherapy for patients with N_2 disease may be used; it decreases the incidence of local recurrence but has not been shown to prolong overall survival.[2,4,28]

Unresectable Stage IIIB or Stage IV Disease

8 About two-thirds of NSCLC patients present with advanced disease (unresectable stage IIIB or IV) at the time of diagnosis.[1,2] Most of these advanced tumors are not surgically resectable as a result of disseminated (multiple sites) metastatic disease or metastatic sites that are not amenable to surgery. Patients with single metastatic sites may undergo surgical resection of both the primary tumor and the metastatic site.[4]

Chemotherapy is the first-line therapy for most patients with advanced NSCLC. The intent of chemotherapy is to palliate symptoms, improve quality of life, and increase the duration of survival. Improved response rates, a modest increase in survival, and decreased toxicity profiles observed with many of the newer chemotherapy agents and combination regimens have led experts to agree that most patients with stage IV disease should receive at least one chemotherapy regimen.[2,4,5]

In the setting of advanced NSCLC, the benefits of cytotoxic chemotherapy—as measured by overall survival and quality of life—were not clearly established until the 1990s. The Non–Small Cell Lung Cancer Collaborative Group reported the pivotal results of a large meta-analysis encompassing more than 25 years and 52 clinical trials of chemotherapy in the management of NSCLC.[29] The results of this meta-analysis and other evidence suggest that chemotherapy, when combined with surgery or radiotherapy or both, improves median survival for patients with advanced stage NSCLC by 2 to 4 months and increases the 1-year absolute survival rate by 10% to 20%.[29,30] Several studies have compared chemotherapy to the best supportive care and have shown consistently better outcomes for chemotherapy.[2,30]

Both the NCCN[4] and American Society of Clinical Oncology guidelines[5] recommend first-line chemotherapy consisting of a doublet with a platinum (i.e., cisplatin or carboplatin) and a newer agent (i.e., gemcitabine, paclitaxel, docetaxel, vinorelbine, and premetrexed) (Table 137–3). Older non-platinum-containing regimens and regimens containing alkylating agents generally produce inferior outcomes.[30] For patients with a contraindication to a platinum agent, the guidelines recommend gemcitabine in combination with paclitaxel or docetaxel.[4,5]

The results of first-line chemotherapy in patients with advanced NSCLC depend on the patient's current performance status (ECOG performance status of 0–2), which appears to be the most consistent predictor of a better response and improved survival after chemotherapy. All patients with a good performance status without significant comorbidities, including elderly patients, should receive first-line doublet chemotherapy. Single-agent chemotherapy should be considered in those patients with an ECOG performance status 2 (PS-2) or significant comorbidities. Patients with poor ECOG performance status (≥ PS-3) do not respond well to chemotherapy. Patients with an unfavorable prognosis (poor performance status or significant concomitant diseases) should receive best supportive care and palliative radiation when necessary.[4,5,7,30]

First-line platinum-based doublet chemotherapy is usually administered for a total of four to six cycles in those patients whose NSCLC is stable or responding to chemotherapy. The optimal number of cycles remains controversial. Response rates and quality of life were not improved with administration of six as compared to three cycles of mitomycin, cisplatin, and vinblastine.[31] For those receiving paclitaxel-carboplatin (PCb), administration of chemotherapy until disease progression had no clinically significant benefit in survival, response rate, or quality of life, but increased toxicity as compared to administration of four cycles.[32] However, pemetrexed was recently approved as maintenance therapy in patients responding to a first-line platinum-containing regimen. The registry trial was performed in 663 patients randomized (2:1) to pemetrexed maintenance or no further therapy until relapse. The results show that pemetrexed maintenance therapy prolonged median overall survival (13.4 months vs. 10.6 months, $P = 0.012$).[33] Interestingly, the benefit was only seen in patients with nonsquamous histology, and the best results occurred in patients with adenocarcinoma (median survival 16.8 months vs. 11.5 for placebo, hazard ratio 0.73, 95% CI 0.56–0.96). This histology specificity is consistent with pemetrexed as first-line with cisplatin and also as second-line as monotherapy.[33] Another recently reported randomized phase III trial shows that maintenance therapy with erlotinib prolongs disease-free survival versus placebo (SATURN Study).[34] Interestingly, this study also appeared most effective in patients with adenocarcinoma histology. Although only one of these studies has been through the peer review process, both are compelling and will likely change the current practice of limiting treatment to four or six cycles of therapy in nonsquamous histology.[5,35]

Second-line chemotherapy is usually offered to those patients with an ECOG performance status of 0–2 who experience disease progression to or after first-line chemotherapy. Third-line therapy can be offered if disease progression continues in a patient with adequate performance status. Best supportive care is recommended by the NCCN guidelines for those patients with disease progression and ECOG performance status worse than 2.[4,5]

Single-Agent Chemotherapy Single-agent chemotherapy is an alternative in elderly patients or those with an ECOG performance status of 2.[4,5] First-line, single-agent chemotherapy has objective response rates of 5% to 25% with no significant effect on overall survival. Complete responses are rare and responses that do occur are of brief duration (i.e., 2 to 4 months months).[2,36] Among the most active cytotoxic chemotherapy agents in NSCLC are cisplatin, carboplatin, docetaxel, paclitaxel, etoposide, gemcitabine, ifosfamide, irinotecan, topotecan, mitomycin, vinblastine, vinorelbine, and pemetrexed.[4,5] The EGFR inhibitor erlotinib is also active as a single agent, as discussed later under Human Epidermal Growth Factor Receptor Inhibitors.[37]

Combination Chemotherapy 8 Response rates for combination chemotherapy regimens are generally higher than for single-agent therapy, but improvement in overall survival rates has not been consistently observed.[2,36] Combination chemotherapy regimens that have consistently reported response rates exceeding 30% have used various combinations of cisplatin, carboplatin, gemcitabine,

ifosfamide, or mitomycin, and vinblastine, vindesine, or vinorelbine (Tables 137–3 and 137–5). Some studies show that cisplatin dose may have an impact on tumor response, and the most widely recommended first-line regimens now include a platinum—either cisplatin or carboplatin—with a newer cytotoxic chemotherapy agent.

Until the mid-1990s, first-line chemotherapy with etoposide and cisplatin (EP) was regarded as the most active regimen in the treatment of advanced NSCLC. Subsequently, numerous randomized, controlled clinical trials demonstrated that a platinum-based doublet with a newer cytotoxic chemotherapy agent had superior response rates or median survival rates.[2,38] Each of these newer chemotherapeutic agents had single-agent activity of greater than 20% in NSCLC and include plant alkaloids (i.e., vinorelbine), taxanes (i.e., paclitaxel and docetaxel), antimetabolites (i.e., gemcitabine), antifolates (i.e., pemetrexed), and topoisomerase I inhibitors (i.e., topotecan and irinotecan).[39] Results from many published trials combining these new chemotherapy agents with platinum-based regimens suggest improved 1-year survival rates in advanced NSCLC of 30% to 40% versus 15% to 25% with older cisplatin-based combination regimens.[38,40,41] A pivotal intergroup study[38] compared four of these newer, more effective regimens, cisplatin-paclitaxel (CP) to gemcitabine-cisplatin (GC), docetaxel-cisplatin (DC), and carboplatin-paclitaxel (PCb). When considering survival, they were all deemed equivalent, but time-to-disease progression was highest with GC. When considering all grade 4 and 5 toxic effects, the PCb regimen was lowest at 57%. The investigators concluded that all four regimens are acceptable, but ECOG chose the PCb regimen for future studies due to the lower grade 4 and 5 toxicity.[38] Table 137–5 shows the outcomes of this study and other selected phase III trials of chemotherapy in patients with advanced NSCLC.[38,40,42–46]

A number of trials and meta-analyses have been performed to determine if carboplatin and cisplatin are equally effective or if one is more effective in NSCLC.[47–49] Individual clinical trials have produced equivocal data; even meta-analyses evaluating both agents disagree.[47,49] However, cisplatin appears to be slightly superior. In one meta-analysis of doublet regimens with a "newer" agent, cisplatin improved survival by 11% (P = 0.039).[48] Clinical trials comparing the two agents have also demonstrated a different toxicity profile; cisplatin is associated with more gastrointestinal (severe nausea and vomiting) and renal toxicity than carboplatin. However, carboplatin is associated with more hematologic toxicity (thrombocytopenia) than cisplatin.[49] Although neither is clearly superior to the other, many clinicians historically used carboplatin because of its more tolerable gastrointestinal toxicity, but over the past few years there seems to be a reversal toward increased use of cisplatin, which could be attributed to improved antiemetics (i.e., the neurokinin-1 receptor antagonist aprepitant).

Nonplatinum doublets (e.g., gemcitabine-paclitaxel and gemcitabine-docetaxel) have been evaluated in the setting of first-line therapy of advanced NSCLC. The results of a meta-analysis comparing platinum-based regimens with either the same regimen without the platinum or with the platinum replaced by another agent demonstrated that platinum provides a modest benefit.[50,51] One meta-analysis[51] evaluated 17 trials with a total of 4,792 patients and found a small but significant 1-year survival benefit with a platinum-based combination regimen compared with nonplatinum combination regimens (relative risk = 1.08, 95% CI 1.01–1.16). Further analysis of carboplatin regimens and cisplatin regimens demonstrated that benefit was only seen with cisplatin-based regimens.[51] Although platinum-based combination regimens remain the preferred treatment, non-platinum-based combinations are acceptable and recommended in patients with a contraindication to a platinum agent.

Addition of a third drug to a platinum doublet has been extensively studied. The combination of three cytotoxic agents has produced equivocal data when it comes to overall survival; however, most increase response rates and toxicity.[52] Because the goal of treatment for advanced-stage disease is to prolong life and improve quality of life, the use of three cytotoxic agents has not become a standard of care. However, the addition of a targeted agent to a platinum doublet appears to improve survival with acceptable increases in toxicity.[4,5,37,53] This is seen with both an EGFR inhibitor and a VEGF inhibitor, which are discussed later in separate sections.

TABLE 137-5 First-Line Combination Regimens in Stage IIIB or IV Non-Small Cell Lung Cancer

Reference	Number Evaluable/ Performance Status	Regimen	Overall Response Rate (%)	Median Survival Duration	Median 1-Year Survival (%)	Time to Disease Progression
Scagliotti et al.[44]	1725	GC	28.2%	10.3 mo	41.9%	5.1 mo
	All PS 0-1	Pem/C	30.6%	10.3 mo	43.5%	4.8 mo

	PS-0-2	PCb	46%	11 mo	43%	7 months

Pem/C, pemetrexed and cisplatin; CP, cisplatin and paclitaxel; DC, docetaxel and cisplatin; ECOG, Eastern Cooperative Oncology Group; EORTC, European Organization for Research and Treatment of Cancer; EP, etoposide and cisplatin; GC, gemcitabine and cisplatin; GCq21, gemcitabine and cisplatin repeated every 21 days; GD, gemcitabine and docetaxel; NR, not reported; PCb, paclitaxel and carboplatin; PG, paclitaxel and gemcitabine; PR, partial response; PS, performance status; PV, paclitaxel and vinorelbine; SWOG, Southwest Oncology Group; VC, vinorelbine and cisplatin; VG, vinorelbine and gemcitabine.

[a]Statistically significant difference.

[b]Statistically significant difference between CP and PG, but not CP and GCq21.

Historically, ECOG PS-2 patients were excluded from NSCLC trials because of excessive toxicity with minimal benefit from combination cytotoxic therapy. A recent randomized phase III trial[54] comparing single-agent weekly docetaxel (n = 171) to docetaxel/gemcitabine (n = 174) in elderly or poor performance status (35% of patients) had disappointing results. No survival differences were observed with docetaxel/gemcitabine versus weekly docetaxel in the 122 poor performance status patients (3.8 months vs. 2.9 months, respectively), and the median survival is short compared with good performance patients.[54] Another recent randomized phase III trial[55] compared single-agent gemcitabine (n = 85) to gemcitabine/carboplatin (n = 85) in PS-2 patients. The median overall survival was not different between gemcitabine and gemcitabine/carboplatin (5.1 months vs. 6.7 months, respectively). The authors concluded that single-agent therapy is still the standard in this setting.[55] The updated ASCO guidelines state that available data support the use of single-agent chemotherapy and data are insufficient to recommend combination therapy.[5] A recent meta-analysis shows that PS-2 patients benefit from treatment.[56]

In summary, cisplatin-based doublets improve survival and quality of life as compared with best supportive care or single-agent chemotherapy in patients with advanced NSCLC. The optimal combination regimen has not yet been identified. Non-platinum-based combination regimens are reasonable options and are recommended for patients with a contraindication to platinums.

Second-Line Chemotherapy Monotherapy with docetaxel, pemetrexed, or erlotinib are options for second-line therapy in patients with a good performance status who progress during or after first-line chemotherapy.[2,4,5] Erlotinib is a relatively nontoxic agent that targets the EGFR and is discussed later in the EGFR inhibitors section. Docetaxel was the first to receive FDA approval for the treatment of advanced NSCLC after failure of a platinum-based chemotherapy regimen. The initial docetaxel dose of 100 mg/m^2 IV over 1 hour every 21 days was decreased to 75 mg/m^2 after an interim analysis showed a greater risk of severe neutropenia with the higher dose. Docetaxel, at the 75 mg/m^2 dose, was superior to best supportive care in terms of time-to-disease progression (10.6 weeks vs. 6.7 weeks, P = 0.001), median survival (7.5 months vs. 4.6 months; P = 0.047), and 1-year survival (37% vs. 11%; P = 0.003).[57] Both doses had a statistically significant improvement in 1-year survival when compared with a control regimen of vinorelbine or ifosfamide (32%, 21%, and 19%, respectively).[58]

Subsequently, pemetrexed (Alimta) was FDA approved for second-line treatment of advanced NSCLC based on results of a phase III trial.[59] In that trial, 571 patients were randomized to receive either pemetrexed 500 mg/m^2 with folate and cyanocobalamin supplementation or docetaxel 75 mg/m^2. No significant differences in overall response rate, stable disease, or median survival between the pemetrexed and docetaxel arms were observed. Docetaxel had significantly more hematologic toxicities as compared with pemetrexed, leading to more hospitalizations and use of growth factors and erythropoiesis-stimulating agents. Patients receiving docetaxel had a significantly higher rate of alopecia, while patients receiving pemetrexed had a significantly higher elevation of alanine aminotransferase.[59]

CLINICAL CONTROVERSY

There is no consensus regarding the optimal second-line treatment of patients with NSCLC. Pemetrexed and docetaxel have similar response and survival rates. These two cytotoxic chemotherapy agents have differing toxicity profiles, which may help choose treatment for an individual patient.

Human Epidermal Growth Factor Receptor Inhibitors The human epidermal growth factor receptor (HER) family consists of four receptors that homo- or heterodimerize upon cytokine binding, enabling them to trigger cellular signaling events (i.e., proliferation, antiapoptosis, etc.). The EGFR (also known as HER1) was the first tyrosine kinase receptor within the HER family to be discovered. EGFR amplification or mutations lead to increased and/or aberrant signaling through downstream pathways, which are commonly observed in NSCLC. The signals most commonly studied and documented in cancer cells and tumors include proliferation and survival of cancer cells. Due to its apparent role in cancer, it quickly became a target for drug development. Today we have three EGFR-targeted agents that have a role in treating NSCLC. Gefitinib and erlotinib are small-molecule tyrosine kinase inhibitors. They bind to the intracellular ATP binding site on the receptor, preventing the receptor from stimulating signal transduction pathways. Cetuximab is a monoclonal antibody that binds to the extracellular portion of the receptor, blocking ligands from binding to the receptor; it also downregulates receptor expression and signaling through the receptor.[2]

Gefitinib (Iressa) was the first EGFR-targeted agent approved for NSCLC. The FDA approved the agent via fast-track designation to be used as monotherapy in patients who had failed a platinum-based combination regimen and docetaxel. However, the Iressa Survival Evaluation in Lung Cancer (ISEL) postmarketing trial (mandated by the FDA), failed to demonstrate a survival advantage for those receiving gefitinib as compared with best supportive care.[60] Thus the FDA has restricted the use of gefitinib to patients who continue to benefit from the medication or who are enrolled in a clinical trial.[61]

Erlotinib, which is structurally and functionally similar to gefitinib, was approved in November 2004 (after gefitinib) with the indication as a single agent for patients with advanced NSCLC whose disease progressed after at least one prior chemotherapy regimen. Its approval was based on an international, multicenter, randomized, double-blind phase III trial (BR.21)[37] in 731 patients with locally advanced or metastatic NSCLC who had failed at least one prior chemotherapy regimen. Patients were randomized to receive either erlotinib 150 mg or placebo orally once daily. Patients in the erlotinib group had a significantly higher objective response rate (9% vs. 1%, $P < 0.001$) and longer median progression-free and overall survival (9.9 weeks vs. 7.9 weeks, $P < 0.001$ and 6.7 months vs. 4.7 months [hazard ratio = 0.73], $P < 0.001$, respectively) than those in the placebo group. Patients in the erlotinib group also had significantly improved symptom control, specifically time to deterioration of cough, dyspnea, and pain.[37]

The potential benefit of adding erlotinib or gefitinib to doublet platinum-based chemotherapy has been studied. Both agents have been studied in two large, randomized, controlled trials, with each enrolling more than 1,000 patients.[62–65] Unfortunately, the results of all four trials showed that adding an EGFR inhibitor to platinum-based doublet therapy in first-line treatment of NSCLC did not improve efficacy.

Although these agents provide relatively modest benefits, some individual patients show a profound response. This has led researchers to investigate patient and/or tumor-specific factors that can be used to select patients likely to respond to an EGFR inhibitor. Consistent epidemiology findings show that patients who have the following characteristics are most likely to respond to EGFR inhibitors: never smokers, women, Asians, and those with adenocarcinoma histology, particularly the bronchial alveolar carcinoma subset of adenocarcinoma.[66] A recent study conducted in an Asian advanced lung cancer population compared first-line gefitinib to the combination of carboplatin and paclitaxel in patients with adenocarcinoma that were former light smokers (stopped > 15 years

prior and < 10 pack-year history) or never smokers.[67] Although median progression-free survival was similar for gefitinib and carboplatin-paclitaxel (5.7 vs. 5.8 months), the 1-year progression-free survival rates were 24.9% versus 6.7%. This trial found gefitinib to be noninferior to carboplatin-paclitaxel and superior based on progression-free survival. Additionally, less grade 3 or 4 toxicity occurred in the gefitinib arm (28.7% vs. 61%). A subset analysis of this study showed the greatest benefit occurred in patients with EGFR mutations.[67] This population does not represent the United States lung cancer patient population, and access to gefitinib is restricted to study patients in the United States, making its practical application unreasonable in general practice.[61] However, it validates that individualizing treatment can produce better results and has stimulated research in this area.

Preclinical and clinical data demonstrate that certain mutations in the kinase domain of EGFR (L858R and del746-750) are associated with significant responses to such agents.[68–70] The presence of other mutations in EGFR (T790M) is associated with resistance to such inhibitors through decreased drug binding to the receptor.[71] Finally, the presence of activating mutations in *K-Ras,* another oncogene which is known to play a role in lung cancer, is also associated with clinical resistance to EGFR inhibitors.[72] These findings have prompted some experts to suggest that patients should have their tumor assessed for EGFR and KRAS mutations to determine the appropriateness of an EGFR inhibitor therapy.[73] However, these molecular tests are not routinely used due to the lack of FDA-approved test kits, which limits the likelihood of third party reimbursement.

Cetuximab is a monoclonal antibody that binds to the extracellular portion of the EGFR receptor. The properties of cetuximab, an IgG1 antibody, include complement fixation and participation in antibody-dependent cellular cytotoxicity. These additional mechanisms of action suggest that it could be more effective than the small-molecule EGFR inhibitors. Recently, the results of adding cetuximab to cisplatin and vinorelbine as first-line treatment of advanced NSCLC have been reported. The primary end point in the study involving 1,125 patients showed that cetuximab prolonged median overall survival by 1.2 months (11.3 months vs. 10.1 months [hazard ratio for death 0.87, 95% CI 0.762–0.996; P = 0.044).[53] Although the study met the primary end point, some have questioned whether the survival advantage is large enough to justify an expensive drug that has toxicity, especially since the quality of life during the additional month has not been evaluated.[74]

Vascular Endothelial Growth Factor Inhibitors Vascular endothelial growth factor (VEGF) is important for the development of vasculogenesis required for tumor cell growth and metastasis, thus making it a key therapeutic target. Bevacizumab (Avastin®) is the recombinant, humanized monoclonal antibody that neutralizes VEGF. Preclinical trials demonstrate synergy when bevacizumab is combined with cytotoxic chemotherapy in a number of malignancies without untoward adverse effects. A phase II trial randomized 99 chemotherapy-naïve patients with advanced or recurrent NSCLC to bevacizumab 7.5 mg/kg or 15 mg/kg plus PCb or PCb alone.[75] Patients with CNS metastases, nonhealing wounds, significant cardiovascular disease, significant peripheral vascular disease, active secondary malignancy, pregnancy, or major surgery within 4 weeks of starting therapy, and those requiring anticoagulation were excluded from the trial because of concern over excessive toxicity to the angiogenesis inhibitor. An independent review faculty evaluated the data and found a response rate of 40%, 22%, and 31% and a median survival of 17.7 months, 11.6 months, and 14.9 months for the high-dose bevacizumab arm, the low-dose bevacizumab arm, and the control arm, respectively. Nineteen patients in the control arm crossed over to the bevacizumab monotherapy upon disease progression. Five patients had disease stabilization, and 12-month survival was 47% following crossover. Adverse effects of chemotherapy were not statistically different with the addition of bevacizumab. However, leucopenia, diarrhea, fever, headache, rash, and chills were slightly more common in the bevacizumab-containing arms. In addition, several patients in the bevacizumab arms developed hypertension, proteinuria, and bleeding. Bleeding events included minor mucocutaneous hemorrhage (most commonly grade 1 or 2 epistaxis) and major hemoptysis. Four patients died as a result of hemoptysis or hematemesis, two others experienced life-threatening bleeding complications. All six patients had centrally located tumors, five had vacitation or necrosis of tumors, and four of the patients had squamous cell carcinoma. A prospective, randomized trial evaluating the addition of bevacizumab 15 mg/kg to PCb was conducted by ECOG.[76] As a result of bleeding complications seen in the phase II trial, patients with squamous cell carcinoma or brain metastases were excluded. The addition of bevacizumab led to an improvement of progression-free survival from 4.5 months to 6.2 months (P < 0.001), median survival from 10.3 months to 12.3 months (P = 0.003), and 1-year survival from 44% to 51%. The risk of bleeding events was significantly higher in the bevacizumab-containing arm (4.4% vs. 0.7%, P < 0.001). Seventeen treatment-related deaths occurred during the study: 2 in the PCb group and 15 in the PCb-bevacizumab group. Other adverse events seen more frequently in the PCb-bevacizumab group include hypertension, neutropenia, febrile neutropenia, thrombocytopenia, hyponatremia, rash, and headache (P < 0.05).[76] NCCN guidelines recommend the addition of bevacizumab to chemotherapy for patients with advanced NSCLC of non–squamous cell histology, no history of hemoptysis, no CNS metastasis, and not receiving therapeutic anticoagulation.[4] Interestingly, a later study that randomized patients to cisplatin and gemcitabine with or without bevacizumab did not find any survival benefit with the addition of bevacizumab.[77] This trial indicates that bevacizumab is not synergistic with all chemotherapy regimens and consequently should only be used in combination with carboplatin and paclitaxel for lung cancer at this time.

Radiation Therapy Palliative radiotherapy with chemotherapy may be helpful in selected patients to control local and systemic disease and to reduce disease-related symptoms. Brain metastases are also commonly treated with radiotherapy; in the case of a solitary brain lesion, surgical resection may be used in conjunction with whole-brain radiation.[2,4,78]

Adverse effects of radiotherapy frequently result in severe esophagitis, pneumonitis, skin desquamation, myelopathies, cardiac abnormalities, and pulmonary toxicity in surrounding normal tissues. Improved radiotherapy delivery techniques, such as multiple daily radiation fractions (hyperfractionated accelerated radiation therapy) and three-dimensional treatment planning, allow delivery of greater dosage fractions specifically to the tumor site while decreasing the toxicity to surrounding normal tissues, as compared to standard radiotherapy. A phase III trial randomized patients with unresectable NSCLC to receive two cycles of PCb followed by either once daily radiation 64 Gy (6400 rad) delivered in 32 2-Gy (200 rad) fractions or hyperfractionated accelerated radiation therapy delivered three times a day for 15 days with a total dose of 57.6 Gy (5760 rad).[78] Of the 14 patients, the median survival for hyperfractionated accelerated radiation therapy arm was 20.3 months as compared to 14.9 months in the daily radiation arm (P = 0.28). Only 42% of the target accrual was met as a consequence of low patient accrual, difficulty in delivering hyperfractionated accelerated radiation therapy, mucosal toxicity, and data from other trials demonstrating the benefit of concurrent over the sequential radiotherapy.

Concurrent radiotherapy plus chemotherapy with radiosensitizing agents, such as cisplatin, paclitaxel, and gemcitabine, improves survival but further complicate the risks for severe toxicity, especially esophagitis.[79] Several trials have evaluated the use of sequential and concurrent chemoradiation, but the results of only one trial have been published. In that trial, Furuse et al. randomized 320 patients to chemotherapy (cisplatin, vindesine, and mitomycin) and radiation (56 Gy [5600 rad] delivered in 28 fractions) beginning on either day 2 of chemotherapy or following the completion of chemotherapy.[80] After a median followup of 5 years, median survival was significantly improved with concurrent chemoradiation when compared to sequential chemotherapy followed by radiotherapy (16.5 vs. 13.3 months, $P = 0.04$). Myelosuppression was increased in the concurrent arm as opposed to the sequential arm, while nonhematologic toxicities were similar between the two groups. Numerous randomized, combined modality trials continue to evaluate the optimal delivery method, schedule, and dosages for radiotherapy in concert with cisplatin and the newer chemotherapy agents.

EVALUATION OF THERAPEUTIC OUTCOMES

For patients who have undergone surgical resection with or without chemotherapy, radiation, or both, a physical examination and chest radiography are recommended every 3 to 4 months for the first 2 years, then every 6 months for 3 years, and then annually. In addition, a low-dose spiral chest CT scan is recommended annually to monitor for evidence of local recurrence. Suspicious symptoms or physical findings (e.g., bone pain, visual abnormalities, or headache, or elevated liver function tests) should prompt an evaluation to rule out distant metastases.[2,4,5]

Tumor response to chemotherapy is generally evaluated at the end of the second or third cycle and at the end of every second cycle thereafter. Patients with stable disease, with objective response, or with measurable decrease in tumor size (complete or partial response) should continue until four to six cycles have been administered. Responding patients with nonsquamous histology should be considered for maintenance therapy with pemetrexed. Following initial therapy for NSCLC, patients must be monitored for evidence of disease progression.[2,4,5]

TREATMENT

Small Cell Lung Cancer

SCLC is a rapidly dividing malignancy that spreads early in the disease course. Consequently, most patients present with extensive-stage disease (approximately 60% to 70% of new cases). When patients with SCLC are not treated, the disease quickly becomes fatal. Fortunately, small cell carcinomas are very responsive to chemotherapy and radiation. In the vast majority of patients, chemotherapy with or without radiotherapy is the treatment of choice. Even after a complete response to therapy, the cancer usually recurs within 6 to 8 months, and survival time following recurrence is typically short (~4 months). With treatment, median survival rates for patients with limited and extensive disease are 14 to 20 months and 9 to 11 months, respectively. Treatment planning starts with stage of disease (i.e., limited vs. extensive-stage), but must also take into account other factors, including: performance status (treatment usually restricted to PS-0 or PS-1 patients), patient age, comorbid conditions (e.g., renal failure), and patient desire to receive treatment.[2,3]

LIMITED DISEASE

7 When a single SCLC mass is found, local therapy with radiation or surgery would be considered. One of the factors differentiating SCLC and NSCLC is the fact that local disease is treated most commonly with radiation instead of surgery. Radiotherapy became the standard in 1969, when a randomized trial showed that it offered the potential for cure.[81] With improved radiologic imaging, there has been renewed interest in identifying patients who would benefit from surgery. There is currently no clear role for surgery in SCLC treatment. Due to the low cure rate with radiation alone, several studies have evaluated the addition of systemic chemotherapy to radiation. The regimen of choice for limited-disease SCLC is etoposide-cisplatin (EP). Carboplatin may be substituted for cisplatin to reduce nausea and vomiting, nephrotoxicity, or neurotoxicity,[82] although increased myelosuppression in the form of thrombocytopenia may result.[83] In patients who are able to tolerate combined therapy, concomitant chemoradiotherapy offers the most substantial survival benefit. In European countries, a three-drug combination containing an anthracycline has been the mainstay of therapy, but mounting clinical evidence shows that these regimens are inferior to EP plus concurrent radiation and have more toxicity.[84] Consequently, the guidelines recommend that the EP regimen be used with concurrent radiotherapy.[85] Since patients with SCLC commonly have a recurrence in the CNS, trials have been performed to evaluate the benefit of prophylactic cranial irradiation (PCI). A pivotal study showed that PCI reduces the incidence of brain metastasis and increases 3-year survival from 15% to 21%.[86,87] Therefore, patients who achieve a complete response with treatment should be offered PCI.

EXTENSIVE DISEASE

8 Platinum regimens are also the treatment of choice in extensive disease, and many studies have failed to show superiority to the EP regimen as first-line treatment. A combination of irinotecan and cisplatin in one Japanese study demonstrated an increased median survival time by approximately 3 months over the EP regimen. This regimen showed a lower incidence of severe neutropenic side effects but exhibited higher rates of moderate- to high-grade diarrhea.[88] However, this study was repeated in the United States and did not show a similar improvement over the EP regimen.[89] Therefore, EP remains the regimen of choice for treating extensive SCLC in the United States, with irinotecan and cisplatin being an acceptable alternative. Concurrent radiotherapy is not used routinely in extensive disease. However, a recent study that randomized extensive-stage patients responding to chemotherapy to observation or PCI reported that PCI decreased the 1-year risk of brain metastasis (14.6% vs. 40.4%), and prolonged survival (27.1% vs. 13.3% at 1 year).[90] This study led to guideline revisions recommending PCI for patients with extensive disease responding to chemotherapy.[3]

RECURRENT DISEASE

SCLC patients who relapse or progress after first-line chemotherapy have a median survival of 4 to 5 months. Unfortunately, when disease recurs, it is usually less sensitive to chemotherapy. The decision of whether or not to use second-line chemotherapy is often based on the length of time between completion of the induction chemotherapy regimen and relapse. If this interval is less than 3 months, the patient has refractory SCLC and is unlikely to respond to second-line therapy, hence they should receive best supportive care or be enrolled in a clinical trial. For those with greater than a 3-month time interval between first-line chemotherapy and relapse, the expected response rate to treatment is approximately

25%, and they should be treated.[2,3] Topotecan (intravenous and oral) are the only FDA-approved second-line therapy for SCLC. The pivotal trial[91] leading to the approval randomized patients to IV topotecan or the CAV regimen. The response rates (24% vs. 18%), time-to-progression (13 vs. 12 weeks), and overall survival (25 weeks vs. 25 weeks) were not different between groups. Interestingly, the proportion of patients experiencing symptom improvement was higher in the topotecan arm. The hematologic toxicity was similar between arms; there was slightly more neutropenia in the CAV arm and more anemia and thrombocytopenia in the topotecan arm. Nonhematologic toxicity appears to be higher in the CAV arm; 11% of patients required a dose reduction compared to 1% in the topotecan arm.[91] Oral topotecan appears to be equally effective and similar in terms of dosing, toxicity, and effectiveness as IV topotecan.[92] Based on these studies, one could consider topotecan the second-line treatment of choice, but due to the modest efficacy other agents warrant consideration. Agents that are recommended in national guidelines[3] include single-agent topotecan, irinotecan, gemcitabine, paclitaxel, docetaxel, and vinorelbine, as well as the CAV (cyclophosphamide, doxorubicin, and vincristine) regimen. These patients could also be enrolled in a clinical trial.

EVALUATION OF THERAPEUTIC OUTCOMES

The effectiveness of first-line therapy is evaluated after two to three cycles of treatment. At this point, therapy is continued for patients with a complete or partial response or stable disease, and discontinued or changed to a non-cross-resistant regimen in patients demonstrating evidence of progressive disease. The induction chemotherapy regimen is administered for four to six cycles if the SCLC is responsive. In those with a response, PCI should be offered. After recovery from first-line therapy, followup visits should occur every 3 months for years 1, 2, and 3, then every 4 to 6 months for years 4 and 5, then annually for patients with either a partial or complete response.[3]

COMPLICATIONS AND SUPPORTIVE CARE

Patients with lung cancer frequently have numerous concurrent medical problems. Such problems may be related to invasion of the primary tumor and its metastases, paraneoplastic syndromes (see clinical presentation earlier), chemotherapy and radiotherapy toxicity, or concomitant disease states (e.g., cardiac disease, renal dysfunction, chronic obstructive pulmonary disease, asthma, or diabetes). Depression is also common and sometimes persistent in patients with SCLC and NSCLC and should be treated. Identification, diagnosis, and treatment of the patient as a whole may improve the patient's overall quality of life and tolerance to cancer treatments.

9 The chemotherapy regimens used in the management of lung cancer are intensive and are associated with a wide variety of toxic effects. Nausea and vomiting may be severe. Cisplatin-containing regimens require the use of aggressive acute and delayed antiemetic regimens containing a serotonin antagonist, dexamethasone, and aprepitant.[93] Patients experiencing protracted nausea and vomiting may require intravenous hydration and nutritional support. Myelosuppression is often the dose-limiting toxicity associated with chemotherapy. Granulocytopenia places patients at a high risk for serious infections. Other toxic effects associated with these chemotherapy regimens include mucositis, anemia, nephrotoxicity, peripheral neuropathies, and ototoxicity.

Approximately 30% to 65% of advanced-stage NSCLC patients will develop bone metastases, which may lead to significant bone pain, pathological fractures, spinal cord compression, and hypercalcemia.[94] Zoledronic acid, an intravenously administered bisphosphonate, has been shown to reduce skeletal-related events in patients with bone metastases at a dose of 4 mg over 15 minutes infused every 3 weeks. Although the data do not show a significant reduction in skeletal-related events, time to first event is significantly increased (230 vs. 163 days for placebo, $P = 0.023$), thereby making zoledronic acid a viable therapy for patients with bone metastases.

Patients receiving radiation therapy may experience complications including severe esophagitis, fatigue, radiation pneumonitis, and cardiac toxicity. These toxicities are usually more common and severe when radiation is combined with chemotherapy. The patient's baseline performance status and the degree of pulmonary dysfunction (e.g., chronic obstructive pulmonary disease from years of tobacco use) must be considered in decisions concerning radiation dosage and fractionation.

It is readily apparent that many lung cancer patients receive complex pharmacologic regimens that may include chemotherapeutic agents, antiemetics, antibiotics, analgesics, anticoagulants, bronchodilators, corticosteroids, anticonvulsants, and cardiovascular agents. Such regimens necessitate intensive therapeutic monitoring in order to avoid drug-related and radiotherapy-related toxic effects and to optimize therapeutic outcome for individual patients.

CHAPTER 138

Colorectal Cancer

LISA E. DAVIS, WEIJING SUN, AND PATRICK J. MEDINA

KEY CONCEPTS

1. Maintaining a diet with high fiber and low fat intake has not been proven to reduce colorectal cancer risk but is beneficial for reducing risk of other chronic diseases.
2. Regular use of aspirin and other nonsteroidal antiinflammatory drugs, estrogen replacement therapy, and calcium and vitamin D supplementation may reduce risk of colorectal cancer in certain selected populations, but they are not currently recommended for routine cancer prevention.
3. Effective colorectal cancer screening programs incorporate regular examination of the entire colon starting at age 50 years for average-risk individuals. Colorectal adenomas can progress to cancer and should be removed.
4. The histologic stage of colorectal cancer upon diagnosis—determined by depth of bowel invasion, lymph node involvement, and presence of metastases—is the most important prognostic factor for disease recurrence and survival.
5. The treatment goal for stages I, II, and III colon cancer is cure; surgery should be offered to all eligible patients for this purpose.
6. Adjuvant therapy consisting of fluoropyrimidine-based chemosensitized radiation therapy should be offered to patients with stage II or III cancer of the rectum. Adjuvant fluoropyrimidine-based chemotherapy plus radiation decreases risk of local and distant disease recurrence as compared to observation alone.
7. Six months of fluoropyrimidine and oxaliplatin-based adjuvant chemotherapy significantly reduces the risk of cancer recurrence and overall mortality as compared with fluoropyrimidine alone in patients with stage III colon cancer.
8. Chemotherapy is palliative for metastatic disease. Fluoropyrimidine-based chemotherapy regimens, administered in a variety of schedules, provide a modest improvement in survival and can be highly beneficial in reducing patient symptoms.
9. Bevacizumab plus chemotherapy as initial therapy for metastatic disease is considered standard of care and provides a survival benefit compared with combination chemotherapy alone. A fluoropyrimidine with oxaliplatin or irinotecan improves survival compared to fluoropyrimidine monotherapy and should be offered to patients who are candidates for aggressive treatment. The ability for patients to receive all active cytotoxic agents (e.g., fluoropyrimidine, oxaliplatin, irinotecan) during the course of their disease improves their overall survival.
10. Capecitabine is an acceptable alternative to intravenous fluorouracil both in adjuvant therapy and in the setting of metastatic disease, as it provides similar efficacy and its oral dosing may offer greater patient convenience.
11. Individuals whose disease progresses or is refractory to chemotherapy may benefit from cetuximab, either alone or combined with continuing irinotecan. Patients with chemotherapy-refractory disease may also benefit from single-agent panitumumab. However, patients with codon 12 or 13 *KRAS* gene mutations should not receive cetuximab or panitumumab as these tumor mutations predict lack of treatment response. Tumor epidermal growth factor receptor (EGFR) immunohistochemistry test results do not predict tumor response to these agents.

Colorectal cancer involves the colon, rectum, and anal canal. It is one of the three most common cancers occurring in adult men and women in the United States and accounts for about one in nine cancer diagnoses. In 2010, an estimated 142,570 new cases will be diagnosed, of which 102,900 will involve the colon and 39,670 the rectum.[1] An additional 5,260 new cases of cancer involve the anus, anal canal, or anorectum.[1]

For both adult men and women, colorectal cancer is the third leading cause of cancer-related deaths in the United States. An estimated 51,370 deaths will occur during 2010.[1]

Mortality and incidence rates associated with colorectal cancer in the United States have decreased over the past 2 decades. Incidence rates vary worldwide, with recent increasing incidence rates in newer economically developed countries in eastern Europe, while incidence rates are relatively stable in longstanding economically developed countries in North America, western Europe, Australia, and Japan.[2] Colorectal cancer mortality rates are comparable between the United States, western Europe, and Japan.[2]

Multiple factors are associated with the development of colorectal cancer, including acquired and inherited genetic susceptibility, environmental elements, and lifestyle choices. Overall, approximately 39% of affected individuals undergo a surgical procedure alone intended for cure. An additional 37% of individuals can potentially be cured by undergoing surgery followed by adjuvant

radiation therapy (XRT), chemotherapy, or both. Curability is influenced primarily by depth of tumor penetration into adjacent tissues or organs, involvement of lymph nodes, and presence of metastatic disease. Five-year survival rates are close to 92% and 89% for persons with early stages of colon and rectal cancer, respectively.[3] After the tumor has spread regionally to adjacent lymph nodes or tissues, 5-year survival rates drop to 70% for colon cancer and to 67% for cancer of the rectum; 5-year survival for individuals with metastatic disease is approximately 12%.

Treatment modalities for colorectal cancer include surgery, XRT, chemotherapy, and other targeted molecular therapies (e.g., angiogenesis inhibitors, epidermal growth factor receptor inhibitors). Surgery is the important and definitive procedure associated with cure; XRT can improve curability following surgical resection in rectal cancer and may reduce symptoms and complications associated with advanced disease. Chemotherapy is used in adjuvant treatment regimens and in treatment for advanced stages of disease. Selected patients with advanced disease who receive aggressive preoperative chemotherapy experience higher resection rates and can be potentially cured. Much progress has been made in the treatment of advanced disease, in the ability to identify candidates for potentially curative surgical procedures, and the availability of active drug regimens that can improve patients' survival.

EPIDEMIOLOGY

Colorectal cancer is the third most common malignancy worldwide, accounting for an estimated 1,023,256 new cases annually.[4] The variation in colorectal cancer occurrence worldwide is at least 25-fold.[2] The highest incidence rates occur in the most highly developed areas such as Australia, New Zealand, North America, Japan, and western and northern Europe. Most recently, incidence rates have increased in newer economically developed countries in eastern Europe such as the Czech Republic and Slovakia.[2] The lowest incidence rates are seen in less-developed areas such as Africa, South Central Asia, and Central America. The influence of environmental factors (e.g., increased intake of caloric-dense foods and physical inactivity) on colorectal cancer risk has become evident through studies of migrants, where the incidence of colorectal cancer increases rapidly within first-generation immigrants who migrate from low- to high-risk areas.[2] However, colorectal cancers are known to develop more frequently in certain families, and genetic predisposition to this disease is also well recognized.

The incidence of invasive colon cancer is greatest among males, who have an age-adjusted incidence rate of 34.59 per 100,000, as compared with females for whom the rate is 29.72 per 100,000.[3] Invasive cancer of the rectum occurs less frequently; the incidence rate is 16.30 and 9.83 per 100,000 for males and females, respectively. Differences in colorectal cancer incidence exist among ethnic groups in American men and women. Although cancer of the colon and rectum is the third most frequent malignancy among white, African American, Asian American/Pacific Islander, and American Indian/Alaska Native males, it ranks second among Hispanic/Latino males.[1] In women, cancer of the colon and rectum is the second most frequent malignancy in African American, Asian American/Pacific Islander, American Indian/Alaska Native, and Hispanic/Latino females, but the third most common cancer in white females.[1] Cultural and genetic factors, as well as disparities in access to healthcare services, may influence risk among population groups.[1]

The overall incidence of colon and rectal cancers in the United States continues to decline, with an annual percent decrease of 2.6% from 1998 to 2007.[3] In almost every ethnic group, the decline in cancer incidence accelerated from 1999 to 2007. An increase in screening and polyp removal may contribute to a part of this trend. Figure 138–1 displays trends for incidence and mortality rates among white and African American males and females in the United States.

The median age at diagnosis is 70 years, with fewer than 20% of patients diagnosed younger than age 54 years.[3] An individual's risk increases with increasing age, and about 40% of cases develop in adults older than 75 years of age. The stage of disease at presentation is similar among different ethnic groups, although the tendency to present with later-stage disease is slightly higher for African Americans than in whites.

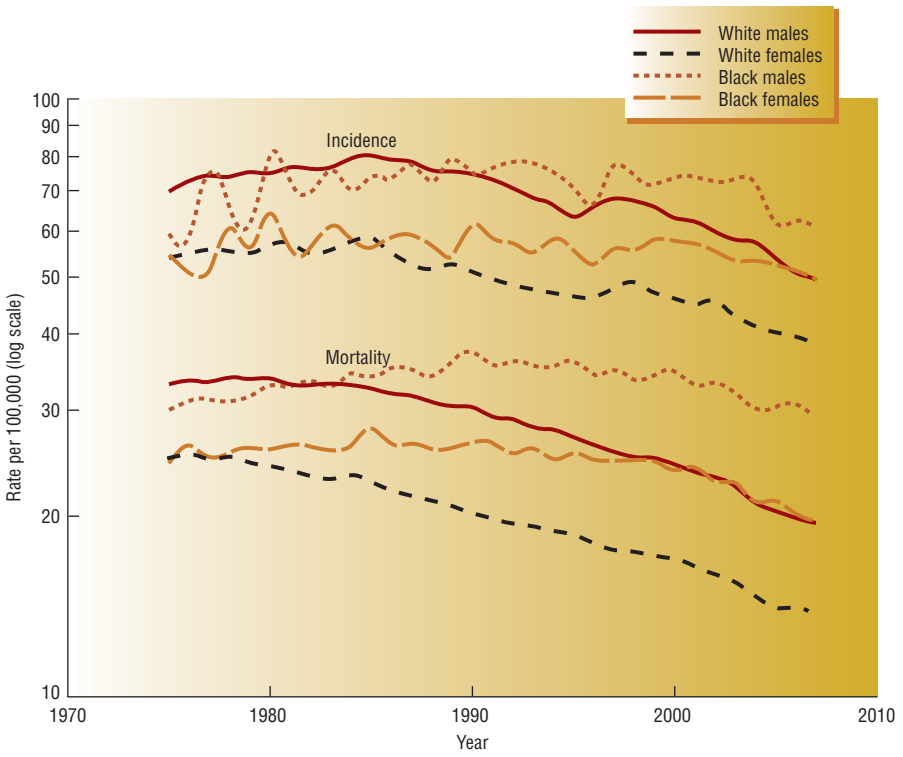

FIGURE 138-1. SEER incidence and mortality rates for invasive colon and rectum cancer, 1975-2007. Rates are per 100,000 and age-adjusted to the 2000 U.S. standard population. (*From reference* 3.)

Cancer of the colon and rectum accounts for approximately 10% of all cancer deaths in the United States. The median age for death from cancer of the colon or rectum is 75 years.[3] It is estimated that 51,370 individuals will die of colorectal cancer in the United States in 2010, which represents a continued decline in overall combined mortality for both colon and rectal cancer observed during the last 20 years. For women, the decline in colorectal cancer mortality rates has been evident since 1950, whereas death rates among men did not start to decline until the late 1970s.[3] Overall mortality rates are also higher among African American males and females, and the rates of decline are lower as compared to those among white, American Indian/Alaska Native, Asian/Pacific Islander, and Hispanic males and females.[3] Factors contributing to the overall decline in colorectal cancer mortality include decreasing incidence rates, screening programs with early polyp removal, and more effective and better tolerated treatments. Differences among different world geographic regions, and in population groups in the United States, may also reflect variations in underlying tumor biology, stage at diagnosis, access to screening programs, and availability of effective treatments.[2,4]

ETIOLOGY AND RISK FACTORS

Numerous studies suggest that the development of colorectal cancer is related to dietary or environmental factors that affect the bowel, lifestyle choices, and certain comorbid conditions, in addition to physical and genetic susceptibilities.

DIETARY INTAKE AND NUTRIENTS

1 Epidemiologic studies of worldwide incidence of colorectal cancer suggest that economic development and dietary habits strongly influence its development. Although findings based on epidemiologic data are subject to potential biases and inconsistencies in how dietary factors are categorized and measured, numerous studies have attempted to ascertain the true contribution of dietary habits as independent risk factors for colorectal cancer development.

Fiber, Fruit, and Vegetables

1 Dietary fiber is composed of remnants of plant cells that are not processed by normal human digestive enzymes.[5] Fibers are frequently classified as either water soluble (pectins, gums, agar, and mucilages) or insoluble (celluloses, hemicellulose, and lignins). The insoluble fibers are most likely to protect against cancer.[5] Foods that are high in fiber include vegetables, fruits, grains, and cereals. Dietary fiber is postulated to reduce colonic mucosal cell exposure to carcinogens through the dilution or reduced absorption of carcinogens in the bowel, reduced fecal pH, reduced bowel transit time, alterations in bile acid metabolism, or increased production of short-chain fatty acids, such as butyrate, which possesses known anticarcinogenic properties.[5,6] A protective effect from a diet high in fruits and vegetables is biologically plausible because certain constituents may reduce oxidative damage to DNA and lipids, induce drug-metabolizing enzymes, or enhance DNA repair processes.[7]

Results from numerous population-focused and epidemiologically based studies that have focused on various forms of dietary fiber intake (e.g., fruit, cruciferous vegetables, wheat bran, whole grains, etc.) have suggested a variety of associations, but recent large, controlled studies do not show an inverse relationship between total fiber intake and risk of colorectal adenomas or carcinoma.[5,7] Although fruit and vegetable intake may be protective against colorectal cancer, there is no consistent evidence to support this effect.[5]

Red Meat and Fat

1 Epidemiologic studies suggest that a relationship exists between dietary fat intake and colorectal cancer risk, although this has not been consistently seen.[5,6] This may have resulted from the use of dietary evaluations that focused on the quantity, origin, or type (saturated, monounsaturated, and polyunsaturated) of fat rather than on the source of dietary fat ingested. Dietary fat may promote cancer development as a result of its effect on fecal bile acid concentrations. The release of bile acids is stimulated following ingestion of dietary fat. These acids are then converted by colonic flora to secondary bile acids, which are associated with bowel mucosal irritation and cell proliferation responses and may promote tumor growth.[8]

The association between red but not white meat consumption and colorectal cancer is strongest, which may be related to the heterocyclic amines and polycyclic aromatic hydrocarbons formed during cooking, or the presence of specific fatty acids in red meat such as arachidonic acid.[9] Processed meat products containing certain preservatives may increase exogenous exposure to carcinogenic *N*-nitroso compounds.[9] Although data support associations between red and processed meat and high saturated fat intake with increased risk of colorectal cancer, the exact nature and magnitude of these risks have not been determined.

Calcium and Vitamin D

2 Inverse associations between dietary calcium, vitamin D intake, and serum 25-hydroxyvitamin D_3 levels, and colorectal cancer risk have been reported in several observational studies.[5,6] Calcium may exert antiproliferative effects by binding to bile and fatty acids in the small intestine, thereby reducing colonic epithelial cell exposure to mutagens.[5,10] In addition, calcium induces differentiating, pro-apoptotic, and direct growth-restraining activities on both normal and tumor cells in the gastrointestinal tract.[5,10] Vitamin D has antiproliferative and differentiation and pro-apoptotic effects on colonic epithelial cells and on a variety of tumor cells.[10,11] Most of its actions are mediated through a high-affinity nuclear vitamin D receptor (VDR), and the expression of this receptor is altered during different phases of colon cancer development.[11] Other genes involved in key signaling pathways that influence colorectal cancer development, such as Wnt/β-catenin, are also regulated by the VDR transcription factor.[11] Thus cellular responsiveness to vitamin D and associated cancer risk is unlikely limited to dietary intake alone. Vitamin D and calcium appear to interact synergistically to protect against adenoma recurrence and colorectal cancer.[5]

Folate and Other Micronutrients

Folate intake has been linked to colorectal cancer risk through epidemiologic and experimental studies in cell lines, animals, and humans.[5,6] However, the underlying basis for this is complex, particularly since alcohol use, smoking, genetic variants of the methylenetetrahydrofolate reductase (MTHFR) gene, and other factors can interfere with folate metabolism.[5,6,12] Folate is a key constituent of dark-green vegetables, citrus fruits, and dried beans, and the contribution of these dietary components is considered beneficial. Cellular folates act to accept and donate methyl groups in cellular processes that influence DNA synthesis and methylation of DNA, RNA, and proteins.[12] Variations in DNA methylation of gene promoter regions influence gene expression and DNA stability. Inappropriate hypermethylation leads to inactivation of tumor suppressor gene function and hypomethylation can result in oncogene activation.[12]

These effects as mechanisms of oncogenic transformation and tumor progression have been described in colon cancer, but the relationship between the timing of folate exposure to the development

of neoplastic foci may influence what appears to be a bimodal impact of folate on tumorigenesis.[6,12] Moderate folate supplementation, if initiated prior to the establishment of neoplastic foci, may be protective, whereas excessive or increased intake might enhance growth of established early neoplastic lesions.[5,6,12] Thus an adequate dietary folate intake may be enough to lower the risk of colorectal cancer, and exceeding normal intake may not be beneficial.

Epidemiologic and animal model data suggest that deficiencies in other dietary micronutrients, including selenium, vitamin C, vitamin E, and carotenoids, may increase colorectal cancer risk, but there is no convincing evidence that the incidence of colorectal cancer is greater in patients with low serum levels than in patients with adequate levels.[6]

LIFESTYLE FACTORS

Nonsteroidal Antiinflammatory Drug and Aspirin Use

2 Several lifestyle factors are known to affect colorectal cancer risk (Table 138–1). Observational studies have demonstrated that regular (at least 2 doses per week) nonsteroidal antiinflammatory drug (NSAID) and aspirin use is associated with a reduced risk of colorectal cancer. In an average-risk individual, regular aspirin use is associated with a 13% to 28% reduction in the risk of colorectal adenoma, and the pooled relative risk reduction in colorectal cancer from cohort studies is approximately 22%.[13] The reduction in risk appears greater for individuals with a history of adenoma. The dose of aspirin may be important, as low-dose aspirin was not beneficial in reducing colorectal cancer incidence in either the Physician's Health Study or the Women's Health Study.[14]

Benefit has also been seen with NSAID and cyclooxygenase-2 inhibitor (COX-2) use. NSAID use over a 10- to 15-year period is associated with protection against adenomas and colorectal cancer, with a 30% to 50% reduction in the risk of colorectal cancer.[5,14,15] Although COX-2 inhibitors reduce the incidence of colorectal adenoma recurrence, there is no evidence to show that they reduce colorectal cancer risk or mortality.[14]

The protective effects of these agents appear to be related to their inhibition of COX-2 and free radical formation. COX-2 overexpression is seen in precancerous and cancerous lesions in the colon and is associated with decreased colon cancer cell apoptosis and increased production of angiogenesis-promoting factors.[15] Up to 50% of colorectal adenomas and 85% of sporadic colon carcinomas have elevated levels of COX-2; COX-2 overexpression in colorectal cancer is associated with a worse survival.[15] COX-2 appears to play a role in polyp formation, and COX-2 inhibition suppresses polyp growth, restores apoptosis, and decreases expression of proangiogenic factors. In contrast, cyclooxygenase-1 (COX-1) levels remain normal in both normal and malignant tissue, although COX-1 inhibition may also be important.[16]

TABLE 138-1 Lifestyle Factors Associated with Colorectal Cancer Risk

Factor	Comments
Elevated risk	
Obesity and physical inactivity	Elevated BMI, waist circumference, waist-to-hip ratio, and physical inactivity associated with increased risk
Alcohol intake	Colorectal cancer risk increased with alcohol intake greater than 30 g/day
Tobacco use	Use of tobacco products contributes to approximately 12% of colorectal cancer deaths annually; higher colorectal cancer risk and mortality with cigarette smoking
Type 2 diabetes mellitus	Associated with 30% increase in risk of colorectal cancer and increased risk of mortality
Western diet	High saturated fat, red, and processed meat consumption; role of low dietary fiber intake less established
Reduced risk	
Aspirin and nonaspirin NSAID use	Regular aspirin or NSAID use associated with 30–50% reduction in colorectal cancer risk
Postmenopausal hormone use	Exogenous hormone intake decreases risk of colon and rectal cancer by about 20%
Calcium and vitamin D intake	Vitamin D 400 international units and calcium intake of 1,000 mg/day (adults < 50 years) or 1,200 mg/day (adults > 50 years) may be sufficient to reduce colorectal cancer risk

BMI, body mass index; NSAID, nonsteroidal antiinflammatory drug.

Postmenopausal Hormone-Replacement Therapy

2 Exogenous postmenopausal oral hormone-replacement therapy is associated with a significant reduction in colorectal cancer risk.[17–19] Risk reduction is seen in postmenopausal women receiving both estrogen only and combined estrogen and progestin therapy, and persists for about 10 years after therapy is discontinued.

Several mechanisms for a protective effect of estrogens on the bowel have been identified.[18] Declining estrogen levels associated with aging are associated with estrogen receptor hypermethylation, resulting in reduced expression of the estrogen receptor gene and dysregulated colonic mucosal cell growth. Estrogen may also interact with bile acids, or alter levels of insulin and insulin-like growth factor-1 (IGF-1), an important mitogen that influences cell-cycle progression in certain cells.

Obesity and Physical Inactivity

Physical inactivity and elevated body mass index (BMI), independent of level of physical activity, are associated with an elevated risk of colon adenoma, colon cancer, and rectal cancer.[20,21] Individuals with a total higher level of activity throughout life have the lowest risk. Hypotheses for these relationships include the observation that physical activity stimulates bowel peristalsis, resulting in decreased bowel transit time, and the possibility that exercise-induced alterations in body glucose, insulin resistance, hyperinsulinemia, and perhaps other hormones may reduce tumor cell growth.[20,22]

In most studies, a 5-unit increase above a healthy BMI was associated with increased risk of colorectal cancer in men, but the relationship is weaker and less consistent for women, possibly because of interactions with age or hormone-replacement therapy.[20] Differences in body composition and distribution of fat weight among men and women could contribute to this discrepancy.[23] Several mechanisms that link body size to colorectal cancer risk have been proposed, including insulin resistance, chronic inflammation, and alterations in growth factors or steroid hormones.[24]

Alcohol and Tobacco Use

Alcohol consumption increases the risk of colorectal cancer, but stronger associations have been observed for men than for women, possibly because alcohol consumption is generally greater in men than in women.[25] Lifetime and baseline alcohol consumption increase risk of cancer of the colon and rectum, and an alcohol intake greater than 30 g/day is associated with a greater apparent increase in risk.[25]

Cigarette smoking is associated with an increased risk of colorectal cancer and mortality, with a stronger association for cancer of the rectum than for cancer of the colon.[26] A dose relationship with

increasing number of pack-years and cigarettes smoked per day was also statistically significant but only among patients who had smoked for at least 30 years. Compared to never-smokers, the relative risks of colorectal cancer and mortality in smokers were 18% and 25% higher, respectively.[26] Participants in the Prostate, Lung, Colorectal, and Ovarian Trial who were current tobacco users had a greater risk of having hyperplastic polyps, adenomas, or concurrent hyperplastic and adenomatous polyps detected when they underwent flexible sigmoidoscopy.[27]

HMG-CoA Reductase Inhibitor Use

Preclinical findings and epidemiologic studies have evaluated the association between HMG-CoA reductase inhibitor (statin) use and colorectal cancer risk.[28,29] Despite two large trials of pravastatin and simvastatin that found a reduction in colon cancer incidence and one report of a reduced risk of stage IV cancer among statin users, more recent epidemiologic studies show no association between chronic statin use and risk of colorectal cancer.[28,29]

Coffee and Tea Consumption

The association between coffee and tea consumption and colorectal cancer risk is controversial, despite findings from several small studies.[30,31] Coffee and tea contain several constituents that have anticarcinogenic properties in vitro and in animal studies, but evidence in humans is limited. In a meta-analysis of studies that addressed black and green tea consumption and colorectal cancer risk, there was inadequate evidence that either type of tea is protective against colorectal cancer.[31] A meta-analysis of studies of coffee consumption and colorectal cancer risk showed no significant effect on cancer risk.[32]

CLINICAL RISK FACTORS

Chronic Inflammatory Diseases

Chronic ulcerative colitis, particularly when it involves the entire large intestine, predisposes individuals to colorectal cancer at a rate that is 5- to 10-fold greater than average.[33] The risk is even greater for young individuals and increases for all affected individuals with increasing extent of bowel involvement and disease duration. The cumulative risk of colorectal cancer is low early in life, but increases from 2% at 10 years after diagnosis to 8% and 18% at 20 and 30 years, respectively.[33] Chronic underlying inflammation, oxidative stress, and release of various cytokines, including nuclear factor-kappaB (NF-κB) and tumor necrosis factor-alpha (TNF-α), appear to promote tumorigenesis.[34] The progressive dysplastic changes that bowel mucosa undergo are similar to those observed in adenomatous polyps. Similarly, patients with Crohn disease are also at increased risk, and the risk is believed to be about that of patients with ulcerative colitis.[33] As compared with sporadic colon cancer or cancer associated with ulcerative colitis, colon cancer in patients with Crohn disease tends to arise in the proximal colon.[33] This is most likely related to the area of bowel affected by the chronic inflammatory process in individuals with Crohn disease. Overall, persons diagnosed with either disease constitute approximately 1% to 2% of all new cases of colorectal cancer each year.

Type 2 Diabetes Mellitus

Type 2 diabetes mellitus, independent of body mass size and physical activity level, is associated with increased colorectal cancer risk, although previous findings have been heterogeneous with regard to sex and cancer subsite.[35] In a meta-analysis of 15 studies, diabetes was associated with a 30% increase in risk of colorectal cancer and increased risk of colorectal cancer mortality.[35] Features associated with type 2 diabetes, such as hyperinsulinemia and elevated levels of free IGF-1 promote tumor cell proliferation.[36] Evidence is also accumulating that supports an association between metabolic syndrome and an elevated risk of colorectal cancer.[37]

GENETIC SUSCEPTIBILITY

Hereditary

Three specific patterns of colon cancer occurrence are generally observed: sporadic, inherited, and familial. Although most cases of colon cancer are sporadic in nature, as many as 10% of cases are thought to be hereditary.[38,39] The two most common forms of hereditary colon cancer are familial adenomatous polyposis (FAP) and hereditary nonpolyposis colorectal cancer (HNPCC). Both forms result from a specific germline mutation. FAP is a rare autosomal dominant trait caused by inactivating mutations of the adenomatous polyposis coli (*APC*) gene and accounts for 0.2% to 1% of all colorectal cancers. The disease is manifested by hundreds to thousands of tiny sessile adenomatous polyps that carpet the colon and rectum, typically arising during adolescence.[39] The polyps continue to proliferate throughout the colon, with eventual transformation to malignancy. The risk of developing colorectal cancer for individuals with untreated FAP is virtually 100%; most will develop colorectal cancer between the fourth and fifth decades of life.[38] Several variants of FAP exist and are associated with different extracolonic manifestations.[40]

HNPCC, also referred to as Lynch syndrome, is an autosomal dominant inherited syndrome that accounts for up to 5% of colon cancer cases.[38] Germline mutations in one of the DNA mismatch-repair (MMR) genes, most commonly *MLH1, MSH2*, or *MSH6*, are responsible for HNPCC.[41] Carriers of a germline mutation have an 80% lifetime risk of developing colorectal cancer.[41] Multiple generations within a family are affected, and colorectal cancer develops early in life, with a mean age at time of diagnosis of about 45 years of age.[38] In contrast to FAP, adenomatous polyps are not a primary manifestation of the HNPCC. Polyps that do form tend to be located primarily in the right-sided, or proximal colon. Because the clinical presentation of HNPCC is difficult to distinguish from "sporadic" forms of colorectal cancer, the diagnosis of HNPCC can be confirmed by the presence of germline mutations in a family of genes responsible for DNA MMR. Criteria for diagnosis of HNPCC have been established, and it is important to identify carriers of these MMR mutations so that they can be counseled and followed appropriately.[42] In addition, these individuals have a moderately increased risk of developing cancers in other organs.

Familial colon cancer represents the least-understood pattern of colorectal cancer. Approximately 20% of patients who develop colorectal cancer will have a family history of colorectal cancer.[38] In these families, the frequency of colorectal cancer is too high to be considered sporadic, but the pattern is not consistent with an inherited syndrome. First-degree relatives of patients diagnosed with colorectal cancer have an increased risk of the disease that is at least two to four times that of persons in the general population without a family history.[39]

Enzyme Polymorphisms

Increasing evidence suggests that genetic polymorphisms in drug-metabolizing enzymes, such as *N*-acetyltransferases (NAT1 and NAT2), cytochrome P450 (CYP) isoenzymes, glutathione-*S*-transferase (GST) enzymes, methylenetetrahydrofolate reductase (MTHFR), and hemochromatosis gene mutations may confer genetic susceptibility to colorectal cancer.[43] Individuals with certain

variations in NAT1, NAT2, CYP1A2, CYP1A1, and CYP2E1 enzyme genotypes may be particularly susceptible to carcinogenic effects of a high dietary intake of meat, tobacco smoke, or other environmental factors.[43,44]

SUMMARY OF RISK FACTORS

In summary, multiple factors are associated with colorectal cancer risk. Lifestyle factors associated with economically developed countries, such as obesity, physical inactivity, chronic hyperinsulinemia, and alcohol and tobacco use, increase risk of colorectal cancer. Observational studies suggest associations between high dietary intake of processed and red meats and saturated fat with increased risk of colorectal cancer, but the majority of evidence does not indicate that low dietary fiber intake plays a role in the development of colorectal cancer. Regular aspirin and NSAID use and postmenopausal hormone replacement therapy decrease risk, but recommendations have not been made because of unresolved issues regarding risk-to-benefit considerations. Inherited genetic susceptibilities and clinical risk factors, such as inflammatory bowel disease, are well known risks for colon cancer.

PATHOPHYSIOLOGY

ANATOMY AND BOWEL FUNCTION

The large intestine consists of the cecum; the ascending, transverse, descending, and sigmoid colon; and the rectum (Fig. 138–2). In adults, it extends about 1.5 m and has a diameter ranging from 8 cm in the cecum to 2 cm in the sigmoid colon. The function of the large intestine is to receive 500 to 2,000 mL of ileal contents per day. Absorption of fluid and solutes occurs in the right colon or the segments proximal to the middle of the transverse colon, with movement and storage of fecal material in the left colon and distal segments of the colon. Mucus secretion from goblet cells into the intestinal lumen lubricates the mucosal surface and facilitates movement of the dehydrated feces. It also serves to protect the luminal wall from bacteria and colonic irritants such as bile acids.

Four major tissue layers, from the lumen outward, form the large intestine: the mucosa, submucosa, muscularis externa, and serosa (Fig. 138–3). Embedded in the submucosa and muscularis externa is a rich lymphatic capillary system. Lymphatic channels do not extend into the mucosa. The muscularis externa consists of circular

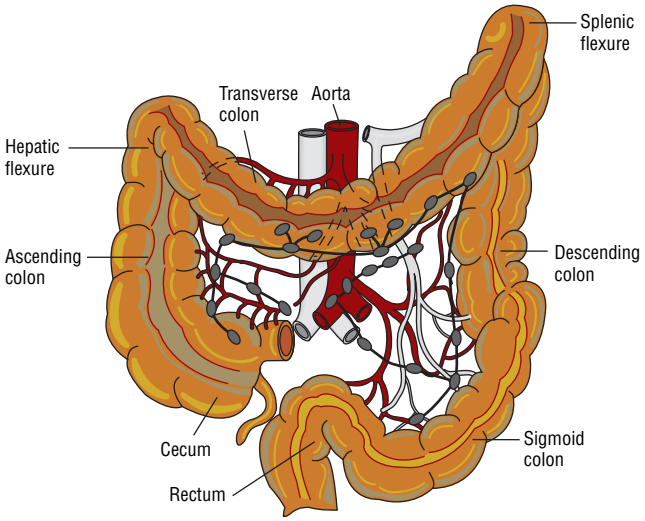

FIGURE 138-2. Colon and rectum anatomy.

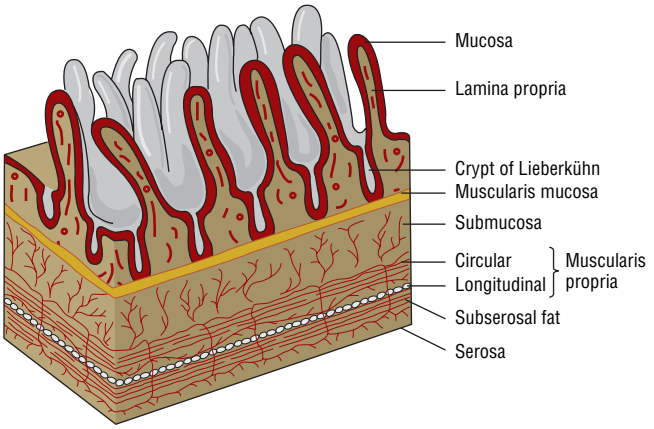

FIGURE 138-3. Cross-section of bowel wall.

smooth muscle and three outer longitudinal smooth muscle bands. Contraction of these muscle groups moves colonic material toward the anal canal. The outermost layer of the colon, the serosa, secretes a fluid that allows the colon to slide easily over nearby structures within the peritoneum. The serosa covers only the anterior and lateral aspects of the upper third of the rectum. The lower third lies completely extraperitoneal and is surrounded by fibrofatty tissue as well as adjacent organs and structures.

The surface epithelium of the colonic mucosa undergoes continual renewal, and complete replacement of epithelial cells occurs every 4 to 8 days. Cell replication normally takes place within the lower third of the crypts, the tubular glands located within the intestinal mucosa. The cells then mature and differentiate to either goblet or absorptive cells as they migrate toward the bowel lumen. The total number of epithelial cells remains relatively constant as the number of cells migrating from the crypts is balanced by the rate of exfoliation of cells from the mucosal surface. This two-phase process is critical to the malignant transformation of the epithelial cells. The number of dysplastic and hyperplastic aberrant crypt foci increases with increasing age; as the mass of abnormal cells accumulates at the top of the crypt and starts to protrude into the stream of fecal matter, their contact with fecal mutagens can lead to further cell mutations and eventual adenoma formation.

COLORECTAL TUMORIGENESIS

The development of a colorectal neoplasm is a multistep process involving several genetic and phenotypic alterations of normal bowel epithelium structure and function, leading to dysregulated cell growth, proliferation, and tumor development. Because most colorectal cancers develop sporadically, with no inherited or familial disposition, efforts have been directed toward identifying these alterations and learning whether detection of such changes may lead to improved cancer detection and/or treatment outcomes.

Features of colorectal tumorigenesis includes genomic instability, activation of oncogene pathways, mutational inactivation of tumor-suppressor genes, and activation of growth factor pathways.[41] A genetic model has been proposed for colorectal tumorigenesis that describes a process of transformation from adenoma to carcinoma. Figure 138–4 is an overview of the adenoma–carcinoma model. The adenoma–carcinoma sequence of tumor development reflects an accumulation of mutations within colonic epithelium that confers a selective growth advantage to the affected cells. Key elements of this process include hyperproliferation of epithelial cells to form a small benign neoplasm or adenoma in conjunction with acquisition of various genetic mutations.[41] These mutations occur early and frequently in sporadic cases of both adenomas and colorectal cancer. Somatic mutations must occur in multiple genes to produce

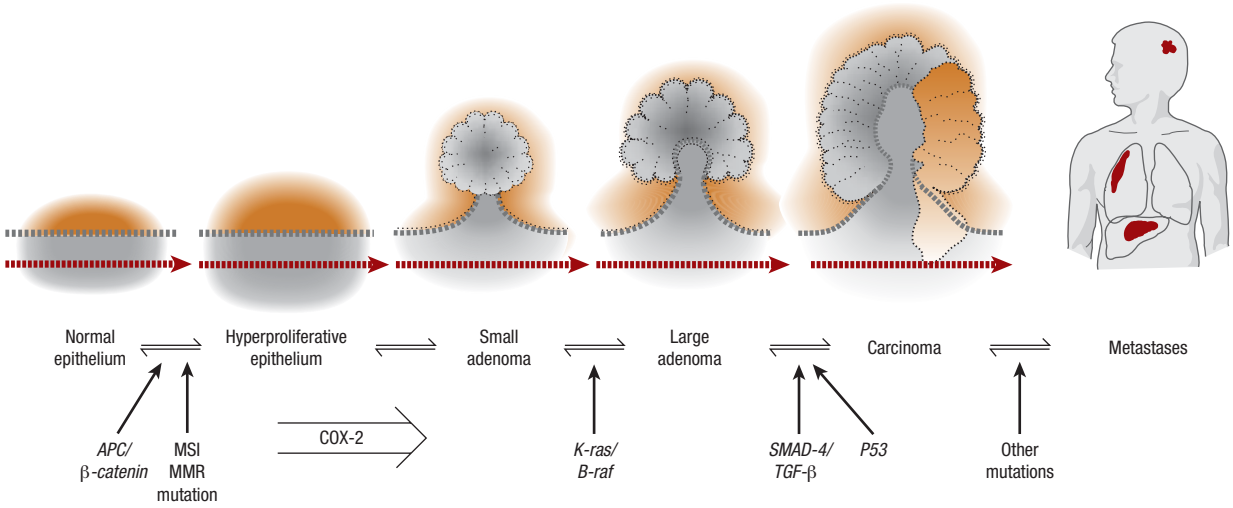

FIGURE 138-4. Genetic changes associated with the adenoma–carcinoma sequence in colorectal cancer. The accumulation of genetic changes in the pathogenesis of colorectal cancer includes DNA hypomethylation across the genome, mutation in the adenomatous polyposis coli *(APC)* gene or abnormalities in *β*-catenin; microsatellite instability (MSI) initiated by mismatch repair (MMR) gene mutation or methylation defects; mutational activation of cyclooxygenase-2 (COX-2); *KRAS* or *BRAF* oncogene activation; tumor suppressor gene deletions in chromosome 18q (SMAD-4 mutations) and disruption of transforming growth factor-*β* receptor type II signaling; and defects in *P53* function. *(Data from references 39, 41, and 45.)*

the malignant transformation. Table 138–2 lists important genetic mutations that are associated with colorectal cancers.

Several patterns of genomic instability may be present in colorectal cancer; the most common type of genomic instability is chromosomal instability, which leads to alterations in chromosomal structure and copy number.[41] An important consequence of chromosomal instability is loss of a wild-type allele of a tumor-suppressor gene, also referred to as loss of heterozygosity (LOH). Up to 85% of sporadic colorectal cancers exhibit chromosomal instability and the tumor suppressor genes *APC*, *P53*, and *SMAD-4* are commonly affected.[41] Other forms include somatic or germline defects in DNA MMR genes, germline inactivation of *MYH*, a base excision repair gene, and aberrant DNA methylation that results in epigenetic silencing of tumor suppressor gene expression.

Mutation or loss of the *APC* tumor suppressor gene is a key factor involved in tumor formation through activation of the Wnt signaling pathway, a mediator of cell proliferation, differentiation, and survival.[41] The *APC* gene encodes for APC protein that binds to and degrades *α*- and *β*-catenin, which belong to a family of proteins associated with intracellular adhesion.[41] *β*-catenin, a downstream component of the Wnt signaling pathway, influences cell–cell communication, cell–cycle regulation, or apoptosis, and may contribute to abnormal epithelial proliferation and differentiation of cells.[11,41] In the absence of functional APC, *β*-catenin accumulates in the cytoplasm, then enters the nucleus and activates transcription of various genes, leading to constitutive activation of the Wnt signaling pathway. Inactivation of the *APC* gene is the single gene defect responsible for FAP, and is frequently an early event in the development of sporadic colorectal cancer cases.[41] A specific *APC* mutation, I1307K, is a factor in the development of familial colon cancer in individuals of Ashkenazi Jewish ancestry.[39]

Mutational inactivation of *P53* represents a second key step in colorectal tumorigenesis.[41] Normal *P53* gene expression is important for G_1 cell-cycle arrest to facilitate DNA repair during replication, and to induce apoptosis, an irreversible cell process resulting in cell death. *P53* is inactivated in up to 55% of sporadic colorectal cancers.[41] A third step in tumor progression is the mutational inactivation of the transforming growth factor-*β* (TGF-*β*) signaling pathway, which facilitates adenoma transition to high-grade dysplasia or carcinoma and also inactivates *SMAD-4*.[41] In normal epithelium, TGF-*β* has an antiproliferative role and induces growth arrest and apoptosis. Alterations in *SMAD-4* or TGF-*β* receptors lead to a loss of the normal growth inhibitory response to TGF-*β*. The frequency of *SMAD-4* mutations in colorectal cancer is reported to range from 10% to 35%.[41]

A distinct group of genetic traits has also been identified for individuals with HNPCC, but they also occur in sporadic cases of colorectal cancer. Replication errors occur frequently and represent widespread alterations in the length of a series of repeated nucleotides, or microsatellites, within tumor DNA. Mutations of the MMR genes that recognize and regulate DNA mismatch-repair errors contribute to microsatellite instability and colorectal tumorigenesis.[41] Failure to repair DNA mismatches results in microsatellite instability, which accelerates further gene mutations, leading to oncogene activation or tumor suppressor gene inactivation. Tumor progression is then facilitated through a link between DNA repair defects and mutations of critical growth regulatory genes.

TABLE 138-2 Genetic Mutations Associated with Colorectal Cancer

Type of Mutation	Disease	Genes
Germline	Familial adenomatous polyposis (FAP)	*APC*
	MYH-associated polyposis (MAP)	*MYH*
	Hereditary nonpolyposis colorectal cancer (HNPCC)	DNA mismatch-repair genes:
		MSH2
		MLH1

		BRAF
		Tumor suppressor genes:
		P53
		SMAD-4
		APC
		TGFβR2

APC, adenomatous polyposis coli; TGF*β*R2, transforming growth factor-*β* receptor type II.
Data from references 39, 41, and 45.

Several oncogene activating mutations play an important role in promoting colorectal cancer.[41] Mutations in members of the Ras gene family—*KRAS*, *HRAS*, and *NRAS*—in addition to *BRAF*, activate the mitogen-activated protein kinase (MAPK) signaling pathway, which stimulates cell proliferation and other activities that promote carcinogenesis. Genetic alterations in other cell signaling pathways may occur, as well.

Aberrant signaling of growth factor pathways also plays an important role in the adenoma-carcinoma transformation process. Activation of prostaglandin signaling is an early step in the adenoma-carcinoma transformation process and can be induced by upregulated expression of COX-2 and inflammation.[41] COX-2 influences apoptosis and other cellular functions. The peroxisome proliferator-activated receptor (*PPAR*) gene, a nuclear receptor that serves as a transcription factor, may interact with the COX pathway and affect tumorigenesis.[45] The PPARd isoform is upregulated in colorectal cancer, and its activation promotes tumor growth. COX-derived prostaglandins indirectly activate PPARd, which further enhances adenoma growth. The protooncogene *C-erbB* is activated in a high percentage of human tumors, including colorectal cancer, and encodes for expression of epidermal growth factor receptor (EGFR), a transmembrane glycoprotein involved in signaling pathways that affect cell growth, differentiation, proliferation, and angiogenesis. EGFR, which is overexpressed in a high proportion (72% to 82%) of colorectal cancers, is associated with increased cell proliferation and metastasis.[46] These mechanisms are potentially important because of the availability of pharmacologic agents that can influence these processes and affect cell growth.

HISTOLOGY

Adenocarcinomas account for more than 90% of tumors of the large intestine.[47] Other histologic types such as mucinous adenocarcinoma, signet-ring adenocarcinoma, carcinoid simplex, and carcinoid tumors occur less frequently. Adenocarcinomas are assigned one of three tumor grade designations based on the degree of cellular differentiation, the degree to which the tumor resembles the structure, and function of its cell of origin. The most differentiated adenocarcinomas are grade I tumors, whereas grade III tumors are considered "high grade," the most undifferentiated, and have frequently lost the characteristics of mature normal cells. Poorly differentiated tumors are associated with a worse prognosis than those that are better differentiated.[47]

Mucinous adenocarcinomas possess the same basic structure as adenocarcinomas but differ in that they secrete an abundant quantity of extracellular mucus. They account for only approximately 10% of colorectal carcinomas but tend to be frequent in patients with HNPCC and patients with coexisting ulcerative colitis.[47] Signet-ring adenocarcinomas have a characteristic appearance because of the displacement of the nucleus to one side by large vacuoles of intracellular mucin. Patients tend to present with a more advanced stage of disease and have a highly invasive tumor. Both mucinous and signet-ring adenocarcinoma histologies confer a poor prognosis.[48]

PREVENTION AND SCREENING

Cancer prevention efforts can be considered as either primary or secondary. Primary prevention strategies aim to prevent the development of colorectal cancer in a population at risk. Secondary prevention approaches are undertaken to prevent malignancy in a population that has already manifested an initial disease process. The basis for primary prevention depends on identification of risk factors followed by eradication or alteration of their effects on carcinogenesis. Primary prevention also includes lifestyle and diet modification. Several primary preventive measures have undergone or are currently undergoing study (Table 138–3).

TABLE 138-3 Prevention Strategies for Colorectal Cancer

Prevention Strategy	Proposed Mechanism of Protective Effect
High-fiber diet supplementation[a]	Decreases fecal bile acids; decreases bowel transit time; direct binding to fecal mutagens; dilution of fecal material
Dietary fat reduction[a]	Decreases fecal bile acids; reduces consumption of heterocyclic amines and other carcinogens that are produced through meat preparation and processing techniques
NSAIDs[b,c]	Inhibit COX-2; induce apoptosis via 15-LOX-1
NO-NSAIDSs	Nitrous-oxide release mimics effects of prostaglandins on gastrointestinal epithelium; suppresses formation of aberrant colonic crypt foci
Selenium	Antioxidant effects
Calcium	Direct binding to bile and fatty acids; inhibits epithelial cell proliferation
Estrogens[c]	Decrease synthesis of secondary bile acids; decrease production of IGF-1; direct antiproliferative effects on colorectal epithelium
5-Aminosalicylic acids	Induce apoptosis via caspase 3 induction; inhibit TNF-α-mediated intestinal cell proliferation and MAPK activation
Bile salts	Reduce concentration of deoxycholic acid in colon; modulate phospholipase A2 expression and protein kinase C; antioxidant effects
HMG-CoA reductase inhibitors	Induce intestinal cell apoptosis and inhibit cell proliferation; suppress angiogenesis; synergistic COX-2 inhibition with NSAIDs
Difluoromethylornithine	Inhibits cellular proliferation through alterations in polyamine metabolism via inhibition of ornithine decarboxylase
Curcumin	Induces glutathione S-transferase (GST) enzymes; inhibits COX-2 expression
Omega-3 fatty acids	Inhibit COX-2 expression
PPAR-γ agonists	Epigenetic modulation
Resveratrol	Antioxidant effects
Green tea polyphenols	Antioxidant effects

COX-2, cyclooxygenase-2; 15-LOX-1, 15-lipoxygenase-1; NSAIDs, nonsteroidal antiinflammatory drugs; NO-NSAIDs, nitrous oxide donating nonsteroidal antiinflammatory drugs; IGF-1, insulin-like growth factor 1; TNF-α, tumor necrosis factor-alpha; MAPK, mitogen-activated protein kinase

[a] To date, findings from randomized trials have failed to demonstrate a protective effect of low-fat high-fiber fruit and vegetable dietary intake in reducing risk of recurrence of colorectal adenomas or colorectal cancer.

[b] Includes COX-2 inhibitors.

[c] Risk of use may outweigh benefit.

Data from references 5, 6, 51, and 52.

DIET

1 Although early studies suggest that a substantial increase in daily dietary fiber and/or decrease in dietary fat intake might significantly reduce colorectal cancer risk, results from recent randomized trials are inconsistent. As such, there is insufficient evidence to support the use of fiber supplementation as a colorectal cancer prevention strategy at this time.

CHEMOPREVENTION

2 The most widely studied agents for the chemoprevention of colorectal cancer are aspirin, nonaspirin NSAIDs, and COX-2 inhibitors, but their use as chemopreventive agents in the general

population has not been established. Nonaspirin NSAIDs and COX-2 inhibitors were associated with reduced risk of colorectal adenomas in cohort and case-control studies, and COX-2 inhibitors were also effective in controlled trials.[14] However, the United States Preventive Services Task Force has concluded that potential harms associated with their use outweigh the benefits of aspirin and NSAIDs for prevention of colorectal cancer in the general population.[49]

In randomized studies of individuals with FAP, sulindac and celecoxib reduced the size and number of adenomatous polyps, but they are not viewed as alternatives to surgery. Sulindac can induce regression of existing adenomas, but in a randomized study of newly diagnosed patients with FAP it did not prevent new adenoma formation.[50] In 1999, the FDA approved the use of celecoxib to reduce the number of adenomatous colorectal polyps in FAP as an adjunct to usual care. This approval was based primarily on results from a trial of 77 patients with FAP who received celecoxib, 400 mg orally twice daily, or placebo, for 6 months. Celecoxib administration significantly reduced the mean polyp number (28% vs. 4.5%) and polyp burden (30.7% vs. 4.9%) as compared with placebo.[51] Recently, celecoxib was shown to decrease sporadic adenoma formation by more than 30% as compared with placebo, but the risk of cardiovascular events was increased in the treatment group, and its use in the general population cannot be recommended at this time.[51] In addition, its benefits are likely to be transient, because patients receiving sulindac experienced an increase in size and number of polyps within 3 months after the sulindac was discontinued.[50]

The use of aspirin as both a primary and a secondary chemopreventive agent remains controversial. Regular use of aspirin reduced the incidence of colorectal cancer in cohort studies by 22%, and it reduced the incidence of adenomas in randomized controlled trials, case-control studies, and cohort studies.[13] The benefits appear greatest with high-dose rather than low-dose (325- vs. 81-mg) aspirin and with administration for periods longer than 10 years, but the risk of bleeding complications is also greater.[13] In addition, aspirin use appears to reduce the risk of colorectal cancers that overexpress COX-2 but not those with absent or weak COX-2 expression.[52]

Randomized trials of calcium and folate supplementation as chemoprevention have also been conducted, and findings do not support their use at this time. In the placebo-controlled Calcium Polyp Prevention Study, patients with a previous colorectal adenoma who received calcium carbonate supplementation for 5 years experienced a moderate reduction in risk of recurrent colorectal adenomas.[5] In another randomized trial, protection was limited to individuals with higher serum vitamin D levels. These findings are in contrast with results from a large, randomized trial of calcium plus vitamin D supplementation for 7 years in 36,282 women from the Women's Health Initiative, which did not demonstrate any difference in the incidence of invasive colorectal cancer between treatment or placebo.[51] Because of the long latency period associated with cancer development, the 7-year duration of this trial may have been too short. However, there is no evidence that calcium intake greater than that recommended to reduce osteoporosis is protective against colorectal cancer. Although calcium intake appears to be inversely related to colon cancer, its role as a chemopreventive agent has not been defined.[51]

Additional intervention trials of various micronutrients, including selenium, folic acid, ursodiol, curcumin, difluoromethylornithine (DFMO), epigenetic modulators (e.g., PPAR agonists, histone deacetylase inhibitors), and other chemopreventive agents have been completed or are ongoing.[5,12,51,52] A randomized, placebo-controlled trial of folate 1 mg daily for up to 6 years as primary prevention of colorectal adenomas did not show reduced adenoma risk.[12] Furthermore, folate supplementation was associated with a nonsignificant increase in adenoma recurrence in two studies.[12] Therefore until the efficacy and safety of folate supplementation to reduce colorectal cancer risk can be evaluated, it is not recommended at this time. Several trials of DFMO, an irreversible inhibitor of the polyamine synthetic pathway, show promising activity as a chemopreventive agent.[53]

SURGICAL RESECTION

Surgical resection remains an option to prevent colon cancer in individuals at extremely high risk for its development. Despite the potential for NSAIDs to reduce adenoma development and to induce adenoma regression in individuals with FAP, their effects are incomplete and their use cannot replace surgical resection as an important means of cancer prevention for these high-risk individuals. Individuals with FAP who are found to have polyposis on lower endoscopy screening examinations should undergo total proctocolectomy and ileal pouch–anal anastomosis or subtotal colectomy with an ileorectal anastomosis.[54] Because of the high incidence of metachronous cancers (45%) in patients with HNPCC, prophylactic subtotal colectomy with an ileorectal anastomosis is recommended for those individuals.[54] Colonoscopic polypectomy, removal of polyps detected during screening colonoscopy, is considered the standard of care for all individuals to prevent the progression of premalignant adenomatous polyps to adenocarcinomas.

SCREENING

3 Based on the recognized incidence of colorectal cancer, identification of high-risk individuals, and the high rate of curability associated with localized lesions, screening recommendations for early detection of colorectal cancer have been established.[55–58] Some tests effectively detect early cancer, whereas others detect colorectal polyps and cancer. Differences exist in specific screening guidelines published by various organizations. This section reviews available screening techniques for colon cancer.

Fecal Occult Blood Testing

3 The use of fecal occult blood tests (FOBTs) annually or biannually, results in an increased number of asymptomatic individuals diagnosed with early stages of disease. Results from randomized, controlled trials where standard FOBTs were administered annually or biennially show a reduction in colorectal cancer mortality by 15% to 33%.[55] Two main methods are available to detect occult blood in the feces: guaiac dye or derivative, and immunochemical methods. The Hemoccult II is a standard guaiac-based test that detects peroxidase activity of heme when hemoglobin comes in contact with a guaiac-impregnated paper. When a solution containing hydrogen peroxide is poured over the paper, a blue color appears if the test is positive. The testing process is complex and requires specific patient counseling to avoid inaccurate results (Table 138–4).

The Hemoccult Sensa, another guaiac-based test, is preferred by some organizations because it may have increased sensitivity and specificity as compared with the Hemoccult II. Clinical guidelines have been developed for performing and interpreting results of FOBT.[59] The limitations associated with fecal occult blood screening remain an issue of active concern. Many early-stage tumors do not bleed, and therefore the false-negative rates are approximately 70% for cancer and 90% for polyps. In addition, the test results may not be valid because the test is often poorly performed both in the home and in physician office settings.[55] However, these concerns are addressed through continued

TABLE 138-4 Patient Counseling Points Prior to Hemoccult II Testing

To Avoid False Positives	To Avoid False Negatives
1. Dietary restrictions • Avoid rare red meat and vegetables with peroxidase activity (turnips, broccoli, cauliflower, and radishes) for 3 days prior to testing 2. Medical restrictions • Avoid iron products, rectal administration of medications, and digital rectal examinations for 3 days prior to testing • Avoid nonsteroidal antiinflammatory drugs for up to 7 days prior to testing	• Avoid vitamin C for 3 days prior to testing • Avoid testing dehydrated samples (rehydrating of samples is not recommended)

Procedure for Hemoccult II testing
Patient applies two separate samples of three different stools to six test card windows.

serial screening with FOBT. In addition, approximately 1% to 5% of randomly selected individuals will have a positive test result, and approximately 2% to 17% of those individuals will be found to have colorectal cancer.[55,59] False-positive results can prove to be very expensive and inconvenient for a patient because of the followup tests required to confirm a positive result. Nevertheless, studies evaluating the effects of FOBT as a screening modality have established that their annual use reduces colorectal cancer mortality by up to 33%.[55,59]

Newer tests, such as immunochemical assays, were developed to reduce the rate of false-positive results associated with the guaiac-based tests. Fecal immunochemical tests (FIT) (InSure and others) use antibodies to detect the globin protein portion of human hemoglobin. These FITs have the advantage of improved specificity and sensitivity.[55] A potential increase in patient compliance is expected because these tests do not react with dietary factors or medications, but performance varies among different available tests. To date, these FITs have not found widespread use in the United States because of commercial and technical reasons, although they, along with guaiac-based tests, are recommended in some screening protocols.[57,58] They are preferred over FOBT by the American College of Gastroenterology.[56]

Flexible Sigmoidoscopy

3 Sigmoidoscopy can examine the lower 35% to 60% of the bowel, depending on the instrument, and thus increases the detection rate by about two- to threefold.[56] Unlike FOBT, sigmoidoscopy detects polyps as well as early cancer. A 60-cm flexible sigmoidoscope can be used to reach the splenic flexure so as to detect 50% to 60% of cancers, but it requires more operator training, is associated with increased risk, and is not tolerated as well as the 35-cm instrument. The combination of sigmoidoscopy plus FOBT appears to improve sensitivity for lesions that will be missed by sigmoidoscopy alone, but the true benefit of this approach to general practice has not been established.[57,58] Because the entire colon cannot be examined with sigmoidoscopy, many clinicians prefer to perform a colonoscopy.[55]

Total Colonic Examination

3 Total colonic examination can be accomplished with colonoscopy or double-contrast barium enema. A colonoscope facilitates examination of the whole bowel to the cecum in most patients, and allows for simultaneous removal of premalignant lesions. Although it allows for greater visualization of the colon, colonoscopy involves greater risk and inconvenience to patients. However, it is the preferred screening method based on its superior ability to detect lesions in the proximal colon as compared with sigmoidoscopy.[55,56] This may become increasingly important, as the proportion of tumors occurring in the proximal or right (cecum, ascending, and transverse colon) side of the colon has increased over the past 30 years, with fewer occurring in the rectum and distal or left (descending and sigmoid colon) side. It remains somewhat controversial whether this observation reflects a change in the biology of the disease or the nature of screening techniques. Most lesions, however, still occur in the distal colon.

A double-contrast barium enema produces an image of the entire colon in most examinations, and the retained barium outlines small polyps and mucosal lesions. This approach is the least-expensive method of examining the entire colon, but is considered inferior to colonoscopy for detecting polyps and colorectal cancer.[55] In addition, a supplemental colonoscopy is required if suspicious lesions are identified. Because of these limitations, the combination of double-contrast barium enema with flexible sigmoidoscopy could be used to increase the sensitivity for detecting a colorectal malignancy compared with a double-contrast barium enema alone. However, it is generally reserved for use if other tests are not available.[55]

Novel Screening Strategies

Molecular screening strategies analyze stool samples for presence of potential markers of malignancy in cells that are shed from premalignant polyps or adenocarcinomas in the bowel.[55–57] These include abnormalities or mutations in DNA, RNA expression patterns that are characteristic of malignancy, and the presence of proteins or other molecular cellular components. Of these, DNA testing has undergone the most testing. In a large-scale comparison of fecal DNA analysis to FOBT in asymptomatic individuals at average risk, neither test was able to identify most of the neoplastic lesions found with colonoscopy, but fecal DNA analysis detected a greater proportion of lesions than did FOBT without compromising specificity.[60] Additional work is ongoing to identify the role of novel molecular markers in colorectal cancer detection, but none to date have shown improvement over FIT. Genetic testing is an important cancer-screening approach for family members of individuals diagnosed with FAP or HNPCC and is appropriate for selected individuals, but it should only be offered in conjunction with genetic counseling.

Computed tomography (CT) colonography (virtual colonoscopy) is an imaging procedure that creates two- or three-dimensional images of the colon by combining multiple helical CT scans. Initial tests are promising, although patients still require bowel cleansing, and many will be referred for colonoscopy to remove detected lesions.[55]

Screening Summary

Table 138–5 outlines current U.S. guidelines for screening and surveillance for early detection of colorectal cancer. Men and women who are 50 years of age and are at average risk (their only risk factor is age >50 years) should be screened annually using a sensitive FOBT or FIT or undergo examination of the colon every 5 to 10 years, depending on the type of test used.[55] Although several methods for examining the colon are available, there is no evidence that one test should be chosen over another.[55] However, colonoscopy is the preferred modality of the American College of Gastroenterology.[56] More rigorous (usually starting at an earlier age) screening recommendations are recommended for moderate- to high-risk individuals.[56,57] The United States Preventive Services Task Force recommends routine screening for individuals age 50 to 75 years with different consideration given to adults 76 to 85 years and those older than 85 years.[58]

DIAGNOSIS

SIGNS AND SYMPTOMS

The signs and symptoms associated with colorectal cancer can be extremely varied, subtle, and nonspecific. Patients with early stage colorectal cancer are often asymptomatic, and lesions are usually found as a result of screening studies. Any change in bowel habits (e.g., constipation, diarrhea, or alteration in size or shape of stool), vague abdominal discomfort, abdominal pain, or distension may all be warning signs of a malignant process. Obstructive symptoms and changes in bowel habits frequently develop with tumors located in the transverse and descending colon. Bleeding may be acute or chronic and most commonly appears as bright red blood mixed with stool. Iron-deficiency anemia, presenting as weakness and occasionally as high-output congestive heart failure, frequently develops as a result of chronic occult blood loss.

PRESENTATION OF COLORECTAL CANCER

General

- Patient symptoms are usually nonspecific and can vary drastically among patients.

Symptoms

- Change in bowel habits (generally an increase in frequency) or rectal bleeding.
- Constipation, depending on the location of the tumor.
- Nausea, vomiting, and abdominal discomfort.
- Fatigue may be present if anemia is severe.

Signs

- Blood in the stool is the most common sign.
- Hepatomegaly and jaundice in advanced disease.
- Leg edema as a consequence of lymph node involvement, thrombophlebitis, fistula formation, weight loss, and pain in the lower back or radiating down the legs are indicative of widespread disease.

Laboratory Tests

- Positive guaiac stool test and anemia (iron deficiency) from blood loss.
- Elevated carcinoembryonic antigen (most patients).
- Elevated liver enzymes may be present with metastatic disease.

Approximately 19% of patients with colorectal cancer present with metastatic disease.[3] Metastatic spread occurs as a result of direct tumor invasion of adjacent tissues or by lymphatic or hematogenous spread. The venous drainage of the colon and rectum influences the pattern of metastases most commonly seen. The most common site of metastasis is the liver, often the only site of metastatic disease in 40% of patients, followed by the lungs and then bones, specifically the sacrum, coccyx, pelvis, and lumbar vertebrae. Liver metastases are present in 5% to 10% of patients at presentation.

WORKUP

When a patient is suspected of having colorectal carcinoma, a careful history and physical examination should be performed. The patient history should include a past medical history and family history, especially noting the presence of inflammatory bowel disease, colorectal cancer, polyps, and cancers of the breast, ovary, and endometrium. A complete physical examination includes careful abdominal examination for the presence of masses or ascites, a rectal examination, and an assessment for possible hepatomegaly and lymphadenopathy. A breast and pelvic examination is recommended in all women, especially in women with a history of breast, ovarian, or endometrial cancer.

An unexplained anemia in an older patient requires surveillance of the entire large bowel, especially the right colon. Red blood cell indices (e.g., hemoglobin, hematocrit, mean corpuscular volume, and reticulocyte count) and a workup of iron status (e.g., serum ferritin, serum iron, and total iron-binding capacity) may be useful to confirm acute or chronic blood loss and/or iron-deficiency anemia. An evaluation of the entire large bowel is undertaken with either colonoscopy or sigmoidoscopy and a double-contrast barium enema. A barium enema may be preferred in situations in which a partially obstructing lesion prohibits passage of the endoscope, but it should be avoided if complete obstruction or perforation of the bowel is suspected. A characteristic finding indicative of colon cancer seen on barium enema is an apple core–shaped lesion with tumor involving the circumference of the bowel. When possible, the endoscope is used to collect tissue for a histologic evaluation and provide a preliminary diagnosis following the procedure.

Baseline laboratory tests should be obtained and include a complete blood cell count, platelet count, international normalized ratio (INR), prothrombin time, activated partial thromboplastin time, liver chemistries, and renal function tests. Abnormal liver chemistry test results may suggest liver involvement with tumor. However, patients with metastatic disease to the liver may have normal liver chemistries, and abnormal liver test results are not always indicative of metastatic disease.

Additional laboratory tests may include a baseline carcinoembryonic antigen (CEA) level if it is likely to augment staging and treatment plans.[61] CEA belongs to a group of cell-surface glycoproteins termed *oncofetal proteins*, which are expressed during embryonic development and reexpressed on the cell surfaces of many carcinomas, particularly those originating from the gastrointestinal tract. CEA concentrations can be measured in the blood and can therefore potentially serve as a marker for colorectal cancer. But not all colorectal cancers produce CEA, and elevated concentrations are more frequent in patients with metastatic disease. It is important to recognize, however, that several concomitant disease states are associated with an elevated CEA: liver diseases, gastritis, peptic ulcer disease, diverticulitis, chronic obstructive pulmonary disease, chronic or acute inflammatory conditions, and diabetes.[61] Most commercially available assays list a value of less than 5 ng/mL (5 mcg/L) as the upper limit of normal. Although CEA measurement is too insensitive and nonspecific to be used as a screening test for early-stage colorectal cancer, it is the surrogate marker of choice for monitoring colorectal cancer response to treatment, particularly if the pretreatment concentration is elevated.[61] The CEA test may have preoperative prognostic implications because it has been shown to correlate with the size and degree of differentiation of the carcinoma. Elevated preoperative CEA levels correlate with a poor survival and may predict likelihood of recurrence, regardless of tumor stage at diagnosis. However, it should not be used to determine whether a patient should receive adjuvant therapy. After a potentially curative resection, CEA levels should return to normal within 4 to 6 weeks. Persistently elevated CEA levels may indicate residual disease, while elevations after normalization may indicate relapsed disease.

Radiographic imaging studies evaluate the extent of disease involvement. Although a chest radiograph is recommended to rule out the presence of metastatic spread to the lungs, a CT scan of the chest is preferred. A CT scan of the abdomen and pelvis is often performed to evaluate hepatic and retroperitoneal involvement and occult abdominal and pelvic disease, and to determine the depth of tumor penetration into the bowel wall and/or invasion to adjacent organs. Detection of lymph node involvement with either study is limited by the difficulty of distinguishing inflammatory or reactive lymph nodes from those infiltrated with tumor. Because CT scans may not adequately detect peritoneal seeding, small distant lymph node metastasis, or liver metastasis in colon cancer, an occasional patient may need to undergo a laparotomy, spiral CT, magnetic resonance imaging, or glucose analog [^{18}F]-fluorodeoxyglucose-positron emission tomography (PET) scan in order to confirm metastatic disease. PET imaging can provide functional information to discriminate between benign and malignant disease by detecting tumor-related metabolic alterations in affected tissues. PET scans are commonly used for the detection of recurrent colorectal cancer in patients with rising CEA levels and inconclusive findings on standard imaging studies. A PET scan is often combined with or followed by a CT scan because anatomical localization of a lesion using PET alone can be difficult.

Endoscopic ultrasound is a technique that is becoming more widely available for the evaluation of patients with rectal cancer. It is useful for detecting the depth of tumor penetration, and like pelvic CT scans, is fair to good in determining lymph node involvement. Cystoscopy or IV pyelography studies are rarely indicated except for very large rectal tumors found on examination, if the patient exhibits symptoms, or if a CT scan suggests bladder involvement. Intraluminal and hepatic magnetic resonance imaging studies may also provide useful information.

Radioimmunoscintigraphy uses tumor-directed antibodies labeled with γ-producing radionuclides such as ^{99m}technetium or ^{111}indium to detect malignant cells.[62] Several tumor-associated proteins have been identified within or on the surface membrane of colorectal malignant cells to which monoclonal antibodies have been targeted. Of these, TAG-72 and CEA are commonly used. Radiolabeled monoclonal antibodies directed against these antigens are used in clinical studies for both external immunoscintigraphy as well as intraoperative localization of tumor. OncoScint, an ^{111}indium-labeled B72.3 monoclonal antibody targeted to the TAG-72 cell-surface antigen, is an FDA-approved diagnostic imaging agent available for determining the location and extent of extrahepatic disease in patients with colorectal cancer. CEA-Scan is a ^{99m}Tc-labeled fragment of the anti-CEA antibody for the assessment of recurrent colorectal carcinoma. The use of these tests is generally reserved for those patients who have completed standard diagnostic imaging tests, but may still require additional information regarding the extent of disease. They may also play an important role in identifying metastatic or recurrent disease in individuals with rising CEA levels and negative standard radiographic studies.

STAGING

4 The purpose of the staging examinations is to determine the extent of disease, which allows the oncologist to develop treatment options and estimate overall prognosis. Traditionally, the Dukes classification, originally published in 1932, was used in the staging of colorectal cancers.[47] Since its original publication, it has undergone several modifications; a modified Astler-Coller version is now used more commonly. In an effort to standardize the staging system for colorectal cancer, the American Joint Committee on Cancer and the Union for International Cancer Control (UICC) jointly recommend the TNM classification system. This classification takes three aspects of cancer growth: T (tumor size), N (lymph node involvement), and M (presence or absence of metastases) into account. The TNM classification also allows for various subdivisions within each of the three categories, which is then used for determining the disease stage. Table 138–6 summarizes the staging definitions using the TNM system and corresponding SEER 5-year survival rates.[63,64] Figure 138–5 shows the relationship between the modified Astler-Coller and American Joint Committee on Cancer/Union for International Cancer Control staging systems.

PROGNOSIS

4 The stage of colorectal cancer upon diagnosis is the most important independent prognostic factor for survival and disease recurrence. Five-year relative survival is approximately 92% for individuals who present with a localized tumor stage at diagnosis as compared with about 11% for individuals with metastatic disease at diagnosis.[3]

Clinical factors present at the time of diagnosis that are associated with a poor prognosis and decreased survival include bowel obstruction or perforation, rectal bleeding, high preoperative CEA level, distant metastases, and location of the primary tumor in the rectum or rectosigmoid area.[47] Along with resection of the primary tumor, a minimum of 12 lymph nodes must be examined to accurately determine regional lymph node involvement and predict lymph node-negative disease.[48] The pathologic assessment also includes determination of TNM stage, tumor type and histologic grade, presence of vascular invasion, and whether the resected margins are free of tumor. Consideration of these factors plays an important role in determining optimal strategies for treatment and appropriate follow-up.

Additional stage-independent pathologic variables that have negative prognostic or predictive value with regard to adjuvant therapy include presence of lymphatic or perineural invasion; mucinous or signet-ring histology; high tumor proliferation indices; tumor

TABLE 138-6 Colon Cancer by TNM Classification and Associated 5-Year Relative Survival

Stage	T	N	M	Dukes[a]	MAC[a]	Survival (%)

T_{is}: Carcinoma in situ: intraepithelial or invasion of lamina propia[b]
T_1: Tumor invades submucosa
T_2: Tumor invades muscularis propria
T_3: Tumor invades through the muscularis propria into pericolorectal tissues
T_{4a}: Tumor penetrates to the surface of the visceral peritoneum[c]
T_{4b}: Tumor directly invades or is adherent to other organs or structures[c,d]
[a]Dukes B is a composite of better (T_3 N_0 M_0) and worse (T_4 N_0 M_0) prognostic groups, as is Dukes C (Any T N_1 M_0 and Any T N_2 M_0). MAC is the modified Astler-Coller classification.
[b]T_{is} includes cancer cells confined within the glandular basement membrane (intraepithelial) or mucosal lamina propria (intramucosal) with no extension through the muscularis mucosae into the submucosa.
[c]Direct invasion in T_4 includes invasion of other organs or other segments of the colorectum as a result of direct extension through the serosa, as confirmed on microscopic examination (for example, invasion of the sigmoid colon by a carcinoma of the cecum) or, for cancers in a retroperitoneal or subperitoneal location, direct invasion of other organs or structures by virtue of extension beyond the muscularis propria (i.e., respectively, a tumor on the posterior wall of the descending colon invading the left kidney or lateral abdominal wall; or a mid or distal rectal cancer with invasion of prostate, seminal vesicles, cervix, or vagina).
[d]Tumor that is adherent to other organs or structures, grossly, is classified cT_{4b}. However, if no tumor is present in the adhesion, microscopically, the classification should be pT_{1-4a} depending on the anatomical depth of wall invasion. The V and L classifications should be used to identify the presence or absence of vascular or lymphatic invasion whereas the PN site-specific factor should be used for perineural invasion.
Data from references 3, 63, and 64.

aneuploidy; absence of host immune response to the tumor; and presence of certain molecular markers (18q/*DCC* mutation or loss of heterozygosity, microsatellite stability [MSS], *RAS* mutations, elevated thymidylate synthase [TS] expression, and *P53* mutation or loss).[47,48,65] Of these, the highest level of evidence supports the consideration of lymphatic invasion as a prognostic factor. The next level of evidence, which is supporting but requires additional validation, is for 18q/*DCC* mutation or loss of heterozygosity and MSS.

The original source for this material is the AJCC Cancer Staging Manual, Seventh Edition (2010) published by Springer Science and Business Media LLC, www.springer.com; UICC, Union for International Cancer Control.)

Colorectal cancers with allelic loss of heterozygosity on chromosome 18q or absent DCC protein are associated with a worse prognosis within stage II disease and may predict response to adjuvant chemotherapy, but data are insufficient to warrant its use at this time.[61,66] MSS can be determined through DNA sequencing or by immunohistochemistry staining for protein products of the *MSH2* or *MLH1* genes. Colorectal cancers that demonstrate high-frequency MSS appear to be associated with a more favorable outcome and may predict the benefit of fluorouracil.[67] Although findings from several studies suggest that MSS status may predict efficacy of adjuvant fluoropyrimidine therapy, this finding must be confirmed in a prospective study before its use can be recommended.[61] Trials that account for MSS are ongoing.

Tumors that overexpress mutant *P53* demonstrate a high degree of resistance to radiation, fluorouracil, and certain other chemotherapeutic agents and are associated with a less-favorable prognosis. However, because of heterogeneous and conflicting results of reported studies, often attributable to methodologies that do not address the functional status of both *P53* alleles, *P53* status does not appear useful as a guide for treatment decisions.[61]

Tumors that overexpress TS, an enzyme that converts deoxyuridine monophosphate to deoxythymidine monophosphate, an essential step for DNA synthesis, are less sensitive to fluorouracil chemotherapy. Patients whose colon cancers have higher levels of TS appear to have a significantly worse overall 5-year survival than patients whose cancers have a low level of TS.[47] The importance of elevated TS and type of therapeutic interventions is unclear. No large cooperative group trial has identified a subgroup of patients who failed to benefit from fluorouracil plus leucovorin therapy based on tumor TS levels. Consideration of tumor TS expression in several adjuvant therapy trials is ongoing.

Tumors that have a high rate of proliferation are generally associated with a poor prognosis. Ki-67 is expressed in cells actively engaged in the cell cycle and has also been used as a measure of colon cancer proliferation. Interestingly, for unknown reasons, high levels of Ki-67 were associated with an increase in overall survival in patients with early-stage colon cancer. EGFR testing of colorectal tumor cells with immunohistochemistry has been a standard component of pathologic analysis, but the value of EGFR positive staining in predicting response to anti-EGFR treatment is still unclear. Although EGFR overexpression may be linked to more advanced disease or predict risk of metastasis, its relationship to overall survival is controversial.[46] Other methods to assess EGFR status are being evaluated.

Evaluation of these factors may predict which patients will benefit most from more aggressive therapy, individuals who may not in the future require systemic chemotherapy, and new therapeutic targets for the treatment of colorectal cancer, but further study is required. The current American Society of Clinical Oncology (ASCO) guidelines do not recommend the use of DNA ploidy, DNA flow cytometric proliferation analysis, *P53* expression or mutation analysis, *RAS* oncogene testing, MSS markers, or 18q loss of heterozygosity/DCC determination to determine prognosis or response to therapy.[61]

TREATMENT

Colorectal Cancer

DESIRED OUTCOME

Treatment goals for cancer of the colon or rectum are based on the stage of disease at presentation. Stages I, II, and III disease are considered potentially curable and are managed with the intent

of eradicating micrometastases that may be present. Based on the numbers and site(s) of metastases, approximately 20% to 30% of patients with metastatic colorectal cancer may be cured, if their metastases are considered resectable. Most patients with stage IV disease are not curable, and treatments for metastatic disease are considered palliative to reduce symptoms, avoid disease-related complications, and prolong survival.

GENERAL APPROACH TO TREATMENT

Although advanced age is not an absolute contraindication for aggressive therapies, the age of the patient, concomitant disease states, lifestyle factors, performance status, and the patient's preferences must be considered in the treatment planning process. Special or emergent conditions, such as bowel perforation, spinal cord compression, and severe pain, anemia, or other symptomatic problems, need to be addressed acutely, after which time a more long-term disease-specific plan can be developed. The treatment approaches for colorectal cancer reflect two primary treatment goals: curative therapy for localized disease and palliative therapy for metastatic cancer.

For patients for whom treatment intent is curative, surgical resection of the primary tumor is the most important component of therapy. Depending on the extent of disease and whether the tumor originated in the colon or rectum, further adjuvant chemotherapy or chemotherapy plus XRT may be appropriate. For selected patients with resectable metastases, surgical resection may be an option. However, for most patients with metastases, systemic chemotherapy is the mainstay of treatment; XRT may also be useful for disease palliation of localized symptoms or when chemotherapy is no longer effective. Patients with metastatic disease who are asymptomatic may benefit from initiation of therapy, and treatment should not be withheld until they develop symptoms.

OPERABLE DISEASE

Surgery

5 Individuals with operable—stages I, II, and III—colorectal cancer should undergo complete surgical resection of the primary tumor mass with regional lymphadenectomy as a curative approach for their disease.[47] The surgical approach for colon cancer generally involves complete resection of the tumor with an appropriate margin of tumor-free bowel and a regional lymphadenectomy. A total colectomy is rarely needed in colon cancer but may be indicated for selected patients with FAP or chronic ulcerative colitis.

Surgery for rectal cancer depends on the region of tumor involvement. A low anterior resection is the procedure of choice in patients with lesions in the middle to upper rectum.[68] Patients with lesions in the lower portion of the rectum may require an abdominoperineal resection if the amount of unaffected bowel is insufficient for a resection far enough away from the tumor, or if the affected bowel is too close to areas that cannot permit an anastomosis. Excision of the mesorectum, the surrounding tissue that contains perirectal fat and draining lymph nodes, has also been advocated. Newer surgical techniques have been developed in an attempt to retain function of the rectal sphincter and still achieve complete tumor resection. Individuals who are not candidates for sphincter-sparing resections or have extensive local spread of tumor will require an abdominoperineal resection. This involves removal of the distal sigmoid, rectosigmoid, rectum, and anus with the establishment of a permanent sigmoid colostomy. Less than one-third of patients will require a permanent colostomy for rectal cancer.[68] Other complications that occur frequently with surgery for rectal cancer include urinary retention, incontinence, impotence, and locoregional recurrence.

Overall, surgery for colorectal cancer is associated with a morbidity and mortality rate of 8% to 15% and 1% to 2%, respectively, depending on the type and extent of procedure.[47,68] Common complications associated with colorectal surgery include infection, anastomotic leakage, obstruction, adhesion formation, and malabsorption syndromes. Laparoscopic colectomy has become an accepted procedure for colon cancer, and there are limited data for patients with rectal cancer.[69] This technique appears to produce similar results to conventional surgery, with the benefits of a smaller surgical incision, shorter hospital stay, and reduced pain.

Adjuvant Therapy for Colon Cancer

Adjuvant therapy in colorectal cancer is administered to selected individuals after complete tumor resection in an attempt to eliminate residual micrometastatic disease, thereby decreasing tumor recurrence and improving survival rates. Because more than 90% of patients with stage I colon or rectal cancer are cured by surgical resection alone, adjuvant therapy is not indicated.[47] The role of adjuvant chemotherapy for stage II colon cancer is less clear because the results of studies in patients with stage II disease are conflicting. Adjuvant chemotherapy for patients with stage II disease has not been shown to be superior to surgery alone, with the exception of some high-risk patients. The ASCO guideline does not recommend routine use of adjuvant chemotherapy in patients with stage II disease unless it is administered in conjunction with a clinical trial.[70] Stage II patients who are at higher risk for relapse include those with inadequate lymph node sampling, perforation of the bowel at presentation, poorly differentiated tumors, and T_4 lesions. Adequate examination of the lymph nodes for tumor involvement is most important for appropriate staging of the patient with colorectal cancer. Various tumor molecular genetic factors (e.g., chromosome 18q deletion, tumor ploidy, mutations of protooncogenes or tumor suppressor genes, tumor TS expression, and MSS) are also being studied in an effort to identify subsets of patients with stage II disease who have an increased risk of relapse. Despite the lack of a consensus regarding the use of adjuvant chemotherapy for individuals with high-risk stage II colon cancer, many practitioners offer this therapy to selected patients, with a detailed discussion with patients regarding the potential benefits versus treatment-related toxicities. Optimal dosing, administration schedule, and duration of therapy have yet to be determined, but most practitioners use the same treatment approach as that used for patients with stage III colon cancer.

Adjuvant chemotherapy is standard therapy for patients with stage III colon cancer. The presence of lymph node involvement with tumor places patients with stage III colon cancer at high risk for recurrence, and the risk of death within 5 years of surgical resection alone is as high as 70%, depending on the number of lymph nodes involved.[47] In this population of patients, adjuvant chemotherapy significantly decreases risk of cancer recurrence and death and is standard of care.

Adjuvant XRT plus chemotherapy is considered standard treatment for patients with stage II/III rectal cancer.[68] Tumors arising in the rectum are technically more difficult to resect with wide circumferential margins and lead to local recurrences more frequently than those seen with colon cancers. Therefore, XRT is an important aspect of adjuvant therapy for rectal cancer to reduce risk of local tumor recurrence.

Adjuvant Radiation Therapy 6 Adjuvant XRT has no definite role in colon cancer because most recurrences are extrapelvic and occur in the abdomen.[47] Although local recurrence and debilitating pelvic pain are uncommon, a subset of patients with T_3 or T_4 tumors located in the cecum and in hepatic and splenic flexures are at increased risk of local recurrence and may benefit from

postoperative XRT and chemotherapy. Early trials with whole-abdominal XRT were limited by considerable toxicity.[68] However, results from studies combining abdominal XRT plus fluorouracil are promising. To date, postoperative local XRT may reduce the risk of local recurrence and improve survival compared to adjuvant chemotherapy alone but should only be considered for select patients with colon cancer.[47] Additionally, intraoperative radiation should be considered for patients with T_4 lesions that are fixed to an adjacent lesion.[71]

In patients undergoing surgery for rectal cancer, XRT is used to reduce risk of local tumor recurrence. Radiation therapy is given prior to or following surgery and can be delivered with a variety of dosing regimens, administration schedules, and techniques.[68] Preoperative XRT may be used to reduce the initial size of the tumor to such an extent that the tumor can be reclassified to a lower stage, or "down-staged," and therefore rendered more resectable. This might lead to improved patient survival or result in the need for a less-extensive surgical procedure. Preoperative XRT is also administered to reduce the amount of tumor seeding that can occur during surgery, but this approach is more likely to affect a greater area than is necessary.[68] Postoperative administration of XRT may more adequately treat a defined area but is associated with more toxicity because of a greater amount of bowel being present in the treatment field.

Adverse effects associated with XRT in colorectal cancer can be acute or chronic. Acute effects primarily include hematologic depression, dysuria, diarrhea, abdominal cramping, and proctitis. Chronic symptoms that sometimes persist for months following discontinuation of XRT include persistent diarrhea, proctitis or enteritis, small bowel obstruction, perineal tenderness, and impaired wound healing.

Adjuvant Chemotherapy For more than 40 years, fluorouracil has been the most widely used chemotherapeutic agent for the adjuvant treatment of colorectal cancer, both as a single agent and in combination with other agents. Newer agents such as oxaliplatin and capecitabine have been incorporated into combination chemotherapy regimens for the adjuvant treatment of colon cancer.[72,73] Investigational chemotherapy agents, biologic therapies that target the underlying tumor biology, and new administration methods are also being developed. Current adjuvant trials focus on combination chemotherapy regimens with newer targeted agents added.

Based on their activity for metastatic colon cancer, fluorouracil and floxuridine were investigated as single-agent chemotherapy agents for use after surgery. In 1988, a meta-analysis of phase III trials showed a small, statistically insignificant improvement in survival with fluorouracil-based regimens as compared with surgery alone.[74] Since then, most trials focused on improving the efficacy of fluorouracil in the adjuvant treatment of colon cancer.

Subsequently, clinicians identified strategies that modified the pharmacology of fluorouracil to increase its antitumor activity. The addition of leucovorin increases the binding affinity of the active fluorouracil metabolite to TS, thus enhancing its cytotoxic activity. Combinations of fluorouracil plus leucovorin have been studied extensively in the adjuvant setting, based on the observation that fluorouracil plus leucovorin substantially improves response rates as compared with fluorouracil alone for metastatic disease.

Schedules of fluorouracil and leucovorin administration vary among the different regimens. In the United States, the Roswell Park regimen and the Mayo Clinic regimen were most commonly used, while in Europe, treatments such as the de Gramont regimen favored a continuous intravenous schedule of fluorouracil (Table 138–7).

Clinical studies comparing the efficacy of bolus and continuous infusion schedules generally favor continuous infusion of fluorouracil, which is probably related to its short plasma half-life and S-phase specificity for optimal TS inhibition. Continuous intravenous (IV) infusions also permit increased fluorouracil dose intensity, which may account for the higher response rates observed with prolonged infusions of fluorouracil. In most common combination regimens, fluorouracil is administered by both IV bolus injection and continuous IV infusion.

Clinically significant differences in toxicity occur based on the dose, route, and schedule of fluorouracil administration. Leukopenia is the primary dose-limiting toxicity of IV bolus fluorouracil, although diarrhea, stomatitis, and nausea and vomiting can also occur.[78] The incidence and severity of stomatitis can be significantly reduced with the use of oral cryotherapy. In this approach, the patient is instructed to chew and hold ice chips in the mouth during the period between 5 minutes prior to and 30 minutes following the bolus injection of fluorouracil. The protective effects of this procedure are probably related to the local vasoconstriction caused by the ice chips, which temporarily reduces blood flow to the oral mucosa, thereby reducing drug exposure to the oral mucosa.

Although continuous IV infusion fluorouracil is generally well tolerated, dose-limiting toxicities can be substantial. A distinct toxicity, palmar–plantar erythrodysesthesia ("hand–foot syndrome" or PPE), and stomatitis occur most frequently with this route of administration.[78] Hand–foot syndrome occurs in 24% to

TABLE 138-7 Chemotherapy Regimens for the Adjuvant Treatment of Colorectal Cancer

Regimen	Agents	Comment
FOLFOX4[72]	Oxaliplatin 85 mg/m² IV day 1 Folinic acid 200 mg/m² per day IV over 2 hours days 1 and 2 Fluorouracil 400 mg/m² IV bolus, after folinic acid then 600 mg/m² CIV over 22 hours days 1 and 2 • Repeat every 14 days	Improved OS and DFS as compared with infusional fluorouracil-leucovorin–based regimens.
FLOX[73]	Oxaliplatin 85 mg/m² IV administered on weeks 1, 3, and 5 Fluorouracil 500 mg/m² IV bolus weekly × 6 Folinic acid 500 mg/m² IV weekly × 6 • Each cycle lasts 8 weeks and is repeated for 3 cycles	Improved DFS as compared with bolus fluorouracil-leucovorin–based regimens. Increased toxicity compared to FOLFOX4.
Capecitabine	Capecitabine 1,250 mg/m² PO twice daily on days 1 through 14 every 21 days	Equivalent DFS as compared with the Mayo Clinic regimen with improved tolerability.
Fluorouracil-based regimens		
Roswell Park regimen[75]	Fluorouracil 600 mg/m² per day IV, day 1 Folinic acid 500 mg/m² per day IV over 2 hours • Repeat weekly for 6 of 8 weeks	
Mayo Clinic regimen[76]	Fluorouracil 425 mg/m² per day IV, days 1–5 Folinic acid 20 mg/m² per day IV, days 1–5 • Repeat every 4 to 5 weeks	
de Gramont regimen[77]	Fluorouracil 400 mg/m² per day IV bolus, followed by 600 mg/m² CIV over 22 hours, days 1 and 2 for 2 consecutive days Folinic acid 200 mg/m² per day IV over 2 hours days 1 and 2 • Repeat every 2 weeks	Improved safety as compared with the Mayo Clinic regimen.

CIV, continuous intravenous infusion; OS, overall survival; DFS, disease-free survival.

40% of patients receiving extended continuous IV infusions and is characterized by painful swelling and erythroderma of the soles of the feet, palms of the hands, and distal fingers. The skin toxicity is fully reversible upon interruption of therapy or dose reduction and is not life threatening, but it can be significant and acutely disabling. The incidence of stomatitis, diarrhea, and hematologic toxicity is not substantial at standard doses, but it increases with increasing fluorouracil doses. No significant difference is noted in the incidence of mucositis, diarrhea, nausea and vomiting, or alopecia between continuous and bolus IV fluorouracil administration.[78]

An additional determinant of fluorouracil toxicity, regardless of the method of administration, is related to its catabolism and pharmacogenomic factors. Dihydropyrimidine dehydrogenase (DPD) is the main enzyme responsible for the catabolism of fluorouracil to inactive metabolites. A rare pharmacogenetic disorder characterized by complete or near-complete deficiency of this enzyme has been identified in patients with cancer. Patients with this enzyme deficiency develop severe toxicity, including death, after fluorouracil administration. Molecular studies have identified a relationship between allelic variants in the *DPYD* gene (the gene that encodes DPD) and a deficiency in DPD activity.[79] Approximately 3% of patients may be genotypically heterozygous for a mutant DPYD allele, although differences between sex and races are unknown at this time.

In summary, fluorouracil and leucovorin can be administered in a variety of treatment schedules, but none has proven superior with regard to overall patient survival. Table 138–7 lists examples of some of these regimens.

7 *Fluorouracil Plus Oxaliplatin.* The role of oxaliplatin in adjuvant chemotherapy was evaluated based on its activity in metastatic disease. In the Multicenter International Study of Oxaliplatin/5-Fluorouracil/Leucovorin in the Adjuvant Treatment of Colon Cancer (MOSAIC) trial, 2,246 patients with stage II or III colon cancer were randomized to receive fluorouracil plus leucovorin or FOLFOX4 (fluorouracil/leucovorin plus oxaliplatin) postoperatively.[80] The addition of oxaliplatin resulted in a 20% risk reduction in disease recurrence and increased 5-year disease-free survival (DFS) (73.3% vs. 67.4%) as compared with fluorouracil plus leucovorin alone. With a median follow up of 81.9 months, the addition of oxaliplatin resulted in an absolute 6-year overall survival (OS) difference of 2.5%, which was statistically significant. Overall, the relative risk of death was reduced by 16%, with the benefit limited to stage III patients. The addition of oxaliplatin was associated with increased risk of paresthesia, neutropenia, and gastrointestinal toxicity (nausea, vomiting, diarrhea) that were manageable with supportive care. Further supporting the role of oxaliplatin in the adjuvant setting are the results of the recently reported National Surgical Adjuvant Breast and Bowel Project C-07 trial, which compared the Roswell Park regimen of bolus fluorouracil/leucovorin with or without oxaliplatin. A 20% risk reduction in disease recurrence was seen with oxaliplatin (hazard ratio [HR] = 0.80, $P = 0.0034$) added to the fluorouracil backbone. As expected, neurotoxicity was increased with oxaliplatin.[81] This method of administration is associated with increased diarrhea and neuropathies as compared with the aforementioned regimen used in the MOSAIC trial. FLOX, a oxaliplatin-containing regimen with bolus fluorouracil and leucovorin, was more toxic as compared to FOLFOX.[73]

The 2010 National Comprehensive Cancer Network (NCCN) guidelines recommend oxaliplatin-based regimens as the first-line option for patients with stage III colon cancer who can tolerate combination therapy, and most practitioners incorporate oxaliplatin into adjuvant treatment regimens.[71]

Further modifications of the FOLFOX4 regimen may also improve tolerability. Capecitabine, an oral prodrug of fluorouracil, and other oral pyrimidines are also being evaluated in adjuvant studies as a replacement for fluorouracil in an attempt to improve the safety and ease of administration of the chemotherapy regimens.

Capecitabine. In addition to being investigated as a replacement for fluorouracil in combination regimens, capecitabine is FDA approved as a single agent in the adjuvant setting. The Xeloda in Adjuvant Colon Cancer Therapy (X-ACT) trial compared capecitabine to the Mayo Clinic regimen of bolus fluorouracil/leucovorin in the adjuvant treatment of 1,987 patients with stage III colon cancer.[82] Both regimens were given for 6 months. This trial was designed to show noninferiority of capecitabine to bolus fluorouracil. DFS between the groups was found to be equivalent. Secondary end points of relapse-free survival (HR 0.86; 95% CI 0.74 to 0.99; $P = 0.04$) and safety were improved with capecitabine. In particular, the incidence of diarrhea, stomatitis, and neutropenia was decreased with capecitabine, but the incidence of hand–foot syndrome was increased with capecitabine.

Investigational Approaches. Despite its proven benefit in the metastatic setting, irinotecan has not shown a benefit in the adjuvant setting and should not be used outside of clinical trials at this time. Three trials have evaluated the addition of irinotecan to bolus or continuous infusion fluorouracil/leucovorin, and all have failed to demonstrate a DFS benefit. Cancer and Leukemia Group B 89803 compared with the irinotecan plus fluorouracil/leucovorin (IFL) regimen to bolus fluorouracil/leucovorin; not only was there no DFS benefit but the IFL regimen was associated with significant toxicity.[83] The Third Pan-European Trial in Adjuvant Colon Cancer (PETACC-3) and ACCORD studies, which used infusional regimens similar to folinic acid, fluorouracil, and irinotecan (FOLFIRI), also found no difference in DFS as compared with infusional fluorouracil/leucovorin.[84,85]

The combination of capecitabine and oxaliplatin (XELOX) as adjuvant therapy for stage III colon cancer has been compared to fluorouracil/leucovorin (either Mayo Clinic or Roswell Park regimens).[86] Efficacy data showed a significantly improved DFS with XELOX as compared to bolus fluorouracil/leucovorin ($P = 0.0024$), with a trend toward improved OS with XELOX, even in patients age 70 years and older.

With the success of cetuximab and bevacizumab in the metastatic setting, adjuvant trials evaluating monoclonal antibodies in combination with the previously mentioned regimens have been conducted. FOLFOX ± bevacizumab or cetuximab are part of large phase III trials currently enrolling or recently completed in cooperative groups to assess the benefit of these monoclonal antibodies in this setting. The final results of the NSABP-C08 trial that compared FOLFOX with or without bevacizumab was recently completed and did not meet its primary end point of DFS.[87] Also, recent results showed no benefit in 3-year DFS ($P = 0.33$) from the addition of cetuximab to the combination of infusional fluorouracil plus oxaliplatin (mFOLFOX6) as adjuvant therapy for patients with *KRAS* wild-type stage III colon cancer.[88] As such, there is no clear role for these agents in the adjuvant treatment setting at this time.

Approach to Selecting an Adjuvant Regimen. Selecting a specific regimen from those listed in Table 138–7 requires an assessment of several patient-specific factors, including the performance status of the patient, comorbid conditions that may exist, and patient preferences for treatment based on lifestyle factors that are important to the patient. If a clinical trial is not an option, most patients with a good performance status will receive oxaliplatin in combination with fluorouracil/leucovorin. Single-agent capecitabine may be the preferred option for patients with preexisting

neuropathies, such as diabetic patients, or those patients wishing not to receive IV chemotherapy for any other reason. Fluorouracil/leucovorin has limited use at this time but is an acceptable option for patients who cannot receive oxaliplatin and are unable to tolerate or take oral capecitabine. For example, patients who develop severe hand–foot syndrome may tolerate bolus fluorouracil/leucovorin because this toxicity is minimal with this administration method.

Adjuvant Therapy for Rectal Cancer

6 Rectal cancer involves those tumors found below the peritoneal reflection in the most distal 15 cm of the large bowel, and as such is distinct from colon cancer in that it has a propensity for both local and distant recurrence. The higher incidence of local failure and overall poorer prognosis associated with rectal cancer is a result of anatomic limitations in excising adequate radial margins around the rectal tumor. Although an abdominoperineal resection of the tumor and adjacent tissues results in a high probability of local control and long-term survival, the sequelae, including need for a permanent colostomy and high incidence of sexual and genitourinary dysfunction, has led to investigation of approaches that use multimodal therapies that preserve the integrity of the anal sphincter.[89] In addition, adjuvant therapy after surgical resection is an important aspect of treatment of the primary tumor. The effectiveness of postoperative XRT and fluorouracil-based chemotherapy for stage II or III rectal cancer is well established. Although T_1 tumors with a favorable histology may be treated successfully with local excision alone, adjuvant XRT plus chemotherapy should be offered for larger lesions. Similar to adjuvant therapy for colon cancer, fluorouracil provides the basis for chemotherapy regimens for rectal cancer. The XRT decreases the rate of local pelvic recurrences, whereas the fluorouracil decreases the risk of distant tumor recurrence and enhances the effectiveness of the XRT. The optimal delivery schedule for these two therapies is the subject of ongoing investigation, but many trials have demonstrated improved local control and survival for patients who receive a combination of postoperative XRT and chemotherapy as compared with surgery alone.[90] The use of concurrent chemotherapy and XRT significantly affects local recurrence, relapse-free survival, and OS as compared with XRT alone and have established fluorouracil plus XRT as the foundation for adjuvant therapy in stages II and III rectal cancer. Treatment with the combined approach should total 6 months.

Many treatment centers now administer continuous-infusion fluorouracil throughout the 5- or 6-week schedule of postoperative XRT for rectal cancer. Several schedules for combining fluorouracil with postoperative XRT provide similar relapse-free survival and OS but differ with regard to toxicity profile and catheter requirements for drug administration.[91] Alternative regimens including FOLFOX and capecitabine may be used in place of fluorouracil.

Preoperative (Neoadjuvant) Therapy 6 Interest in preoperative or neoadjuvant therapy has increased based on advances in imaging techniques to more accurately stage rectal tumors preoperatively and the success of combined XRT plus fluoropyrimidine-based chemotherapy administered in the postoperative setting. By shrinking and thereby downstaging the tumor prior to surgical resection, preoperative XRT improves sphincter preservation, but the primary concern with this approach is potential overtreatment with XRT in some patients.

Neoadjuvant chemoradiotherapy may further enhance tumor shrinkage and improve the rate of tumor resectability with rectal sphincter preservation. The European Organization for Research and Treatment of Cancer 22921 trial evaluated the addition of fluorouracil plus leucovorin to preoperative XRT and showed an improvement in tumor shrinkage with lower lymph node involvement.[92] The 2010 NCCN guidelines for rectal cancer indicate that preoperative infusional fluorouracil-based chemotherapy plus XRT is the preferred treatment for resectable T_3 N_0 or any T, N_{1-2} lesions (category 1 recommendation).[90] This should be followed by additional adjuvant chemotherapy after surgery to total 6 months of chemotherapy (combined total from preoperative and postoperative regimens). Neoadjuvant fluorouracil or capecitabine chemoradiation followed by abdominoperineal resection or low anterior resection should be considered for locally unresectable tumors (T_4). Postoperative therapy should be administered to all patients who received preoperative chemotherapy for rectal cancer, regardless of whether the disease was initially resectable.[90]

METASTATIC DISEASE

Initial Therapy

8 Several advances have been made in developing efficacious treatment options for metastatic colorectal cancer. Although surgery and XRT are usually used to manage isolated sites of tumor, chemotherapy is most useful for patients with disseminated disease and is the primary treatment modality for unresectable metastatic colorectal cancer.

Surgery Complete surgical resection of discrete hepatic, pulmonary, abdominal, or brain metastases in patients with colorectal cancer, if possible, may extend DFS in selected patients. Patients who have from one to three small nodules isolated to the liver, lungs, or abdomen have the most favorable outcomes. Up to 25% of patients will present with hepatic metastases at time of diagnosis, and 60% of patients with colorectal cancer will develop hepatic metastases sometime during the course of their disease. Approximately 35% of patients who undergo resection of hepatic-limited metastases can be cured.[93] These results are substantially better than those in patients with unresectable metastatic colorectal cancer, in whom 5-year survival is uncommon. Patients with no significant general medical risk factors, fewer than four hepatic lesions, CEA levels less than 200 ng/mL (200 mcg/L), small tumor size, lack of extrahepatic tumor, and adequate surgical margins have the best opportunity for an improved long-term outcome. The primary site of tumor should also be completely resected. Ablative therapies that involve destroying the tumor through freezing and thawing (cryoablation), heat (radiofrequency), or alcohol injection may be useful for patients who have very small hepatic lesions and are unable to undergo liver resection surgery but are less successful than surgical interventions. Outcomes associated with resection of isolated pulmonary, abdominal, and brain metastases have been less studied, but this approach is potentially curative and should be considered for patients with resectable disease who are appropriate surgical candidates.

Because about two-thirds of patients who undergo resection of hepatic metastases will have disease recurrence, postoperative treatments (e.g., adjuvant systemic and hepatic arterial infusion chemotherapy) have been studied in an attempt to improve long-term outcomes. A randomized trial that compared 6 months of hepatic floxuridine and dexamethasone plus IV fluorouracil with leucovorin to IV fluorouracil with leucovorin alone following resection of hepatic metastases in 156 patients showed improved 2-year DFS (86% vs. 72%) and hepatic recurrence-free survival at 2 years (90% vs. 60%) with the combined therapy.[94] Many practitioners offer adjuvant chemotherapy to selected patients following potentially curative hepatic resection, but further studies, especially those involving more active agents, are needed to determine an optimal treatment regimen.[95]

Neoadjuvant (Conversional) Chemotherapy. Patients that present with metastatic disease isolated to the liver and who

undergo resection of all metastatic and primary lesions have an increased probability of survival compared with those whose liver lesions remain unresected.[96] Therefore, strategies to increase the success rate of these resections (or convert unresectable lesions to resectable) is the primary goal in patients with liver metastasis. Administration of neoadjuvant chemotherapy, also referred to as conversional chemotherapy, is the primary method to increase complete resection rates in both patients with resectable or unresectable liver lesions.

Patients with initially resectable disease should receive 2 to 3 months of preoperative chemotherapy. The choice of agents depends on patient-specific factors but may include regimens such as FOLFOX, FOLFIRI, or CapeOx. Biologic agents have been added to the foregoing regimens. If patients receive bevacizumab, surgery should not occur within 6 weeks of the last dose of therapy, and bevacizumab should not be restarted until 6 to 8 weeks after surgery. EGFR inhibitors should be considered only in patients that have tumors with wild-type *KRAS*. Postoperative chemotherapy should be administered to patients to complete a total of 6 months of chemotherapy (pre- and postoperative).[71]

Patients with unresectable lesions are eligible for the same chemotherapy regimens already noted. However, since the primary goal is surgical resection whenever possible, patients should be evaluated for possible resection after every 2 months of therapy. If resection occurs, adjuvant chemotherapy should be administered to complete a total of 6 months of chemotherapy.

Radiation Symptom control is the primary goal of XRT for patients with advanced or metastatic colorectal cancer.

Chemotherapy 8 Accepted initial chemotherapy regimens for metastatic colorectal cancer consist of oxaliplatin plus fluorouracil and leucovorin, irinotecan plus fluorouracil and leucovorin, bevacizumab plus a fluorouracil-based regimen, capecitabine alone, or fluorouracil plus leucovorin alone (Table 138–8). The site(s) of tumor involvement and history of prior chemotherapy help to define an appropriate management strategy. In general, treatment options are similar for metastatic cancer of the colon and rectum.

Currently, most metastatic colorectal cancers are incurable, and treatment goals are to reduce patient symptoms, improve quality-of-life, and extend survival. Two recent meta-analyses have estimated the magnitude of benefit and harm associated with palliative chemotherapy for metastatic colorectal cancer. In a pooled analysis of randomized trials comparing chemotherapy to observation or supportive care alone, a total of nine trials that included 614 patients were evaluated.[106] All trials used fluorouracil-based chemotherapy, but three trials in which hepatic arterial or portal vein administration was used were also included. Several trials allowed delayed or discretionary use of chemotherapy in patients assigned to observation or supportive care alone; 12% to 57% of control patients received at least one course of chemotherapy. Despite these discrepancies, chemotherapy was associated with a significant reduction in mortality at 1 year (relative risk [RR] 0.69) but not at 2 years (RR 0.93). The second meta-analysis analyzed individual patient data and summary statistics from 13 randomized trials that included 1,365 patients.[107] Eligible trials compared palliative chemotherapy given via any route of administration to supportive care alone or treatments not involving chemotherapy. Trials that allowed chemotherapy use in control patients were not excluded. In the analysis of seven trials in which individual patient data were available, palliative chemotherapy was shown to reduce the risk of death by 35%, which translates to a prolongation of median survival by 3.7 months. The investigators were unable to determine the effect of treatment on toxicities or quality-of-life because of inadequate data. However, the results of both analyses suggest that palliative chemotherapy is beneficial and improves survival in metastatic colorectal cancer. Because many patients assigned to control arms eventually received chemotherapy, the magnitude of survival benefit associated with chemotherapy could be underestimated.

Fluorouracil continues to be incorporated into current first-line chemotherapy regimens used for metastatic colorectal cancer. The addition of irinotecan to fluorouracil plus leucovorin significantly improves response rates, progression-free survival (PFS), and median survival. Oxaliplatin in combination with fluorouracil and leucovorin has been shown to be equivalent to the combination of irinotecan plus fluorouracil and leucovorin in the initial treatment of metastatic colon cancer when administered in a similar schedule. The addition of bevacizumab to fluorouracil-based regimens improves efficacy compared with chemotherapy alone. Either of these three- or four-drug combinations may be considered as first-line therapy for metastatic colorectal cancer. Ongoing trials are evaluating the sequencing of these regimens and comparing the efficacy of combinations of fluorouracil plus leucovorin, to investigational treatments with capecitabine, oral fluoropyrimidines, and newer agents, such as cetuximab. Table 138–9 summarizes comparative outcome data from potentially useful chemotherapeutic treatments for metastatic colorectal cancer.

Fluorouracil-Based Regimens. 8 Fluorouracil has been administered as a single agent by IV bolus injection but response rates are only 10% to 20%. As such, IV bolus fluorouracil as a single agent is considered ineffective for metastatic colorectal cancer. A variety of continuous IV infusion fluorouracil regimens have been developed to increase the duration of drug exposure during the S-phase of the cell cycle and increase cytotoxicity. Despite differences in dose intensity among the different regimens, no clear survival advantages or trends are observed for any particular regimen. However, in comparison to IV bolus fluorouracil, response rates with continuous infusion fluorouracil are about doubled. However, these effects are generally considered as marginal. Additional clinical benefit with continuous infusion fluorouracil has been demonstrated when fluorouracil is administered with other agents and is becoming commonplace in clinical practice.

Numerous studies have evaluated various doses and administration schedules of fluorouracil plus leucovorin in an attempt to improve treatment response rates and survival in metastatic colorectal cancer. Response rates of 14% to 58% have been observed with a variety of doses of fluorouracil in combination with leucovorin at doses ranging from 20 to 500 mg/m^2.[47] The administration sequence and timing of leucovorin may be important factors in the efficacy of biochemical modulation with leucovorin. Leucovorin administration prior to fluorouracil is the most effective approach to enable intracellular-reduced folates to accumulate prior to fluorouracil administration. Despite significantly higher response rates and improved PFS achieved with leucovorin-modulated fluorouracil regimens, their effect on OS is modest.

The Mayo Clinic regimen was the reference regimen in metastatic colon cancer for many years, but the limitations of this regimen (increased toxicity and no survival advantage) have made it largely obsolete.[76] Weekly bolus regimens such as the Roswell Park regimen may also be used but are also associated with significant toxicity.[75]

Bimonthly and weekly regimens of infusional fluorouracil are most commonly administered in the metastatic setting. Increased response rates are noted in bimonthly regimens of fluorouracil administered first as an IV bolus infusion followed by a 22-hour continuous infusion in combination with high-dose leucovorin administered over 2 hours (de Gramont regimen).[100] Although this did not translate to improved median survival as compared with the Mayo Clinic schedule, it was associated with a lower incidence

TABLE 138-8 Chemotherapeutic Regimens for Metastatic Colorectal Cancer

	Regimen	Major Dose-Limiting Toxicities/Comments
Initial therapy		
Oxaliplatin plus fluorouracil plus leucovorin		
Oxaliplatin plus bimonthly infusional fluorouracil; FOLFOX4[72]	Oxaliplatin 85 mg/m² IV day 1 plus bolus fluorouracil 400 mg/m² IV plus leucovorin 200 mg/m² IV followed by fluorouracil 600 mg/m² IV in 22-hour infusion on days 1 and 2, every 2 weeks	Sensory neuropathy, neutropenia
mFOLFOX6[97]	Oxaliplatin 85 mg/m² IV day 1 plus leucovorin 400 mg/m² IV on day 1 followed by fluorouracil 400 mg/m² IV bolus on day 1, then 1200 mg/m²/day × 2 days (total 2,400 mg/m² over 46–48 hours) continuous infusion, repeat every 2 weeks	Sensory neuropathy, neutropenia; easier administration as compared to FOLFOX4
Irinotecan plus fluorouracil plus leucovorin		
Irinotecan plus infusional fluorouracil; FOLFIRI[77]	Irinotecan 180 mg/m² IV plus leucovorin 400 mg/m² IV plus bolus fluorouracil 400 mg/m² IV, followed by fluorouracil 2,400 mg/m² continuous IV infusion over 46 hours on day 1, repeated every 2 weeks	Nausea, diarrhea, mucositis, neutropenia
Biweekly irinotecan plus infusional fluorouracil[98]	Irinotecan 180 mg/m² IV day 1 plus leucovorin 400 mg/m² then fluorouracil 400 mg/m² IV, followed by fluorouracil 600 mg/m² continuous IV infusion over 22 hours, days 1 and 2, repeated every 2 weeks	Neutropenia, diarrhea
Bevacizumab		
Bevacizumab plus fluorouracil-based regimens	Bevacizumab 5 mg/kg IV every 2 weeks plus fluorouracil and leucovorin (given in any schedule below) or FOLFOX or CapeOx or FOLFIRI	Hypertension, thrombosis, proteinuria from bevacizumab added to toxicities of regimen chosen
Capecitabine		
Capecitabine monotherapy[99]	See Table 138–7[a]	Diarrhea, hand–foot syndrome
CapeOx[97]	Oxaliplatin 130 mg/m² day 1 plus capecitabine 850 mg/m² twice a day for 14 days, repeat every 3 weeks	Diarrhea, hand–foot syndrome, neuropathies
Fluorouracil plus leucovorin only		
Bolus plus infusional fluorouracil; (LV5FU2)[100]; de Gramont regimen	See Table 138–7[a]	Neutropenia, mucositis
Salvage therapy[b]		
Irinotecan		
Weekly irinotecan[101]	Irinotecan 125 mg/m² IV every week for 4 of 6 weeks	Neutropenia, diarrhea
Every 3-weeks irinotecan[102]	Irinotecan 350 mg/m² IV every 3 weeks	Neutropenia, diarrhea (less-than-weekly irinotecan)
Oxaliplatin plus fluorouracil plus leucovorin		
Oxaliplatin plus bimonthly infusional fluorouracil; FOLFOX4[103]	Same as FOLFOX4 above; CapeOx may be used in place of FOLFOX4	Sensory neuropathy, neutropenia
Cetuximab		
Cetuximab plus irinotecan[c,104]	Continue irinotecan as previously dosed, plus cetuximab 400 mg/m² IV loading dose, then cetuximab 250 mg/m² IV weekly thereafter; if cetuximab is used with FOLFIRI the dose is the same	Asthenia, diarrhea, nausea, acneiform rash, vomiting
Cetuximab[d,104]	Cetuximab 400 mg/m² IV loading dose, then cetuximab 250 mg/m² IV weekly thereafter	Papulopustular and follicular rash, asthenia, constipation, diarrhea, allergic reactions, hypomagnesemia
Panitumumab		
Rash, hypomagnesemia, rare allergic reactions	6 mg/kg IV over 60 minutes every 2 weeks	
Fluorouracil		
Protracted continuous infusion[105]	Fluorouracil 250–300 mg/m² per day continuous IV infusion until disease progression	Mucositis, hand–foot syndrome

[a]Doses and schedule the same as in the adjuvant setting.
[b]See Figure 138–6 for comments on salvage regimens.
[c]If irinotecan-refractory disease.
[d]If patient cannot tolerate irinotecan.

of severe granulocytopenia, diarrhea, and mucositis.[100] Similar increases in response rate and lower toxicity rates have been seen in patients receiving weekly fluorouracil as a continuous 24-hour IV infusion in combination with high-dose leucovorin given over 2 to 24 hours.[115]

In summary, a weekly or bimonthly schedule of leucovorin plus fluorouracil (either bolus or continuous infusion) may be more convenient for the patient in terms of fewer scheduled clinic appointments, less interference with work schedules, and ease of dose adjustments based on toxicity. However, the incorporation of newer agents into treatment regimens rather than continual adjustments of fluorouracil and leucovorin doses and administration schedules have led to the greatest advances in drug therapy for metastatic colorectal cancer and will be discussed in the following sections.

Fluorouracil and Leucovorin Plus Irinotecan 8 Based on irinotecan's activity against untreated and fluorouracil-resistant colorectal cancer, several investigations have been completed to determine whether the addition of irinotecan to fluorouracil

TABLE 138-9 Comparative Outcomes from Selected Trials in Metastatic Colorectal Cancer

Trial	Number	Outcome Measures	Results
First-line			
Goldberg[108]	795	Primary: TTP; secondary: OS, ORR, time to treatment discontinuation	Median TTP: IFL vs. FOLFOX 6.9 vs. 8.7 months ($P = 0.0014$). Median survival 15.0 months with IFL vs. 19.5 months with FOLFOX ($P = 0.001$). ORR with FOLFOX (45%) higher compared to IFL (31%; $P = 0.002$) and IROX (35%, $P = 0.03$). TTP and OS with IROX (6.5 and 17.4 months) no different from FOLFOX.
de Gramont[103]	420	Primary: PFS; secondary: ORR, OS, tolerability, QOL	Median PFS: 9.0 vs. 6.2 months ($P = 0.0003$); ORR: 50.7 vs. 22.3% ($P = 0.0001$), oxaliplatin plus LV5FU2 vs. LF5FU2 alone; no difference in OS (16.2 vs. 14.7 months) or QOL between oxaliplatin plus LV5FU2 vs. LV5FU2 alone.
Saltz[101]	683	Primary: PFS; secondary: ORR, OS	Median PFS longer with IFL (7.0 months) vs. FU/LV (4.3 months; $P = 0.004$); PFS similar with irinotecan alone (4.2 months) compared with FU/LV; ORR higher with IFL vs. FU/LV (50 vs. 28%; $P < 0.001$); median survival longer with IFL (14.8 months) vs. 12.6 months with FU/LV ($P = 0.04$), which was similar to irinotecan (12.0 months).
Douillard[98]	387	Primary: ORR; secondary: TTP, response duration, TTF, OS, QOL	Significantly higher ORR with infusional IFL vs. infusional FU/LV alone (35 vs. 22%; $P < 0.005$) by ITT; TTP longer with IFL (6.7 vs. 4.4 months; $P < 0.001$) and OS longer with IFL vs. infusional FU/LV alone (17.4 vs. 14.1 months; $P = 0.031$).
Tournigand[77]	226	Test the best sequence of FOLFIRI vs. FOLFOX6; primary: second PFS; secondary: PFS, OS, ORR, safety	Median survival 21.5 months with FOLFIRI then FOLFOX6 vs. 20.6 months with FOLFOX6 then FOLFIRI; median PFS also no different (14.2 vs. 10.9 months), or ORR or median PFS with first treatment: FOLFOX6 54% and 8.0 months, vs. 56% and 8.5 months with FOLFIRI.
Hurwitz[109]	925	Primary: OS; secondary: PFS, ORR, response duration, QOL	Bevacizumab plus IFL increased median survival (20.3 months) vs. IFL alone (15.6 months; $P = 0.00003$), PFS (10.6 vs. 6.24 months; $P < 0.00001$), ORR (45% vs. 35%; $P = 0.0029$), and duration of response (10.4 vs. 7.1 months; $P = 0.0014$).
Twelves[99]	1,207	Primary: ORR; secondary: TTP, OS, response duration	Tumor response to capecitabine greater than with FU/LV (25.7 vs. 16.7%; $P < 0.0002$), but no difference in median TTP (4.6 vs. 4.7 months) or median survival (392 vs. 391 days).
Hochster[97]	360	Primary: toxicity; secondary ORR, TTP, OS	Grade 3/4 toxicity not increased with bevacizumab. TTP, ORR, and OS all greater when bevacizumab added to CapeOx, FOLFOX, or bolus fluorouracil/leucovorin. Median survival with bevacizumab-containing regimens was 24.4 months vs. 18.4 months without bevacizumab (not a randomized trial).
Saltz[110]	1,401	Primary: PFS; Secondary ORR, OS	PFS increased from 8 to 9.4 months with bevacizumab added to oxaliplatin-containing regimens (XELOX or FOLFOX). ORR and OS not different between groups.
Fuchs[111]	547	Primary: PFS; Secondary ORR, OS, toxicity	PFS increased with FOLFIRI compared with IFL (7.6 vs. 5.9 months, $P = 0.004$); addition of bevacizumab improved OS (28 months for FOLFIRI + bevacizumab vs. 19.2 months for IFL + bevacizumab; $P = 0.037$). Cape Iri equivalent to IFL and not included in final analysis.
Bokemeyer[112]	337	Primary: ORR; Secondary PFS, OS, toxicity	ORR and PFS increased in patients with wild-type *KRAS* treated with FOLFOX + cetuximab compared with FOLFOX alone; *KRAS* mutant patients had no benefit with cetuximab (ORR 33 vs. 49%, $P = 0.106$ in cetuximab + FOLFOX and FOLFOX treated patients, respectively).
Van Cutsem[113]	1,198	Primary: PFS	FOLFIRI + cetuximab increased PFS by 0.9 months and ORR by 8% compared with FOLFIRI alone. Similar to FOLFOX + cetuximab in that benefit limited to *KRAS* wild-type patients.
Second-line			
Rougier[105]	267	Primary: OS; secondary: PFS, ORR, symptom-free survival, adverse effects, QOL	Irinotecan improved median PFS (4.2 vs. 2.9 months; $P = 0.030$) compared with infusion fluorouracil and 1-year survival (45% vs. 35%; $P = 0.035$) but not median OS (10.8 vs. 8.5 months). Median pain-free survival was similar ($P = 0.06$; 10.3 vs. 8.5 months) between irinotecan and fluorouracil, as was QOL.
Cunningham[102]	279	Primary: OS; secondary: performance status, body weight, tumor-related symptoms, QOL	Compared to best supportive care, OS was improved with irinotecan (13.8% 1-year survival vs. 36.2%; $P = 0.0001$); survival without deterioration in performance status, weight loss greater than 5%, and pain-free survival were also improved with irinotecan.
Cunningham[104]	329	Primary: PFS; secondary: ORR, OS, safety	Panitumumab plus BSC prolonged PFS compared to BSC alone, with a median PFS of 8 weeks with panitumumab (hazard ratio 0.54; 95% CI, 0.44–0.66).
Giantonio[72]	829	Primary: ORR; secondary: TTP, OS	Addition of cetuximab to continuing irinotecan associated with 22.9% ORR compared with 10.9% with cetuximab alone ($P = 0.0074$); median survival with cetuximab plus irinotecan similar to cetuximab alone (8.6 vs. 6.9 months; $P = 0.48$), but TTP was longer with cetuximab plus irinotecan (4.1 vs. 1.5 months; hazard ratio 0.54; 95% CI, 0.42–0.71).
Van Cutsem[114]	463	Primary: OS; secondary: PFS, ORR, toxicity	Addition of bevacizumab to FOLFOX4 in patients previously treated with irinotecan and a fluoropyrimidine improved median OS (12.2 vs. 10.8 months; P = 0.001), PFS (7.3 vs. 4.7 months; P < 0.0001), and ORR (22.7% vs. 8.6%, P < 0.0001) compared with FOLFOX4 alone.

BSC, best supportive care; FU5LV2, bolus plus infusional fluorouracil and leucovorin; FU/LV, fluorouracil plus leucovorin; IFL, irinotecan plus fluorouracil plus leucovorin; IROX, irinotecan plus oxaliplatin; ITT, intention to treat; OS, overall survival; PFS, progression-free survival; QOL, quality-of-life; ORR, overall response rate; TTF, time-to-treatment failure; TTP, time-to-tumor progression.

plus leucovorin as initial therapy for metastatic disease could further improve survival. In a randomized trial of 387 previously untreated patients with advanced colorectal cancer, irinotecan plus fluorouracil and leucovorin was compared to fluorouracil plus leucovorin with regard to tumor response, survival, and quality-of-life (see Table 138–9).[98] Patients randomized to fluorouracil plus leucovorin could receive weekly fluorouracil (2,600 mg/m^2) as a 24-hour IV infusion plus leucovorin (500 mg/m^2), or the de Gramont regimen of IV bolus and infusional fluorouracil. For the three-drug treatment, a weekly regimen of irinotecan (80 mg/m^2) with a 24-hour infusion of fluorouracil (2,300 mg/m^2) plus leucovorin 500 mg/m^2, or an every-2-week regimen consisting of irinotecan (180 mg/m^2) on day 1 with IV bolus fluorouracil (400 mg/m^2) followed by a 22-hour IV infusion (600 mg/m^2) plus leucovorin (200 mg/m^2 given on days 1 and 2) can be used. Tumor response, median time-to-disease progression, and OS were all

greater in the irinotecan group. Diarrhea and neutropenia were the most common toxicities and were worse in the irinotecan-containing groups. Diarrhea was the most common reason for dose reduction or treatment discontinuation with the weekly regimens and led to hospital admission for 32% of patients receiving irinotecan as compared with 12% of patients who received only fluorouracil plus leucovorin. Neutropenia was the most common cause of dose reductions with the every-2-weeks regimens. Results from questionnaires indicated that quality-of-life consistently declined later in the irinotecan group.

A second randomized trial compared the addition of irinotecan (125 mg/m^2) to weekly fluorouracil plus leucovorin (fluorouracil 500 mg/m^2 IV bolus plus leucovorin 20 mg/m^2 IV bolus, each given weekly for 4 weeks, repeated every 6 weeks; IFL regimen) to the Mayo Clinic regimen and to irinotecan alone (125 mg/m^2 IV weekly for 4 weeks, repeated every 6 weeks) as first-line therapy in 683 patients with metastatic colorectal cancer.[101] The combination of irinotecan, fluorouracil, and leucovorin resulted in significantly increased tumor response rates and improved PFS and OS as compared with fluorouracil plus leucovorin and irinotecan alone, respectively. The combined incidence of grade 3 or 4 diarrhea was 22.7% with the three-drug combination, as compared with 13.2% with fluorouracil plus leucovorin and 31% with irinotecan alone. However, the incidence of grade 3 diarrhea was almost threefold greater with triple-drug therapy as compared with the two-drug regimen. Midcycle dose reductions caused by neutropenia, which were more common with the three-drug treatment, could potentially have lowered subsequent risk of grade 4 diarrhea. Mucositis was more frequent in the fluorouracil plus leucovorin group. Quality-of-life analyses did not indicate that the addition of irinotecan to fluorouracil plus leucovorin compromised quality of life.

Modifications of the original IFL regimen have been made to give irinotecan on an every-2-weeks schedule with fluorouracil as a continuous infusion (FOLFIRI regimen). The median OS is improved by 5.7 months with decreased toxicity by this method of administration, and irinotecan administered as IFL is no longer recommended.[71,116]

The most common adverse effects of irinotecan in these regimens are diarrhea, neutropenia, nausea and vomiting, asthenia, abdominal pain, and alopecia; diarrhea and neutropenia are dose limiting.[98,101] Two distinct patterns of diarrhea have been described. Early-onset diarrhea occurs during or within 2 to 6 hours after irinotecan administration and is characterized by lacrimation, diaphoresis, abdominal cramping, flushing, and/or diarrhea. These cholinergic symptoms, thought to be caused by inhibition of acetylcholinesterase, respond to atropine 0.25 to 1 mg given intravenously or subcutaneously. Approximately 10% of patients experience the acute symptoms during or shortly following the irinotecan. More commonly, late-onset diarrhea occurs 1 to 12 days after irinotecan administration and may last for 3 to 5 days. Late-onset diarrhea may require hospitalization or discontinuation of therapy, and fatalities have been reported. The incidence of late-onset diarrhea was as high as 39% in some studies but is now much lower with aggressive antidiarrheal intervention.[47] Aggressive intervention with high-dose loperamide therapy should consist of 4 mg taken at the first sign of soft or watery stools, followed by 2 mg orally every 2 hours until symptom-free for 12 hours; this regimen can be modified to 4 mg taken orally every 4 hours during the night.

The severity of delayed diarrhea has been correlated with the systemic exposure (i.e., area under the concentration-versus-time curve) of irinotecan and SN-38 (irinotecan's active metabolite) and with genetic polymorphisms in the enzyme uridine diphosphate-glucuronosyltransferase (UGT1A1), which is responsible for the glucuronidation of SN-38 to inactive metabolites. Reduced or deficient levels of the UGT1A1 enzyme are observed in Gilbert syndrome, a familial hyperbilirubinemia disorder, and correlate with irinotecan-induced diarrhea and neutropenia.[117] An FDA-approved test for deficiency in this enzyme is available, and clinicians can consider obtaining these results for individual patients prior to initiating irinotecan-based therapy to see if a dose-reduction is warranted.

Based on these studies, the addition of irinotecan to fluorouracil plus leucovorin (FOLFIRI or IFL) increases survival when compared to fluorouracil plus leucovorin in the first-line treatment of metastatic colorectal cancer. These data support the current consensus that the three-drug treatment regimen be considered a first-line option for metastatic colorectal cancer. Accordingly, irinotecan is FDA-approved as first-line therapy for metastatic colorectal cancer in combination with fluorouracil and leucovorin. FOLFIRI is preferred for most patients because it has fewer toxicities and improved OS compared to IFL.

Fluorouracil and Leucovorin Plus Oxaliplatin. 9 Oxaliplatin, a 1,2-diaminocyclohexane platinum carrier ligand with a mechanism of action similar to cisplatin, in combination with infusional fluorouracil plus leucovorin, is FDA-approved for use in first-line and salvage regimens for metastatic colorectal cancer (see Table 138–8). Oxaliplatin differs from cisplatin in that the DNA damage induced by oxaliplatin may not be as easily recognized by the DNA MMR complex.[118] Thus oxaliplatin-induced DNA damage may play a particularly important role in colorectal cancers that are associated with defects in MMR genes, which are common in HNPCC. Oxaliplatin's incorporation into fluorouracil-based regimens as first-line therapy for metastatic colorectal cancer is associated with higher response rates and improved PFS, with variable effects on OS.[103]

Intergroup Trial N9741, a comparison of oxaliplatin plus fluorouracil and leucovorin (FOLFOX4) to weekly irinotecan plus IV bolus fluorouracil and leucovorin (IFL), and a combination of irinotecan plus oxaliplatin (IROX) in 795 patients with previously untreated metastatic colorectal cancer showed superior efficacy with FOLFOX4.[108] The IROX arm showed no advantage over either of the other two arms. Significant improvements in response rates, PFS, and median survival were seen with FOLFOX4 as compared with IFL (see Table 138–9).[108] The study design allowed patients who failed either regimen to cross over to irinotecan or oxaliplatin, depending on their initial treatment assignment. Sixty percent of patients who failed FOLFOX4 received salvage irinotecan, whereas 24% of IFL failures received salvage oxaliplatin. The impact that this crossover had on survival is unknown but may have resulted in improved survival for the FOLFOX4 arm. In addition, the method of fluorouracil administration, and its impact on study results, has been called into question. Patients on the IFL arm received weekly IV bolus fluorouracil, while patients on the FOLFOX4 arm were administered fluorouracil as IV bolus followed by continuous-infusion IV, which is known to increase response rates. Consequently, it is not possible to evaluate the true contributions of oxaliplatin and irinotecan combined with fluorouracil plus leucovorin in this study. The deletion of fluorouracil (or any fluorinated pyrimidine) from a first-line regimen may be undesirable.

In a phase III cooperative group study, a simplified combined bolus and infusional fluorouracil regimen with irinotecan (FOLFIRI) was compared with oxaliplatin combined with the same fluorouracil plus leucovorin schedule (FOLFOX6) in previously untreated patients with advanced colorectal cancer to determine whether the sequence of administration of both regimens differed with regard to efficacy and toxicities.[77] Patients were randomized to receive initial treatment with FOLFIRI or FOLFOX6, and at disease progression the patients then received the alternate regimen. Both sequences resulted in similar response rates, PFS, and median survival, but the grade 3 or 4 toxicity profiles were different.

Neurotoxicity, neutropenia, and thrombocytopenia were more common with FOLFOX6, while febrile neutropenia, nausea/vomiting, mucositis, and fatigue were significantly more frequent with FOLFIRI.

Oxaliplatin has minimal renal toxicity, myelosuppression, and nausea and vomiting when compared with other platinum-based drugs. Oxaliplatin is associated with both acute and persistent neuropathies.[119] The acute neuropathies occur within 1 to 2 days of dosing and resolve within 2 weeks. The neuropathies usually occur peripherally, but may also occur in the jaw and tongue. A rare acute syndrome of pharyngolaryngeal dysesthesia (1% to 2% of patients) is characterized by subjective sensations of difficulty in swallowing and shortness of breath. Overall, acute neuropathies occur in approximately 90% of patients, and are precipitated or exacerbated by exposure to cold temperatures or cold objects. Thus patients should be instructed to avoid cold drinks and use of ice, and to cover skin before exposure to cold or cold objects. Several prophylactic and treatment strategies have been studied with varying degrees of success. Carbamazepine, gabapentin, amifostine, and calcium and magnesium infusions have been used to both prevent and treat oxaliplatin-induced neuropathies. Persistent neuropathy is typically a cumulative adverse effect, occurring after 8 to 10 cycles, and is seen mostly in patients who are responding to therapy.[108] The neuropathy is characterized by paresthesia, dysesthesia, and hypoesthesia, but may also include deficits in proprioception that can interfere with daily activities (e.g., writing, buttoning, swallowing, and difficulty walking as a result of impaired proprioception), and occur in half of patients receiving oxaliplatin with infusional fluorouracil plus leucovorin, but usually resolve with dosage reductions or cessation of oxaliplatin therapy.[119,120]

CLINICAL CONTROVERSY

The results of N9741 have been debated among clinicians since their presentation. Whether an irinotecan-containing regimen (IFL or FOLFIRI) or FOLFOX4 should be the first regimen used in metastatic colon cancer is an unanswered question. Sequencing trials suggest that it does not matter, and most patients should receive both irinotecan- and oxaliplatin-containing regimens at some point during treatment for their disease.

Capecitabine. 10 Capecitabine (Xeloda®) is an oral, tumor-activated and tumor-selective fluoropyrimidine carbamate. Capecitabine is converted to fluorouracil through a three-step activation process, the final step being activation by thymidine phosphorylase, which is present in greatest concentrations at the tumor site. These activation steps lead to about a 3-fold increase in tumor and 1.4-fold increase in hepatic fluorouracil levels. Capecitabine was compared to fluorouracil plus leucovorin as first-line therapy for metastatic colorectal cancer in two randomized phase III trials. In a pooled analysis of 1,207 patients randomized to capecitabine (1,250 mg/m^2 orally twice daily for 14 days, repeated every 3 weeks) or the Mayo Clinic regimen, tumor response to capecitabine was superior to that of fluorouracil plus leucovorin (25.7% vs. 16.7%).[99] Time-to-tumor-progression and median survival, however, were no different. Hand–foot syndrome was more common with capecitabine, whereas grade 3 or 4 neutropenia and stomatitis were more common with fluorouracil plus leucovorin. The convenience of oral administration and different toxicity profile make capecitabine a useful alternative to IV fluorouracil regimens in the setting of metastatic disease. However, because the IV treatment arm in these comparative studies could be considered more toxic than the weekly IV fluorouracil plus leucovorin treatment schedule, it is premature to conclude that capecitabine is as efficacious as and less toxic than all parenteral fluorouracil-based regimens. Infusional fluorouracil is generally considered to be superior to bolus administration, and oral capecitabine may mimic this method of fluorouracil administration. These data, along with capecitabine's ease of administration, and data that irinotecan and oxaliplatin appear to have a greater effect when combined with infusional fluorouracil has led to capecitabine being evaluated as a replacement for infusional fluorouracil.

Both irinotecan and oxaliplatin have been combined with capecitabine. In a study of over 2,000 patients with metastatic colon cancer, FOLFOX was compared with the combination of CapeOx (capecitabine/fluorouracil/leucovorin) and found to have equivalent OS and PFS. Toxicity was as expected with increased grade 3/4 neutropenia (including neutropenic fever) and increased diarrhea and hand–foot syndrome seen with oxaliplatin and capecitabine-based regimens, respectively.[120] Based on these results, CapeOx is an acceptable first-line option for the treatment of metastatic colorectal cancer.[71]

The combination of capecitabine with irinotecan resulted in no survival benefit compared with IFL and showed inferior results when compared with FOLFIRI in a randomized trial of 430 patients. Additionally, the combination of capecitabine with irinotecan had higher rates of nausea, vomiting, and dehydration and is not recommended for use outside of clinical trials.[116]

The current FDA-approved indication for capecitabine in metastatic colon cancer is when therapy with a fluoropyrimidine alone is desired. Replacement of fluorouracil-leucovorin with capecitabine in other regimens is not currently approved, although completed trials demonstrate that capecitabine is a suitable replacement for infusional fluorouracil in combination with oxaliplatin.

Biologic Therapy. 9 Bevacizumab is a recombinant, humanized monoclonal antibody that inhibits vascular endothelial growth factor. Bevacizumab, in combination with intravenous fluorouracil-based chemotherapy, was FDA approved in 2004 for initial treatment of patients with metastatic colorectal cancer. This represents the third available combination regimen for first-line treatment. Results from two randomized trials show increased benefit as compared with chemotherapy alone.

A phase III trial of bevacizumab in combination with IFL as first-line therapy in patients with metastatic colorectal cancer has also been completed. Patients were randomized to receive IFL plus placebo or IFL plus bevacizumab 5 mg/kg every 2 weeks.[109] The addition of bevacizumab to IFL therapy resulted in an increase in response rate (34.7% vs. 44.9%) and median survival (15.6 vs. 20.3 months) and PFS (6.24 vs. 10.6 months) as compared with IFL alone. The frequency of typical adverse effects associated with IFL chemotherapy was not increased with the addition of bevacizumab. Grade 3 hypertension was significantly increased in the bevacizumab group. The incidence of other safety concerns with bevacizumab, such as bleeding, thromboembolism, and proteinuria, were not increased in the bevacizumab group as compared with placebo. The hypertension is easily managed with oral antihypertensive agents. The risk of gastrointestinal perforation was increased by the addition of bevacizumab to IFL, and patients complaining of abdominal pain associated with vomiting or constipation should be considered for this rare but potentially fatal complication. Bevacizumab is also associated with a twofold increased risk of arterial thrombotic events, with patients who are older than age 65 or who have a prior history of arterial thrombotic events at greatest risk. Nevertheless, because these individuals derive the same survival benefits with bevacizumab as do other patients, they may be appropriate candidates to receive bevacizumab.

Similar to what was noted previously when IFL was compared with FOLFIRI without bevacizumab, infusional fluorouracil should be administered in combination with bevacizumab and irinotecan. A randomized phase III trial demonstrated a median survival of 28 months compared with 19.2 months with FOLFIRI and IFL, respectively (HR for death 1.79; $P = 0.037$) when given in combination with bevacizumab.[111]

Bevacizumab has also been combined with oxaliplatin in a variety of chemotherapy regimens for the initial treatment of metastatic colon cancer. In contrast to irinotecan-containing regimens, the method of fluorouracil administration (or substitution with capecitabine) does not appear to significantly affect outcomes. One trial, randomized one cohort of patients to one of three oxaliplatin-based regimens (TREE-1 [arm 1: oxaliplatin plus infusional 5-FU; arm 2: oxaliplatin plus bolus 5-FU; arm 3: oxaliplatin plus oral capecitabine]) while the second cohort of patients (TREE-2) received the same chemotherapy regimens plus bevacizumab as their first-line treatment for metastatic colon cancer. The addition of bevacizumab was associated with increased overall response rate and longer time-to-progression and median survival, although these differences were not significant as a consequence of the small sample size. Overall median survival was 18.2 months in the TREE-1 cohort and 23.7 months in the TREE-2 cohort with the addition of bevacizumab.[97] In a separate phase III trial, the addition of bevacizumab to oxaliplatin-based chemotherapy (XELOX or FOLFOX) significantly improved PFS but not OS.[110] Studies that compare the addition of bevacizumab to FOLFOX4 to irinotecan-based combinations of bevacizumab are ongoing.

CLINICAL CONTROVERSY

Currently, continuation of bevacizumab after disease progression is not recommended. Some clinicians have taken retrospective data that demonstrate improved survival with duration of bevacizumab use and applied it to clinical practice, but insurance coverage for patients may be difficult to obtain.

Investigational First-Line Approaches

Targeted Agents Results with cetuximab in the first-line metastatic setting combined with either FOLFOX or FOLFIRI suggest that the combination improves response rates and PFS to either chemotherapy regimen without adding substantial toxicity.[112,113]

The benefit in either of these combinations is limited to patients with wild-type *KRAS* tumors and should not be used in patients with tumor *KRAS* mutations. Cetuximab combined with FOLFIRI demonstrated an increase in PFS of 1.2 months and improved median OS from 21 to 24.9 months (HR 0.84, P = NS) compared with FOLFIRI alone in the subset of patients with wild-type *KRAS*.[113] No benefit is seen in patients with mutant *KRAS*. Similar results have been reported with cetuximab in combination with FOLFOX.[112] Cetuximab in combination with FOLFOX demonstrated an increased response rate and a decreased PFS (HR 0.57; $P = .0163$) as compared with FOLFOX-4 alone in patients with wild-type *KRAS*.

Panitumumab was also combined with FOLFIRI or IFL in a phase II trial and demonstrated activity without substantially increasing toxicity of FOLFIRI but not IFL.[121] The effect of *KRAS* status on response was not evaluated.

For reasons that are not well understood, the addition of panitumumab or cetuximab to bevacizumab plus irinotecan- or oxaliplatin-containing chemotherapy *reduces* PFS and is currently not recommended. The Panitumumab Advanced Colorectal Cancer Evaluation Study (PACCE) trial and the CAIRO2 demonstrated a decrease in PFS of 1.4 months when panitumumab and 1.3 months when cetuximab was added to bevacizumab-containing chemotherapy, respectively.[122,123] Both of these results were clinically and statistically significant. The results from these trials demonstrate the potential pitfalls of treating patients with multiple biologic agents outside of the setting of a clinical trial and why this practice should be avoided.

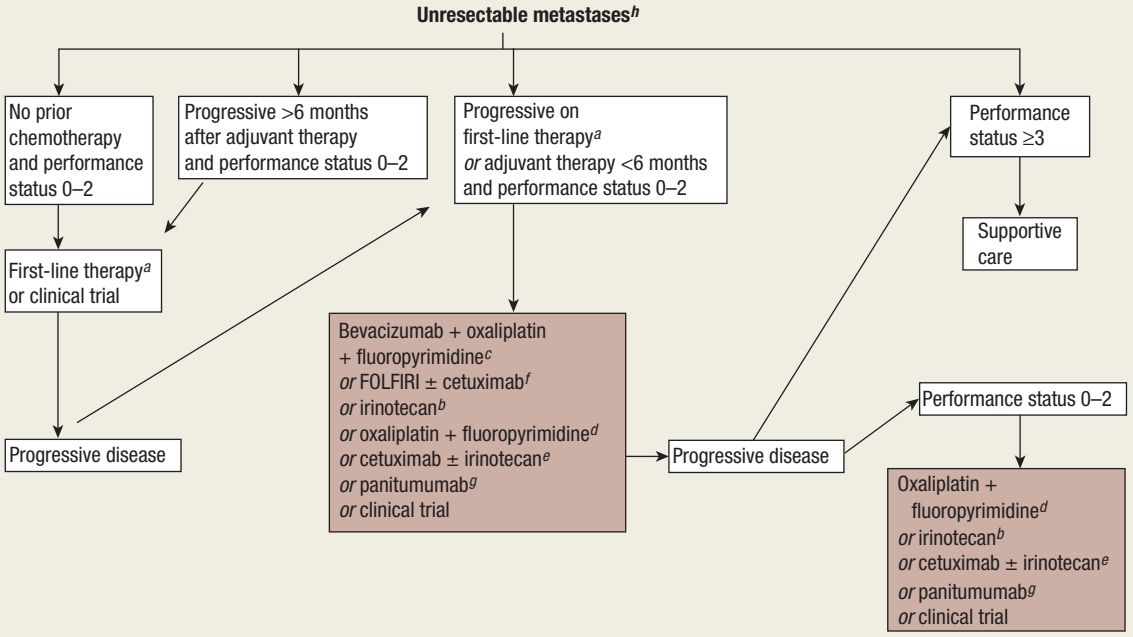
Hepatic Artery Infusion. Although hepatic chemotherapy infusion for metastatic colorectal cancer remains an area of investigation, it has not been shown to be superior to systemic chemotherapy. The rationale for hepatic artery infusion (HAI) is based on the principle that normal liver hepatocytes and early micrometastases obtain their primary blood supply from the portal vein. In contrast, tumors in the liver are thought to receive most of their blood supply via the hepatic artery.[124] Consequently, drug administration via the hepatic artery should result in delivery of high drug concentrations to the tumor cells with a much lower exposure to normal liver tissue.

Because the liver is a common site of colorectal cancer metastasis, and the only site of metastatic involvement in up to one-third of patients, hepatic-directed therapies continue to be explored. Historically, floxuridine and fluorouracil have undergone the most study for hepatic artery infusion, but other active agents such as irinotecan and oxaliplatin have also been studied. Trials involving HAI have been conducted in patients with unresectable liver metastases and as adjuvant therapy following curative resection of isolated metastases.

Regional HAI can be accomplished using a hepatic arterial port, a totally implantable pump, or a percutaneously placed catheter into the hepatic artery that is connected to an external pump. Early trials of HAI revealed objective response rates ranging from 30% to 88%, many of which were observed in previously treated patients, and increased survival rates as compared with historic controls. Because supportive care alone is no longer considered standard of care for metastatic disease, when HAI was compared with systemic chemotherapy, most comparisons did not yield a survival benefit.[124] Furthermore, most studies allowed patients in the systemic therapy treatment groups to cross over to HAI upon tumor progression; therefore, the impact of these treatments on survival is difficult to interpret. Most recently, HAI was compared with systemic fluorouracil plus leucovorin in patients with hepatic-only metastasis.[125] HAI was associated with significantly longer OS (median: 24.4 vs. 20 months, $P = 0.003$) and time-to-hepatic-progression (median: 9.8 vs. 7.3 months, $P = 0.034$) as compared with systemic chemotherapy. As expected, time-to-extrahepatic-progression was longer with systemic chemotherapy. This study has been criticized for the systemic chemotherapy treatment arm, which is considered less-than-optimal therapy by current standards.

Given the significant improvements with systemic chemotherapy for metastatic disease achieved with systemic chemotherapy over the past several years, attention has been directed to HAI with nonfluoropyrimidines, including irinotecan, oxaliplatin, and biologic agents. Early studies show promising results, but it is not clear whether this approach offers any advantage compared with systemic therapy.

Because of toxicities associated with HAI, most patients require some transient interruption of therapy, a decrease in dosage, or discontinuation of therapy. Furthermore, extrahepatic disease progression with HAI therapy alone remains a clinical problem. Although increased response rates and a trend toward improved survival have been reported, the costs and toxicities with this approach are significant. Therefore, for the minority of patients who present with unresectable disease to the liver only, HAI may represent a reasonable therapeutic option, but it is not considered standard therapy at this time.



[a] Bevacizumab + oxaliplatin + fluoropyrimidine (e.g., infusional 5-FU/LV (FOLFOX) *or* capecitabine (CapeOx)); *or* bevacizumab + irinotecan + infusional 5-FU/LV (FOLFIRI); *or* bevacizumab + 5FU/LV; *or* capecitabine ± bevacizumab; *or* 5-FU/LV ± bevacizumab.

[b] If no prior irinotecan.

[c] If first-line regimen did not contain bevacizumab or oxaliplatin.

[d] If no prior oxaliplatin.

[e] If irinotecan-refractory or intolerant and no prior cetuximab.

[f] If *KRAS* wild-type and first-line regimen did not contain irinotecan.

[g] If *KRAS* wild-type and no prior cetuximab or panitumumab.

[h] Initial unresectable metastases may be converted to resectable disease in selected patients who exhibit a good tumor response to systemic chemotherapy. Those patients may be candidates for surgical tumor resection followed by adjuvant chemotherapy.

FIGURE 138-6. Algorithm for treatment of unresectable or refractory metastatic colorectal cancer.

Approach to Selecting an Initial Metastatic Regimen

Practitioners can select first-line treatment for metastatic colorectal cancer from among four main options: oxaliplatin plus fluorouracil plus leucovorin (FOLFOX); irinotecan plus fluorouracil plus leucovorin (FOLFIRI); capecitabine plus oxaliplatin (CapeOx); or fluorouracil plus leucovorin.[71] The most important factor in patient survival is not the initial regimen but whether or not the patient is able to receive all three active cytotoxic drugs (fluorouracil, irinotecan, and oxaliplatin) at some point in the treatment course.[126] Based on the comparable results of FOLFIRI versus FOLFOX6, combined with the inferiority of IFL to FOLFOX4, either of these regimens (FOLFOX or FOLFIRI) are considered the reference standard in metastatic colorectal cancer. The IFL regimen is no longer recommended in clinical practice. Similar to the adjuvant setting, patient-specific factors may lead practitioners to choose between FOLFOX and FOLFIRI. Preexisting neuropathies may lead to FOLFIRI being chosen initially, whereas increased bilirubin or known UGT1A1 deficiency (known risk factors for delayed diarrhea) may lead to FOLFOX as the initial choice. The 2010 NCCN guidelines recommend the addition of bevacizumab to any initial fluorouracil-based regimen unless its use is contraindicated in an individual patient.[71] Cetuximab may be added to FOLFIRI, FOLFOX, or CapeOx in patients with wild-type *KRAS* tumors only.

Capecitabine may be an appropriate substitute for intravenous fluorouracil in oxaliplatin combination regimens; the 2010 NCCN guidelines list CapeOx plus bevacizumab as an acceptable initial regimen based on data that demonstrated its equivalence to oxaliplatin plus continuous infusion 5-FU.[97] Fluorouracil plus leucovorin alone or capecitabine monotherapy is also appropriate first-line treatment for those individuals who cannot tolerate three-drug combination regimens.

Second-Line Therapy

Systemic chemotherapy represents the mainstay of therapy for patients whose disease progresses following initial treatment for metastatic disease. Figure 138–6 depicts an algorithm for treatment of refractory metastatic disease. Treatment options are based on the type of and response to prior treatments, the site and extent of disease, and patient factors and treatment preferences.

Systemic Chemotherapy Upon disease progression following standard initial therapy, appropriate treatment options may include oxaliplatin plus fluorouracil and leucovorin with or without bevacizumab, irinotecan plus cetuximab, cetuximab, panitumumab irinotecan, continuous-infusion fluorouracil, capecitabine plus oxaliplatin, capecitabine, intrahepatic therapy for selected patients, supportive care, or participation in a clinical trial. The choice of

specific agents depends primarily on the type of prior therapy received. Because most patients will have received a combination of a fluoropyrimidine with either irinotecan or oxaliplatin, second-line therapy with the alternate regimen should be considered. Patient survival can exceed 2 years.

Irinotecan. Two important trials have delineated an appropriate standard of care for patients who experience disease progression with fluorouracil therapy for metastatic colorectal cancer.[102,105] The results of these trials demonstrate a survival benefit associated with irinotecan, which was FDA approved in 1996 as second-line therapy for recurrent or progressive disease following fluorouracil. In phase II studies of previously treated patients with metastatic colorectal cancer, objective response rates of 13% to 27% have been observed.[102,105]

In a phase III trial of 189 patients with metastatic colorectal cancer that had progressed within 6 months of treatment with fluorouracil, irinotecan was compared to supportive care alone with regard to survival, quality-of-life, and other clinical variables.[102] Irinotecan was administered as 350 mg/m^2 IV every 3 weeks; the dose was reduced to 300 mg/m^2 for individuals who were 70 years of age or older, who had a World Health Organization performance status of 2, or who had clinical risk factors for developing excessive treatment-related toxicity. Supportive care could include any symptomatic therapy with the exception of irinotecan or any other topoisomerase I inhibitor. With the exception of more patients with poor performance status in the supportive care group, baseline patient characteristics were similar between groups. Median survival was 9.2 months with irinotecan, as compared to 6.5 months with supportive care alone. One-year survival was significantly greater with irinotecan (36.2% vs. 13.8%) and was not associated with significantly worse quality-of-life scores except for diarrhea. Clinical variables such as cognitive functioning, pain, dyspnea, and appetite loss were in favor of irinotecan therapy. The most common grade 3 or 4 side effects with irinotecan included leukopenia and neutropenia (22%), diarrhea (22%), nausea (14%), and vomiting (14%). Seventy-two percent of patients receiving irinotecan required hospital admission for adverse events, as compared with 63% of supportive care patients. Thus irinotecan was associated with an improved survival and quality-of-life as compared with supportive care alone that appeared to balance treatment-related toxicities.

A comparison of irinotecan to continuous-infusion fluorouracil in a similar population of 267 patients allocated patients to irinotecan, 300 to 350 mg/m^2 IV every 3 weeks, or one of three continuous-infusion fluorouracil regimens: leucovorin 200 mg/m^2 IV over 2 hours followed by IV bolus fluorouracil (400 mg/m^2) and 22-hour continuous-infusion fluorouracil (600 mg/m^2), given the first 2 days of every 2-week period; fluorouracil 250 to 300 mg/m^2 as prolonged continuous IV infusion until disease progression; or fluorouracil 2,600 to 3,000 mg/m^2 per day IV over 24 hours, with or without leucovorin (20 to 500 mg/m^2 IV), given weekly for 6 weeks, with a 2-week rest period between cycles.[105] Median follow up after 15 months revealed a longer 1-year survival (45% vs. 32%) and median survival (10.8 months vs. 8.5 months) with irinotecan, as compared with fluorouracil. Sixty-nine percent of patients receiving irinotecan experienced at least one grade 3 or 4 toxicity, as compared with 54% of patients receiving fluorouracil. The most common toxicities with irinotecan were diarrhea, neutropenia, pain, vomiting, and asthenia, while pain, asthenia, diarrhea, and dermatologic toxicities were most common with fluorouracil. The hospitalization requirement for adverse effects did not differ between treatments.

Finally, the use of the FOLFIRI regimen after progression with first-line FOLFOX demonstrated an objective response rate of 4% with a median PFS of 2.5 months.[77] These results are consistent with the meta-analysis that demonstrated improved outcomes in those patients who are able to receive all active cytotoxic agents during the course of their disease.[126]

Based on these results, irinotecan should be considered standard second-line therapy for patients who have failed prior treatment with oxaliplatin and fluorouracil-based regimens. Initial administration of irinotecan at the lower dose should be considered for patients who have received significant prior pelvic or abdominal irradiation. Protracted continuous-infusion fluorouracil (FOLFIRI) or single-agent irinotecan should be considered the regimen of choice with or without cetuximab as will be explained in the following section on cetuximab.

Oxaliplatin. Oxaliplatin plus fluorouracil and leucovorin should be considered for patients who received primary treatment with irinotecan plus fluorouracil. Despite the low activity of single-agent oxaliplatin against fluorouracil-refractory disease, when oxaliplatin has been administered in a bimonthly regimen with high-dose leucovorin and continuous fluorouracil infusion, a 20.6% response rate with a median survival in excess of 10 months has been reported.[127] The combination of oxaliplatin plus fluorouracil and leucovorin is also effective as salvage therapy after initial treatment with irinotecan plus fluorouracil and leucovorin, with a response rate of approximately 20%.[128] Although irinotecan can be used effectively as a single agent in colorectal cancer, it should be noted that oxaliplatin does not have substantial activity alone, and should only be given in combination with a fluoropyrimidine.

In patients who did not receive bevacizumab in their initial treatment, FOLFOX plus bevacizumab is recommended based on phase III data. Results from Eastern Cooperative Group 3200 demonstrated that bevacizumab, in combination with FOLFOX4, improved survival in patients with previously treated advanced colorectal cancer.[72] It should be noted that patients were excluded if they received prior oxaliplatin or bevacizumab and the dose of bevacizumab was 10 mg/kg instead of 5 mg/kg. Median survival was improved from 10.7 to 12.5 months (P = 0.0018). Data to support the use of bevacizumab after progression on first-line bevacizumab is retrospective, and its use beyond initial progression is not recommended at this time.

Biologic Therapy. 11 Cetuximab is a chimeric monoclonal antibody directed against an EGFR that received FDA approval in 2004. Cetuximab may be administered in combination with irinotecan but can be used as a single agent in patients who cannot tolerate irinotecan-based chemotherapy.

In a phase II study, patients with EGFR-expressing metastatic colorectal cancer who experienced disease progression with an irinotecan-based regimen received open-label cetuximab, 400 mg/m^2 IV as a loading dose, followed by weekly infusions of 250 mg/m^2 IV until disease progression.[129] Of 57 patients treated, five achieved a partial response, with a minor response or stable disease developing in 21 additional patients. The median survival was 6.4 months. The most common grade 3 or 4 adverse events were papulopustular, follicular skin rash (18% grade 3), and adverse effects characterized as asthenia, lethargy, malaise, or fatigue (9% grade 3).

The combination of cetuximab plus irinotecan was also compared with cetuximab as a single agent in patients with EGFR-positive colorectal cancer that had progressed on irinotecan.[104] Three hundred and twenty-nine patients were randomized in a 2:1 ratio to receive cetuximab plus continuation of the irinotecan or cetuximab alone. The objective response rates, 22.9% and 10.8% with cetuximab plus irinotecan and cetuximab alone, respectively, were very encouraging, and resulted in the endorsement of cetuximab by the FDA via accelerated approval. Median survival was 8.6 months for the combination and 6.9 months with monotherapy (P = 0.48). Time-to-disease-progression was significantly longer with cetuximab plus irinotecan than with cetuximab alone (4.1 vs. 1.5 months;

HR 0.54), even among patients who also had oxaliplatin-refractory disease. The incidence of grade 3 or 4 adverse effects was as anticipated based on previous trials; asthenia and a follicular rash occurred most commonly with cetuximab alone, and in addition to typical irinotecan-related side effects (e.g., nausea, vomiting, and diarrhea) with combination treatment. Interestingly, tumor response was not associated with the intensity of EGFR-positive staining. Because patients who experienced disease progression on monotherapy were allowed to cross over to combination treatment, any difference in OS between the two groups is difficult to ascertain.

Cetuximab should be considered in patients with irinotecan- and oxaliplatin-refractory colorectal cancer. As a single agent, cetuximab is associated with a 23% improvement in OS compared with best supportive care. Current evidence does not support restricting the use of cetuximab to patients with immunohistochemical evidence of EGFR-positive staining.[130]

An important caveat for most of these initial trials is that *KRAS* testing was not initially performed. Retrospective analysis on subsets of patients with known *KRAS* testing has been performed in limited patients with tumor samples available. One study tested 394 of 572 patient tumor samples for *KRAS* mutations.[131] These patients were treated with cetuximab plus best supportive care versus best supportive care. Patients with *KRAS* mutations had a shorter PFS and OS compared with those with wild-type *KRAS*. Overall survival was improved by 4.7 months (HR 0.55; $P < 0.001$) and PFS by 1.8 months (HR 0.40; $P < 0.001$) when treated with cetuximab. No benefit was seen with cetuximab in patients with mutant *KRAS*.

These results stress the influence of *KRAS* mutations on the efficacy of EGFR inhibitors, including cetuximab and panitumumab, in treating colorectal cancer. *KRAS* is located downstream from the EGFR receptor and is involved in the EGFR signaling cascade by activating the MAP kinase pathway that influences cellular proliferation. Activating mutations in exon 2 are able to activate *KRAS* independent of EGFR receptor activation.[131] Therefore, EGFR receptor inhibition strategies are not effective in controlling cancer proliferation and growth. Several studies have demonstrated that *KRAS* mutational status predicts response to EGFR inhibitors used in colorectal cancer and its status should be determined prior to starting therapy directed at the EGFR receptor. Therapy with an EGFR inhibitor is not recommended in patients with mutant *KRAS*.[71]

Tumors harboring *BRAF* mutations are also associated with a poor prognosis and a poor response to EGFR inhibitors in patients with wild-type *KRAS*.[132] Although *BRAF* mutation testing is not routinely recommended at this time, *BRAF* mutation status may be considered in patients with wild-type *KRAS*. Individuals with *BRAF* mutations should not receive EGFR inhibitors.

Panitumumab is a fully human monoclonal antibody targeted to the EGFR that was FDA approved for use in patients with metastatic colorectal cancer that no longer responds to previous therapy. The approval was based on a comparison of panitumumab to best supportive care in patients who had experienced disease progression after standard chemotherapy, including a fluoropyrimidine, irinotecan, and oxaliplatin. Patients received best supportive care or panitumumab (6 mg/kg IV every 2wo weeks) until tumor progression.[114] Those patients who received panitumumab showed a 46% decrease in the rate of tumor progression compared with those who only received best supportive care (HR 0.54, 95% CI 0.44 to 0.66). Retrospective analysis of *KRAS* testing demonstrated that the benefit was limited to patients with wild-type *KRAS* in that a 0% overall response rate and decreased PFS was reported in patients with *KRAS* mutations treated with panitumumab.[133] As expected, dermatologic toxicities were observed in patients receiving panitumumab, as well as fatigue, abdominal pain, nausea, and diarrhea. Only one hypersensitivity reaction was reported. As with cetuximab, EGFR-positivity with immunohistochemistry should not be used to determine appropriate candidates for panitumumab but *KRAS* mutational status should be determined.[134]

Neither of the EGFR inhibitors should be used in the second-line setting if they were part of a patient's initial treatment regimen.

Miscellaneous Salvage Chemotherapy Similar to initial treatment of metastatic colon cancer, capecitabine is being investigated as a replacement for infusional fluorouracil in salvage regimens in combination with irinotecan or oxaliplatin.

One interesting subject of debate is whether treatment could be suspended once disease stabilization occurs, and restarted upon disease progression. In the OPTIMOX study, patients were randomized to receive continuous FOLFOX4 until disease progression, or a simplified regimen, FOLFOX7, with intermittent oxaliplatin.[135] The results of this study demonstrated that oxaliplatin could be stopped after six cycles of chemotherapy, but that an appropriate strategy to reintroduce chemotherapy needed to be developed. Ongoing studies are evaluating various agents as maintenance treatments in conjunction with a similar intermittent treatment regimen. Patients whose disease progresses following standard treatment for metastatic colorectal cancer should be encouraged to participate in a clinical trial evaluating new treatment approaches for this incurable disease.

Hepatic-Directed Therapies Patients with hepatic-predominant disease whose disease progresses with systemic therapy may be candidates for chemoembolization, cryotherapy, or radiofrequency ablation. Percutaneous ethanol injection can be performed but is considered relatively ineffective against colorectal hepatic metastases.[136] Response rates to HAI therapy in patients who are refractory to fluorouracil-based therapy may be as high as 33%.

The largest experience with hepatic arterial chemoembolization has been seen in patients with metastatic carcinoid tumors or primary hepatocellular carcinomas. Most recently, small trials have been expanded to include hepatic metastases caused by colorectal cancer. Hepatic arterial chemoembolization delivers high concentrations of cytotoxic agents directly to the tumor and results in the embolization or devascularization of the liver, which blocks perfusion of the tumor and eliminates its blood supply. This procedure involves the instillation of a mixture that incorporates chemotherapeutic agents, radioactive contrast dye, and/or an embolic agent directly into the hepatic artery. Agents and doses most commonly studied include doxorubicin (40 to 60 mg), mitomycin (10 to 20 mg), and cisplatin (100 to 150 mg), which are usually dissolved in about 10 to 15 mL of a radiographic contrast dye.[137] Addition of an embolic agent to the mixture results in either a temporary or permanent occlusion of the hepatic artery. Although approximately 80% of patients in one trial experienced a response, the number of patients with colorectal cancer who have undergone this procedure thus far is relatively low, and patients still experience eventual disease progression. However, preliminary results from small series suggest that the high tumor responses might be associated with a survival benefit, and randomized trials comparing systemic therapy to hepatic chemoembolization for unresectable disease are ongoing.

Cryosurgery involves placement of a cryoprobe into the tumor, either percutaneously or intraoperatively, and then lowering the probe temperature to −100°C (− 148°F).[136] This is repeated in cycles, resulting in formation of an ice ball that causes tumor destruction. Cryosurgery may be used alone or in conjunction with other localized procedures, such as radiofrequency ablation, which is becoming increasingly used for colorectal liver metastases. The technique involves placement of a chilled perfusion electrode needle into the tumor with subsequent application of alternating electrical current through the electrode, resulting in thermal coagulative necrosis of the tumor.[136] Laser interstitial thermal therapy represents an

alternate method for causing tumor coagulative necrosis using a laser. Radiofrequency ablation is also being evaluated in conjunction with HAI, in an effort to reduce local recurrence of metastatic tumors. Procedure-related complications can include bleeding, coagulopathy, liver abscess, biliary stricture, and pleural effusion.[136] Although these approaches represent potential treatment strategies for patients with unresectable, yet limited hepatic metastases, additional experience is needed to determine long-term outcomes. Furthermore, extrahepatic sites of disease continue to be a problem even for those individuals in whom the liver tumors can be eradicated.

New Strategies and Agents in Development

At present, fluorouracil plus leucovorin, bevacizumab, capecitabine, irinotecan, oxaliplatin, and cetuximab are the most frequently used chemotherapeutic agents for cancer of the colon and rectum. New chemotherapy agents have been studied in an attempt to further improve antitumor efficacy and reduce treatment toxicities. Oral fluorinated pyrimidines and TS inhibitors, such as fluorouracil prodrugs and inhibitors of fluorouracil catabolism, can prolong in vivo fluorouracil exposure and enhance antitumor effects without the use of continuous IV infusions. But traditional chemotherapy agents, which target rapidly dividing cells, kill both malignant and nonmalignant cells, and new cancer therapies are needed to improve therapeutic outcomes. In particular, targeted therapies aimed at the underlying cancer pathology are increasingly being developed and used in colorectal cancer treatment. A variety of agents targeted toward augmenting the host immune system response have undergone, or are currently undergoing, study for colorectal cancer, including monoclonal antibodies and tumor vaccines. Another potential strategy is regulating tumor growth through the inhibition of various cell signal-transduction pathways. Agents that can alter microenvironmental factors which support angiogenesis and tumor metastases may also be of benefit.

In addition, observations that various tumor characteristics (e.g., TS expression), patient drug-metabolizing enzymes (e.g., DPD and plasma uracil-to-dihydrouracil ratio), and molecular markers (e.g., chromosome 18q allelic loss, microsatellite instability, and *P53* mutation or loss) may predict prognosis and response to certain therapies and provide the rationale for pharmacogenomic strategies to select first-line therapies for individual patients.[138–140] Although patients who are deficient in DPD experience severe and potentially life-threatening toxicities with conventional doses of fluorouracil, determination of DPD activity is relatively time consuming and the techniques are not amenable to routine clinical practice. As an alternative, plasma ratio determinations of uracil and dihydrouracil, which are more easily obtainable, can identify individuals with DPD deficiency who are at risk of developing significant toxicities. Of factors predictive for tumor sensitivity to fluorouracil, TS expression has been most studied. Results from in vitro studies demonstrate that pretreatment intratumoral TS levels are inversely correlated to tumor response to fluorouracil. Whether increased tumor TS expression reflects a biologically more aggressive tumor or is directly related to fluorouracil resistance is unknown. Studies are under way to use this and other information to identify rational therapeutic approaches for select patients.

One of these strategies involves measuring plasma fluorouracil concentrations and adjusting individual patient dosing regimens to achieve fluorouracil concentrations within an established therapeutic range to optimize efficacy and minimize side effects. Published data suggest that only 20% to 30% of patients treated with fluorouracil achieve therapeutic concentrations.[141] A prospective study that compared pharmacokinetically guided fluorouracil dosing with conventional dosing in patients with metastatic colorectal cancer demonstrated that pharmacokinetically guided dose adjustments reduced grade 3/4 toxicities, increased the objective tumor response rate, and provided a higher yet not significantly increased survival rate.[142] Valid assay methods that facilitate therapeutic drug monitoring are now available and are being used in some centers. Whether clinicians adopt this strategy and if it will indeed advance therapeutic outcomes have yet to be established. For those patients with tumors that have *KRAS* mutations or *BRAF* mutations, more studies are needed.

PHARMACOECONOMIC CONSIDERATIONS

The estimated expenditures for colorectal cancer in the United States alone are between $5.3 and $6.5 billion per year.[143] The total lifetime cost for managing a patient with cancer of the colon based on North American data is close to $100,000.[143] Costs for patients with rectal cancer are approximately 15% higher because of the added expense of XRT. The highest treatment costs are incurred during the initial and terminal phases of care. Thus a long-term approach is needed to accurately estimate the cost of treating patients diagnosed with colorectal cancer. In addition, long-term cancer-related excess costs were calculated with the Surveillance, Epidemiology, and End Results (SEER)-Medicare–linked database as $33,700 and $36,500 for colon and rectal cancer, respectively.[143] The impact of changes in clinical practice on treatment costs, such as increased use of adjuvant therapy, changes in duration of hospital stay and outpatient delivery of health services, and incorporation of costly agents into standard treatment regimens, must also be continually considered.

The cost of the drugs alone (based on 95% of average wholesale price in 2004) were estimated for a 70-kg, 170-cm tall patient with colorectal cancer for a typical treatment period of 8 weeks.[143] The cost of biweekly infusional fluorouracil plus leucovorin (LV5FU2) is only about $263, but the incorporation of irinotecan (FOLFIRI) or oxaliplatin (FOLFOX) increases drug costs to $9,381 and $11,889, respectively. Total drug costs are about $21,000 with the addition of bevacizumab; an 8-week treatment course of standard cetuximab-containing regimens costs about $31,000. Thus, while the availability of these newer cytotoxic and biologic agents has extended median survival of patients with metastatic colorectal cancer, the economic impact of drug therapy alone on the healthcare system is of increasing importance.

Most recently, an observational registry of patients receiving chemotherapy for colorectal cancer at clinics across the United States was used to determine actual costs associated with eight commonly prescribed treatment regimens.[144] The costs were determined by adding the cost of each chemotherapeutic agent, as well as other commonly prescribed drugs. The costs associated with regimens varied widely. FOLFOX, the most common regimen, cost $2,931 per cycle; patients receiving this regimen also had the greatest utilization of white blood cell growth factors and erythropoiesis-stimulating agents. Depending on the regimen, total cost of chemotherapy for a full course of treatment could vary by as much as $36,999.

The cost-effectiveness of therapeutic regimens in various treatment settings has also been evaluated. The addition of irinotecan to fluorouracil and leucovorin as first-line therapy for metastatic disease was supported in the United Kingdom based on an incremental cost-effectiveness ratio of £14,794 per life-year gained.[145] A comparison of the costs and effects of FOLFOX compared with IFL, based on the perspective of a United States payer, showed total costs of $94,693 for FOLFOX and $66,231 for IFL, with a gain in survival of 4.4 months with FOLFOX at an incremental cost-effectiveness ratio of $80,410 per life-year gained.[145] The associated $11,890 per quality-adjusted life-year gained is considered an acceptable oncology intervention within the United States.

In adjuvant treatment, a cost-effectiveness analysis of FOLFOX4 compared to LV5FU2 from a Medicare perspective showed an incremental cost-effectiveness ratio with FOLFOX4 of $20,603 per life-year gained and $22,804 per quality-adjusted life-year gained.[146] At a threshold of $50,000 per quality-adjusted life-year, FOLFOX4 would be viewed as cost-effective adjuvant therapy for stage III colon cancer. Substitution of intravenous fluorouracil with oral capecitabine may have positive economic effects, but data are limited.[145] Reduced costs for capecitabine with regard to drug administration and drug-related adverse effects offset its higher acquisition cost as compared with fluorouracil plus leucovorin in adjuvant therapy for stage III colon cancer, but a cost-effectiveness analysis was not reported.[147]

The cost-effectiveness of combination chemotherapy with cetuximab, bevacizumab, or panitumumab in the United States has not been established. A report by the National Institute for Health and Clinical Excellence (NICE) suggests that neither first-line bevacizumab nor second-line or subsequent treatment cetuximab would be considered cost-effective.[145]

Colorectal cancer screening is regarded as cost-effective, but only approximately 35% of the population age 50 years and older undergoes regular screening.[148] The cost-effectiveness of standard methods varies. Base-case estimates, adjusted to year 2000 dollars, were $6,300 to $19,700 per life-year saved, $13,600 to $36,300 per life-year saved, and $7,300 to $22,000 per life-year saved for FOBT, sigmoidoscopy, and colonoscopy, respectively.[148] When adjusted average cost-effectiveness ratios were calculated and compared among FOBT, colonoscopy, and sigmoidoscopy, colonoscopy was the most cost-effective screening strategy when performed every 10 years. Based on an average estimated adherence rate with FOBT or sigmoidoscopy of approximately 50%, the ability to offer patients a choice of screening alternatives has been proposed in an attempt to increase acceptance of screening.[148] A base-rate estimate of the cost-effectiveness of offering a choice of cancer screening options to individuals age 50 years and older is $11,900 per life-year gained.[148] Because most accepted screening strategies have cost-effectiveness ratios that are well below the accepted benchmark of $50,000 per life-year saved, this strategy is considered cost-effective. As many as 12,000 deaths each year might be prevented if all individuals who were candidates for colorectal screening participated in a regular program.[148]

EVALUATION OF THERAPEUTIC OUTCOMES

The goal of monitoring is to evaluate whether the patient is receiving any benefit from the management of the disease or to detect recurrence. Similarly, examinations help to determine whether preventive interventions or screening studies effectively reduce an individual's risk for developing colorectal cancer or presenting with an advanced stage of disease. During treatment for active disease, patients should undergo monitoring for measurable tumor response, progression, or new metastases; these tests may include chest CT scans or radiographs, abdominal or pelvic CT scans or radiographs, depending on the site of disease being evaluated for response, and CEA measurements every 3 months if the CEA is or was previously elevated. In addition, a complete blood cell count should be obtained prior to each course of chemotherapy administration to ensure that hematologic indices are adequate. Baseline liver function tests and an assessment of renal function should be evaluated prior to and periodically during therapy. These tests and other selected serum chemistries should also be evaluated with the development of any new symptoms or significant change in disease status. Patients should be evaluated during every treatment visit for the presence of anticipated side effects, which generally include loose stools or diarrhea, nausea or vomiting, mouth sores, fatigue, and fever, as well as other side effects such as neuropathy and skin rash that are typically associated with oxaliplatin and cetuximab, respectively. Patients receiving bevacizumab should be evaluated for hypertension and proteinuria.

Symptoms of recurrence such as pain syndromes, changes in bowel habits, rectal or vaginal bleeding, pelvic masses, anorexia, and weight loss develop in less than 50% of patients. A greater percentage of recurrences are detected in asymptomatic patients because of increased serum CEA levels that lead to further examination. Although the value of CEA monitoring for asymptomatic disease recurrence is questioned by some because of the related expense and emotional stress associated with false-positive elevations, CEA monitoring plays an important role in postoperative followup studies for most individuals. A PET scan can be considered to identify localized sites of metastatic disease when a rising CEA level suggests metastatic disease but CT scans and other imaging studies are negative.

Patients who undergo curative surgical resection, with or without adjuvant therapy, require close follow up based on the premise that early detection and treatment of recurrence could still render them cured. In addition, early treatment for asymptomatic metastatic colorectal cancer appears superior to delayed therapy. Specific practice guidelines for postoperative surveillance examinations were developed by ASCO and include: history and physical examination every 3 to 6 months for the first 3 years, every 6 months during the fourth and fifth years, and then at the discretion of the physician; annual chest and abdominal CT scan for 3 years following primary therapy; and colonoscopy at 3 years after operative treatment. These guidelines also recommend against routinely monitoring liver function tests, complete blood cell count, FOBT, annual chest radiographs in asymptomatic patients.[149]

Recent advances in the treatment for cancer of the colon and rectum now offer the potential to improve patient survival, but for many patients, improved DFS and PFS represent equally important therapeutic outcomes. Although treatment approaches for metastatic colorectal cancer have been historically assessed by their ability to produce a measurable objective tumor response, which is generally believed necessary for any treatment to improve survival, the effects of therapies on survival are clinically more meaningful than their ability to induce a tumor response. However, with the availability of multiple active treatments for metastatic disease, and the likelihood that patients will receive more than one during the course of their treatment, improvements in OS with new therapies will be increasingly difficult to determine.

In the absence of the ability of a specific treatment to demonstrate improved survival, important outcome measures should include the effects of the treatment on patient symptoms, daily activities and performance status, and other quality-of-life indicators, as well as PFS and time-to-treatment failure. Because most metastatic colorectal cancers are incurable, a specific decision regarding an individual patient's care will ultimately be required. This decision should be based on a careful assessment of the balance between risks associated with treatment (or lack thereof) and benefits of treatment. Effort should also be made to ensure that the costs of screening, diagnostic tests, treatments, and procedures for colorectal cancer are consistent with their value in improving patient outcomes.

ABBREVIATIONS

APC: adenomatous polyposis coli (gene)

ASCO: American Society of Clinical Oncology

BMI: body mass index

CAPEOX: capecitabine, oxaliplatin
CEA: carcinoembryonic antigen
COX: cyclooxygenase
CT: computed tomography
CYP: cytochrome P450 isoenzyme
DFMO: difluoromethylornithine
DFS: disease-free survival
DPD: dihydropyrimidine dehydrogenase
EGFR: epidermal growth factor receptor
FAP: familial adenomatous polyposis
FIT: fecal immunochemical test
FOBT: fecal occult blood test
FOLFIRI: fluorouracil, leucovorin, irinotecan
FOLFOX: fluorouracil, leucovorin, oxaliplatin
5-FU: fluorouracil
HAI: hepatic artery infusion
HNPCC: hereditary nonpolyposis colorectal cancer
HR: hazard ratio
IFL: irinotecan plus fluorouracil plus leucovorin

CHAPTER 139

Prostate Cancer

LEANN B. NORRIS AND JILL M. KOLESAR

KEY CONCEPTS

1. Prostate cancer is the most frequent cancer in U.S. men. African American ancestry, family history, and increased age are the primary risk factors for prostate cancer.
2. Prostate-specific antigen is a useful marker to detect prostate cancer at early stages, predict outcome for localized disease, define disease-free status, and monitor response to androgen-deprivation therapy or chemotherapy for advanced-stage disease.
3. The prognosis for prostate cancer patients depends on the histologic grade, the tumor size, and the disease stage. More than 85% of patients with stage A_1 disease but less than 1% of those with stage D_2 can be cured.
4. Androgen deprivation therapy with a luteinizing hormone–releasing hormone (LH-RH) agonist plus an antiandrogen should be used prior to radiation therapy for patients with locally advanced prostate cancer to improve outcomes over radiation therapy alone.
5. Androgen deprivation therapy, with either orchiectomy, an LH-RH agonist alone or an LH-RH agonist plus an antiandrogen (combined hormonal blockade), can be used to provide palliation for patients with advanced (stage D_2) prostate cancer. The effects of androgen deprivation seem most pronounced in patients with minimal disease at diagnosis.
6. Antiandrogen withdrawal, for patients having progressive disease while receiving combined hormonal blockade with an LH-RH agonist plus an antiandrogen, can provide additional symptomatic relief. Mutations in the androgen receptor have been documented that cause antiandrogen compounds to act like receptor agonists.
7. Chemotherapy, with docetaxel and prednisone improves survival in patients with hormone-refractory prostate cancer. Patients with hormone-refractory prostate cancer should be considered for entry into clinical trials investigating new therapies for prostate cancer.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Prostate cancer is the most commonly diagnosed cancer in American men.[1] For most men, prostate cancer has an indolent course, and treatment options for early disease include expectant management, surgery, or radiation. With expectant management, patients are monitored for disease progression or development of symptoms. Localized prostate cancer can be cured by surgery or radiation therapy, advanced prostate cancer is not yet curable. Treatment for advanced prostate cancer can provide significant disease palliation for many patients for several years after diagnosis. The endocrine dependence of this tumor is well documented, and hormonal manipulation to decrease circulating androgens remains the basis for the treatment of advanced disease.

EPIDEMIOLOGY

1 Prostate cancer is the most frequent cancer among American men and represents the second leading cause of cancer-related deaths in all males.[1] In the United States alone, it is estimated that 217,730 new cases of prostatic carcinoma were diagnosed and more than 32,050 men died from this disease in 2010.[1] Although prostate cancer incidence increased during the late 1980s and early 1990s owing to widespread prostate-specific antigen (PSA) screening, deaths from prostate cancer have been declining since 1995.[1]

ETIOLOGY

Table 139–1 summarizes the possible factors associated with prostate cancer.[2,3] The widely accepted risk factors for prostate cancer are age, race-ethnicity, and family history of prostate cancer.[2,3] The disease is rare under the age of 40, but the incidence sharply increases with each subsequent decade, most likely because the individual has had a lifetime exposure to testosterone, a known growth signal for the prostate.[3]

RACE AND ETHNICITY

The incidence of clinical prostate cancer varies across geographic regions. Scandinavian countries and the United States report the highest incidence of prostate cancer, while the disease is relatively rare in Japan and other Asian countries.[4] African American men have the highest rate of prostate cancer in the world, and in the United States, prostate cancer mortality in African Americans is more than twice that seen in Caucasian populations.[1] Hormonal, dietary, and genetic differences, and differences in access to healthcare may contribute to the altered susceptibility to prostate cancer in these populations.[2,3] Testosterone, commonly implicated in the pathogenesis of prostate cancer, is 15% higher in African American men compared with Caucasian males. Activity of 5-α-reductase,

TABLE 139-1 Risk Factors Associated with Prostate Cancer

Factor	Possible Relationship
Probable risk factors	
Age	More than 70% of cases are diagnosed in men greater than 65 years old
Race	African Americans have higher incidence and death rate
Genetic	Familial prostate cancer inherited in an autosomal dominant manner
	Mutations in *p53*, *Rb*, E-cahedrin, α-catenin, androgen receptor, *KAI1*, microsatellite instability, loss of heterozygocity at 1, 2q, 12p, 15q, 16p, and 16q, *BRCA1* and *BRCA2* mutation
	Candidate prostate cancer gene locus identified on chromosome 1
Possible risk factors	
Environmental	Clinical carcinoma incidence varies worldwide
	Latent carcinoma similar between regions
	Nationalized males adopt intermediate incidence rates between those of the United States and their native country
Occupational	Increased risk associated with cadmium exposure
Diet	Increased risk associated with high-meat and high-fat diets
	Decreased intake of 1,25-dihydroxyvitamin D, lycopene, and β-carotene increases risk
Hormonal	Does not occur in eunuchs
	Low incidence in cirrhotic patients
	Up to 80% are hormonally dependent; African Americans have 15% increased testosterone
	Japanese have decreased 5-α-reductase activities
	Polymorphic expression of the androgen receptor

the enzyme that converts testosterone to its more active form, dihydrotestosterone (DHT), in the prostate, is decreased in Japanese men compared with African Americans and Caucasians.[2,3] In addition, genetic variations in the androgen receptor exist. Activation of the androgen receptor is inversely correlated with CAG repeat length. Shorter CAG repeat sequences have been found in African Americans. Therefore the combination of increased testosterone and increased androgen receptor activation may account for the increased risk of prostate cancer for African American men.[2,3] The Asian diet is generally considered to be low in fat and high in fiber with a high concentration of phytoestrogens, potentially explaining their decreased risk.[4,5]

FAMILY HISTORY

Men with a brother or father with prostate cancer have twice the risk for prostate cancer as compared with the rest of the population.[5] There appears to be a familial clustering of a prostate cancer syndrome, and genomewide scans have identified potential prostate cancer susceptibility candidate genes. Male carriers of germline mutations of *BRCA1* and *BRCA2* are known to have an increased risk for developing prostate cancer.[6] Common exposure to environmental and other risk factors may also contribute to increased risk among patients with first-degree relatives with prostate cancer.[5,7]

DIET

A number of epidemiologic studies support an association between high fat intake and risk of prostate cancer. A strong correlation between national per capita fat consumption and national prostate cancer mortality has been reported, and prospective case-control studies suggest that a high-fat diet doubles the risk of prostate cancer.[5,8] This relationship between high fat intake and prostate cancer may explain differences in insulin-like growth factor-1 (IGF-1). High calorie and high fat diets stimulate hepatic production of IGF-1, which is involved in the regulation of proliferation and apoptosis of cancer cells.[5,8] High levels of IGF-1 are associated with an increased risk for prostate cancer.[5]

Other dietary factors implicated in the development or prevention of prostate cancer include retinol, carotenoids, lycopene, and vitamin D consumption.[5,7,9] Retinol, or vitamin A, intake, especially in men older than 70, is correlated with an increased risk of prostate cancer, whereas intake of its precursor, β-carotene, has a protective or neutral effect. Lycopene, obtained primarily from tomatoes, decreases the risk of prostate cancer in small cohort studies. Men who developed prostate cancer in one cohort study had lower levels of $1,25(OH)_2$-vitamin D than matched controls, although a prospective study did not support this. Clearly, dietary risk factors require further evaluation, but because fat and vitamins are modifiable risk factors, dietary intervention may be promising in prostate cancer prevention. Investigations of selenium and vitamin E supplementation are discussed further in the section titled chemoprevention.

OTHER FACTORS

Benign prostatic hyperplasia (BPH) is a common problem among elderly men, affecting more than 40% of men over the age of 70 (see Chapter 93). BPH results in the urinary symptoms of hesitancy and frequency. Since prostate cancer affects a similar age group and often has similar presenting symptoms, the presence of BPH often complicates the diagnosis of prostate cancer, although it does not appear to increase the risk of developing prostate cancer.[2,7]

Smoking has not been associated with an increased risk of prostate cancer, but smokers with prostate cancer have an increased mortality resulting from the disease when compared with nonsmokers with prostate cancer (relative risk 1.5 to 2).[2,7] In addition, in a prospective cohort analysis, alcohol consumption was not associated with the development of prostate cancer.

CHEMOPREVENTION

Currently, the most promising agents for the prevention of prostate cancer are the 5-α reductase inhibitors, finasteride and dutasteride.[7,10,11] These medications inhibit 5-α reductase, an enzyme that converts testosterone to its more active form, dihydrotestosterone (DHT), which is involved in prostate epithelial proliferation. There are two types of 5-α reductase, type I and type II; both are implicated in the development of prostate cancer. Finasteride selectively inhibits the 5-α reductase type II isoenzyme, whereas dutasteride inhibits both isoenzymes.[11] Both finasteride and dutasteride falsely lower the PSA by approximately 50% in patients, and this needs to be adjusted for when measuring the PSA in patients on these medications.[7,11]

The Prostate Cancer Prevention Trial (PCPT) compared finasteride 5 mg daily for 7 years to placebo for the prevention of prostate cancer.[7] When compared with placebo, the point prevalence of prostate cancer was reduced for those on finasteride by 25% (hazard ratio [HR] = 0.75, 95% confidence interval [CI], 18.6-30.6%). However, in those that did develop prostate cancer, there was an increase in the number of high-grade (Gleason grade 7–10) tumors detected at biopsy in the finasteride group. Overall, finasteride did reduce the frequency of prostate cancer, but the prostate cancers that were diagnosed in the finasteride group were more aggressive. Since the original trial was reported, a number of biases in cancer detection caused by finasteride have been proposed, including improved detection of overall and high-grade prostate cancer, increased sensitivity of digital rectal examination, and increased sensitivity of biopsy for high-grade cancer detection. Redman and colleagues recently reevaluated the data from the PCPT trial to determine what effect these potential biases had on the diagnosis of aggressive

prostate cancer in the finasteride group.[12] The analysis had an additional 3 months of follow-up, with unadjusted prostate cancer rates of 23% (4.8% with high grade) in the placebo group compared to 17% (5.8% with high grade) in the finasteride group. When the results were adjusted for these biases, prostate cancer rates were estimated to be 21% (4.2% high-grade) in the placebo group compared to 15% (4.8% high-grade), corresponding to a 30% risk reduction in prostate cancer (relative risk [RR] = 0.70, 95% CI, 0.64–0.76; $P < 0.0001$) and a nonsignificant, 14% increase in high-grade cancer (RR, 1.14; 95% CI, 0.96-1.35; $P = 0.12$) with finasteride.[12]

Following this reanalysis, the American Society of Clinical Oncology and the American Urological Association published a joint practice guideline for prostate cancer chemoprevention.[13] While dutasteride is still being investigated for prostate cancer prevention, preliminary reports from REDUCE suggest that effects of dutasteride and finasteride are similar, and both agents were considered in the guideline.[13]

The guideline recommends that asymptomatic men with a prostate-specific antigen (PSA) ≤3.0 ng/mL (3.0 mcg/L) who are regularly screened with PSA for early detection of prostate cancer may benefit from a discussion of both the benefits of dutasteride or finasteride for 7 years for the prevention of prostate cancer and the potential risks.[13]

The guideline does not recommend the use of finasteride or dutasteride for prostate cancer chemoprevention and noted that, while most panel members believed the higher risk of high-grade cancer in the finasteride group seen in the PCPT is most likely related to biases, cancer induction or promotion by finasteride cannot be excluded with certainty. Additionally, while finasteride reduces the prevalence of prostate cancer, the impact of finasteride on prostate cancer morbidity and mortality has not been demonstrated. Patients considering finasteride or dutasteride for prostate cancer chemoprevention or taking it for benign conditions such as BPH must weigh the risks and benefits of treatment. The primary benefit is that these agents reduce the incidence of prostate cancer by approximately 25%, and improve lower urinary tract symptoms of BPH, but the risks include the potential for more high-grade prostate cancers; the long-term benefit of these agents is not known; and reversible sexual adverse effects can occur.[13]

Selenium and vitamin E alone or in combination were evaluated in the *Sel*enium and Vitamin *E* Cancer Prevention *T*rial (SELECT), a clinical trial investigating their effects on the incidence of prostate cancer. The data and safety monitoring committee found that after 5 years selenium and vitamin E taken alone or together did not prevent prostate cancer. Based on these data and safety concerns, the trial was halted.[14] Other agents, including vitamin D, lycopene, green tea, nonsteroidal antiinflammatory agents, isoflavones, and statins are under investigation for prostate cancer and show promise, however, none are currently recommended for routine use outside of a clinical trial.[15]

SCREENING

Digital rectal examination (DRE) has been recommended since the early 1900s for the detection of prostate cancer. The primary advantage of DRE is its specificity, reported at greater than 85%, for prostate cancer. Other advantages of DRE include low cost, safety, and ease of performance. However, DRE is relatively insensitive and is subject to interobserver variability. DRE as a single screening method has poor compliance and has had little effect on preventing metastatic prostate cancer in one large case-control study.[16]

2 Prostate-specific antigen (PSA) is a useful marker for detecting prostate cancer at early stages, predicting outcome for localized disease, defining disease-free status, and monitoring response to androgen-deprivation therapy or chemotherapy for advanced-stage disease. PSA is used widely for prostate cancer screening in the United States, with simplicity its major advantage and low specificity its primary limitation.[17] PSA may be elevated in men with acute urinary retention, acute prostatitis, and prostatic ischemia or infarction, as well as BPH, a nearly universal condition in men at risk for prostate cancer. PSA elevations between 4.1 (4.1 mcg/L) and 10 ng/mL (10 mcg/L) cannot distinguish between BPH and prostate cancer, limiting the utility of PSA alone for the early detection of prostate cancer. Additionally, only 38% to 48% of men with clinically significant prostate cancer have a serum PSA outside the reference range.[18]

Early detection of potentially curable prostate cancers is the goal of prostate cancer screening. For cancer screening to be beneficial, it must reliably detect cancer at an early stage, when intervention would decrease mortality. Whether prostate cancer screening, with PSA, DRE or a combination fits these criteria has generated considerable controversy, and two recent studies have done little to resolve the controversy.[19–21] The European Randomized Study of Screening for Prostate Cancer (ERSPC) evaluated the effect of PSA screening on prostate cancer mortality. More than 182,000 men from seven different European countries were randomized between being offered screening with PSA to no screening. The frequency of screening and PSA threshold for a biopsy varied by country. Most centers used a PSA cutoff of 3 ng/mL (3 mcg/L), but Belgium allowed up to 10 ng/mL (10 mcg/L). Most centers screened every 4 years, although Sweden screened every 2 years. Eighty-two percent of men in the screening group had at least one PSA performed. With a median follow-up of 9 years, the cumulative incidence of prostate cancer was 8.2% in the screening group and 4.8% in the control group.[20] The rate ratio for death from prostate cancer in the screening group, compared with the control group, was 0.80 (95% CI, 0.65 to 0.98; adjusted $P = 0.04$), which corresponds to about one less death in the screened group compared with the nonscreened group. Of the 126,462 PSA tests performed, 16.2% of the tests were positive. Biopsies were performed for elevated PSAs, with 75.9% having a false-positive result.[20]

In the United States, clinicians believe that neither DRE nor PSA is sensitive or specific enough to be used alone as a screening test. Although the relative predictability of DRE and PSA is similar, the tumors identified by each method are different. Catalona and associates[22] confirmed that the combination of a DRE plus PSA determination is a better method of detecting prostate cancer than DRE alone.

In the United States, the Prostate, Lung, Colon and Ovarian Screening study (PLCO) randomized 76,693 men to receive either annual screening (38,343 subjects) or usual care as the control (38,350 subjects). In the screening group, men were offered annual PSA testing for 6 years and DRE for 4 years with compliance with screening was 85%. Men in the usual care group were able to receive screening, with the rate of PSA testing ranging from 40% to 52% and DRE from 41% to 46%. After 7 years of follow-up, the incidence of death per 10,000 person-years was not significantly different between the two groups with 2.0 (50 deaths total) in the screening group and 1.7 (44 deaths total) in the control group (rate ratio, 1.13; 95% CI, 0.75 to 1.70).[21]

The common approach to prostate cancer screening today involves offering a baseline PSA and DRE at age 40 with annual evaluations beginning at age 50 to all men of normal risk with a 10-year or greater life expectancy. Men with an increased risk of prostate cancer, including men of African American ancestry and men with a family history of prostate cancer, may begin screening earlier, at age 40 to 45.

Despite this common practice, the benefits of prostate cancer screening remain controversial.[23] The ERSPC demonstrated that PSA testing every 4 years was better than no PSA testing, decreasing prostate cancer deaths in the screened group by approximately

1 per 1,000 men screened compared with the unscreened group, but the false-positive rate was 76%, resulting in more than 13,000 unnecessary biopsies. The PLCO screening study showed no reduction in prostate cancer death between the annual (PSA and DRE) screening group and the usual care group, which is not surprising given the small reduction in death expected and that about one-half of the patients in the usual screening groups had PSA and DRE screening performed. Both studies demonstrated that screening identifies more prostate cancers than not screening.[19–23] PSA measurements can identify small, subclinical prostate cancers, where no intervention may be required. Detecting prostate cancer in those not needing therapy not only increases the cost of care through unnecessary screening and workups, but also increases the toxicity of therapy, by subjecting some patients to unnecessary therapy.[24,25] The American College of Physicians currently recommends that rather than screening all men for prostate cancer as a matter of routine, physicians should describe the potential benefits and known risks of screening, diagnosis, and treatment, listen to the patient's concerns, and then decide on an individual's screening method. That recommendation is based on the uncertain benefit of prostate cancer screening on prostate cancer mortality, and the well-established risks, including pain, drug toxicity and psychological distress of unnecessary screening, biopsies, and treatment.

PATHOPHYSIOLOGY

The prostate gland is a solid, rounded, heart-shaped organ positioned between the neck of the bladder and the urogenital diaphragm (Fig. 139–1). The normal prostate is composed of acinar secretory cells arranged in a radial shape and surrounded by a foundation of supporting tissue. The size, shape, or presence of acini is almost always altered in the gland that has been invaded by prostatic carcinoma. Adenocarcinoma, the major pathologic cell type, accounts for more than 95% of prostate cancer cases.[26,27] Much rarer tumor types include small cell neuroendocrine cancers, sarcomas, and transitional cell carcinomas.

Prostate cancer can be graded systematically according to the histologic appearance of the malignant cell and then grouped into well, moderately, or poorly differentiated grades.[27,28] Gland architecture is examined and then rated on a scale of 1 (well differentiated) to 5 (poorly differentiated). Two different specimens are examined, and the score for each specimen is added. Groupings for total Gleason score are 2 to 4 for well differentiated, 5 or 6 for moderately differentiated, and 7 to 10 for poorly differentiated tumors. Poorly differentiated tumors grow rapidly (poor prognosis), while well-differentiated tumors grow slowly (better prognosis).

Metastatic spread can occur by local extension, lymphatic drainage, or hematogenous dissemination.[28,29] Lymph node metastases are more common in patients with large, undifferentiated tumors that invade the seminal vesicles. The pelvic and abdominal lymph node groups are the most common sites of lymph node involvement (Fig. 139–1). Skeletal metastases from hematogenous spread are the most common sites of distant spread. Typically, the bone lesions are osteoblastic or a combination of osteoblastic and osteolytic. The most common site of bone involvement is the lumbar spine. Other sites of bone involvement include the proximal femurs, pelvis, thoracic spine, ribs, sternum, skull, and humerus. The lung, liver, brain, and adrenal glands are the most common sites of visceral involvement, although these organs are not usually initially involved. About 25% to 35% of patients will have evidence of lymphangitic or nodular pulmonary infiltrates at autopsy. The prostate is rarely a site for metastatic involvement from other solid tumors.

Normal growth and differentiation of the prostate depend on the presence of androgens, specifically DHT.[29,30] The testes and the adrenal glands are the major sources of circulating androgens. Hormonal regulation of androgen synthesis is mediated through a series of biochemical interactions between the hypothalamus, pituitary, adrenal glands, and testes (Fig. 139–2). Luteinizing hormone–releasing hormone (LH-RH) released from the hypothalamus stimulates the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the anterior pituitary gland. LH complexes with receptors on the Leydig cell testicular membrane and stimulates the production of testosterone and small amounts of estrogen. FSH acts on the Sertoli cells within the testes to promote the maturation of LH receptors and to produce an androgen-binding protein. Circulating testosterone and estradiol influence the synthesis of LH-RH, LH, and FSH by a negative feedback loop operating at the hypothalamic and pituitary level.[31] Prolactin, growth hormone, and estradiol appear to be important accessory regulators for prostatic tissue permeability, receptor binding, and testosterone synthesis.

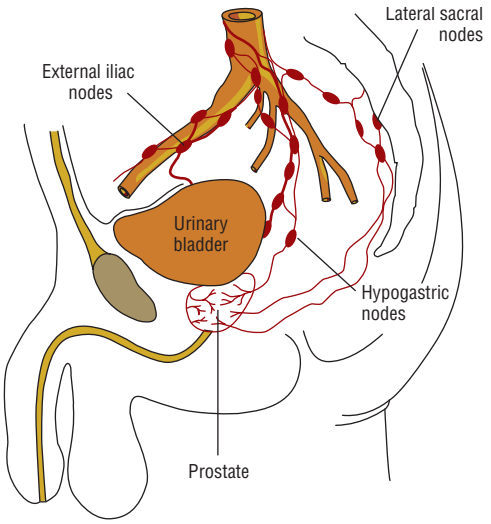

FIGURE 139-1. The prostate gland.

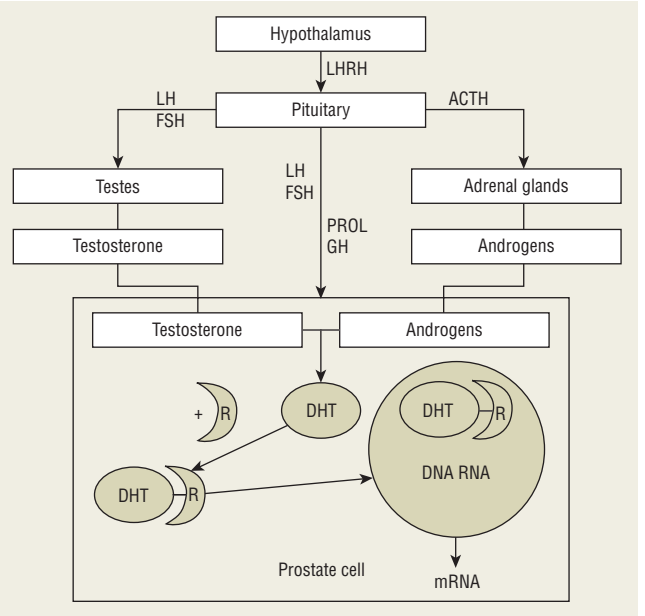

FIGURE 139-2. Hormonal regulation of the prostate gland. (ACTH, adrenocorticotropic hormone; DHT, dihydrotestosterone; FSH, follicle-stimulating hormone; GH, growth hormone; LH, luteinizing hormone; LH-RH, luteinizing hormone–releasing hormone; PROL, prolactin; R, receptor).

TABLE 139-2 Hormonal Manipulations in Prostate Cancer

Androgen source ablation	Antiandrogens
Orchiectomy	Flutamide
Adrenalectomy	Bicalutamide
Hypophysectomy	Nilutamide
LH-RH or LH inhibition	Cyproterone acetate[b]
Estrogens	Progesterones
LH-RH agonists	5-α-Reductase inhibition
Progesterones[a]	Finasteride[b]
Cyproterone acetate[b]	
Androgen synthesis inhibition	
Aminoglutethimide	
Ketoconazole	
Progesterones[a]	

[a]Minor mechanisms of action.
[b]Investigational compounds or use.
LH, luteinizing hormone; LH-RH, luteinizing hormone–releasing hormone.

Testosterone, the major androgenic hormone, accounts for 95% of the androgen concentration. The primary source of testosterone is the testes; however, 3% to 5% of the testosterone concentration is derived from direct adrenal cortical secretion of testosterone or C19 steroids such as androstenedione.[28–30]

In early-stage prostate cancers, aberrant tumor cell proliferation is promoted by the presence of androgens. For these tumors, blockade of androgens induces tumor regression in most patients. Hormonal manipulations to ablate or reduce circulating androgens can occur through several mechanisms[29,30] (Table 139–2). The organs responsible for androgen production can be removed surgically (orchiectomy, hypophysectomy, or adrenalectomy). Hormonal pathways that modulate prostatic growth can be interrupted at several steps (see Fig. 139–2). Interference with LH-RH or LH can reduce testosterone secretion by the testes (estrogens, LH-RH agonists, progestogens, and cyproterone acetate). Estrogen administration reduces androgens by directly inhibiting LH release, by acting directly on the prostate cell, or by decreasing free androgens by increasing steroid-binding globulin levels.[28–30]

Isolation of the naturally occurring hypothalamic decapeptide hormone luteinizing hormone–releasing hormone or LH-RH has provided another group of effective agents for advanced prostate cancer treatment. The physiologic response to LH-RH depends on both the dose and the mode of administration. Intermittent pulsed LH-RH administration, which mimics the endogenous release pattern, causes sustained release of both LH and FSH, whereas high-dose or continuous intravenous administration of LH-RH inhibits gonadotropin release due to receptor downregulation.[23] Structural modification of the naturally occurring LH-RH and innovative delivery have produced a series of LH-RH agonists that cause a similar downregulation of pituitary receptors and a decrease in testosterone production.[31]

Androgen synthesis can also be inhibited in the testes or in the adrenal gland. Aminoglutethimide inhibits the desmolase-enzyme complex in the adrenal gland, thereby preventing the conversion of cholesterol to pregnenolone. Pregnenolone is the precursor substrate for all adrenal-derived steroids, including androgens, glucocorticoids, and mineralocorticoids. Ketoconazole, an imidazole antifungal agent, causes a dose-related reversible reduction in serum cortisol and testosterone concentration by inhibiting both adrenal and testicular steroidogenesis.[32] Megestrol is a synthetic derivative of progesterone that exhibits a secondary mechanism of action by inhibiting the synthesis of androgens. This inhibition appears to occur at the adrenal level, but circulating levels of testosterone are also reduced, suggesting that inhibition at the testicular level may also occur.[32]

Antiandrogens inhibit the formation of the DHT-receptor complex and thereby interfere with androgen-mediated action at the cellular level.[32] Megestrol acetate, a progestational agent, is also available and has antiandrogen actions.[32] Finally, the conversion of testosterone to DHT may be inhibited by 5-α-reductase inhibitors.[7]

In advanced stages of disease, prostate cancer cells may be able to survive and proliferate without the signals normally provided by circulating androgens.[33] When this occurs, the tumors are no longer sensitive to therapies that are dependent on androgen blockade. These tumors are often referred to as hormone refractory or androgen independent.

CLINICAL PRESENTATION

Localized Disease

- Asymptomatic

Locally Invasive Disease

- Ureteral dysfunction, frequency, hesitancy, and dribbling
- Impotence

Advanced Disease

- Back pain
- Cord compression
- Lower extremity edema
- Pathologic fractures
- Anemia
- Weight loss

Prior to the implementation of routine screening, prostate cancers were frequently identified on the investigation of symptoms, including urinary hesitancy, retention, painful urination, hematuria, and erectile dysfunction. With the introduction of screening techniques, most prostate cancers are now identified prior to the development of symptoms.[34]

The information obtained from the diagnostic tests is used to stage the patient (Table 139–3). There are two commonly recognized staging classification systems (Table 139–4). The formal international classification system (tumor, node, metastases; TNM), adopted by the International Union Against Cancer in 1974, was last updated in 2002. The AUS classification is the most commonly used staging system in the United States. Patients are assigned to stages

TABLE 139-3 Diagnostic and Staging Workup for Prostate Cancer

Initial tests	Digital rectal examination (DRE)
	Prostate-specific antigen (PSA) Transrectal ultrasonography (TRUS) if either DRE is positive or PSA is elevated
	Biopsy
Staging tests	Gleason score on biopsy specimen
	Bone scan
	Complete blood count
	Liver function tests
	Serum phosphatases (acid/alkaline)
	Excretory urogram
	Chest x-ray
Additional staging tests (depends on tumor classification, PSA, and Gleason score)	Skeletal films
	Lymph node evaluation
	Pelvic computed tomography
	^{111}In-labeled capromab pendetide scan
	Bipedal lymphangiogram
	Transrectal magnetic resonance imaging

TABLE 139-4 Staging and Classification Systems for Prostate Cancer

AUS[a] Stage (A–D)	AJCC-UICC[b] Classification (TNM)
A (occult, nonpalpable)	$T_xN_xM_x$ (cannot be assessed)
A_1: Focal	$T_0N_0M_0$ (nonpalpable)
A_2: Diffuse	T_0: Focal or diffuse
B (confined to prostate)	$T_1N_0M_0$, $T_2N_0M_0$
B_1: Single nodule in one lobe, less than 1.5 cm	T_1 (Clinically inapparent tumor not palpable or visible by imaging) T_{1a}: Tumor incidental histologic finding in 5% or less of tissue resected T_{1b}: Tumor incidental histologic finding in 5% or more of tissue resected T_{1c}: Tumor identified by needle biopsy (e.g., because of elevated PSA)
B_2: Diffuse involvement of whole gland, greater than 1.5 cm	T_2: (Tumor confined within the prostate[c]) T_{2a}: Tumor involves half of a lobe or less T_{2b}: Tumor involves more than half a lobe, but not both lobes T_{2c}: Tumor involves both lobes
C (localized to periprostatic area)	$T_3N_0M_0$, $T_4N_0M_0$
C_1: No seminal vesicle involvement, less than 70 g	T_3: (Tumor extends through the prostatic capsule[d]) T_{3a}: Unilateral extracapsular extension T_{3b}: Bilateral extracapsular extension T_{3c}: Tumor invades the seminal vesicle(s)
C_2: Seminal vesicle involvement, greater than 70 g	T_4: (Tumor is fixed or invades adjacent structures other than the seminal vesicles) T_{4a}: Tumor invades any of bladder neck, external sphincter, or rectum T_{4b}: Tumor invades levator muscles and/or is fixed to the pelvic wall
D (metastatic disease)	Any T, N_{1-4}, M_0, or N_{0-4}, M_1
D_1: Pelvic lymph nodes or ureteral obstruction	N_1: Metastasis in a single lymph node, 2 cm or less in greatest dimension
D_2: Bone, distant lymph node, organ, or soft tissue metastases	N_2: Metastasis in single lymph node more than 2 cm but not more than 5 cm in greatest dimension; or multiple lymph node metastases, none more than 5 cm in greatest dimension N_3: Metastasis in lymph node more than 5 cm in greatest dimension M_{1a}: Nonregional lymph node(s) M_{1b}: Bone(s) M_{1c}: Other site(s)

[a]American Urologic System.
[b]American Joint Committee on Cancer–International Union Against Cancer.
[c]Note: Tumor found in one or both lobes by needle biopsy, but not palpable or visible by imaging, is classified as T_{1c}.
[d]Note: Invasion into the prostatic apex or into (but not beyond) the prostatic capsule is not classified as T_3 but as T_2.

A through D and corresponding subcategories based on size of the tumor (T), local or regional extension, presence of involved lymph node groups (N), and presence of metastases (M). Some studies classify patients who have progressed after hormonal therapy as stage D_3.[35] Based on men diagnosed with prostate cancer at Walter Reed Army Medical Center from 1988 to 1998, including over 2,042 prostate cancer diagnoses, localized prostate cancer (stage T_1 and T_2) was diagnosed more frequently (89% vs. 68%), and advanced disease (stages T_3, T_4, and D) was diagnosed less frequently (11% vs. 32%) when comparing the 1998 to the 1988 incidence rates.

3 The prognosis for patients with prostate cancer depends on the histologic grade, the tumor size, and the local extent of the primary tumor.[27] The most important prognostic criterion appears to be the histologic grade, because the degree of differentiation ultimately determines the stage of disease. Poorly differentiated tumors are highly associated with both regional lymph node involvement and distant metastases.[27]

From 1999 to 2005, 5-year overall survival rates were estimated at 100% for whites and 97% for African Americans.[1] For this same period, the survival rates for localized or regional disease (100%), and distant disease (30%) in white males were about the same as the survival rates for localized or regional disease (100%), and distant disease (29%) in African American males.[1] A 4.1% decline in age-adjusted mortality has been observed for the period 1994 to 2006. Ten-year cancer-specific survival is estimated as 95% for stage A_1, 80% for stages A_2 to B_2, 60% for stage C, 40% for stage D_1, and 10% for stage D_2.[36] It is estimated that more than 85% of patients with stage A_1 can be cured, whereas fewer than 1% of patients with stage D_2 will be cured.

TREATMENT

Prostate Cancer

DESIRED OUTCOME

The desired outcome in early-stage prostate cancer is to minimize morbidity and mortality due to prostate cancer.[37] The most appropriate therapy of early-stage prostate cancer is a matter of debate. Early-stage disease may be treated with surgery, radiation, or expectant management. While surgery and radiation are curative, they are associated with significant morbidity and mortality. Since the overall goal is to minimize morbidity and mortality associated with the disease, watchful waiting is appropriate in selected individuals. Advanced prostate cancer (stage D) is not currently curable, and treatment should focus on providing symptom relief and maintaining quality of life.[38] The mainstay of treatment for advanced prostate cancer is androgen deprivation therapy, with a goal of reducing testosterone to castrate levels, with either an orchiectomy or an LH-RH agonist.

GENERAL APPROACH TO TREATMENT

The initial treatment for prostate cancer depends primarily on the disease stage, the Gleason score, the presence of symptoms, and the life expectancy of the patient.[37] Prostate cancer is usually initially diagnosed by PSA and DRE and confirmed by a biopsy, where the Gleason score is assigned. Asymptomatic patients with a low risk of recurrence, those with a T_1 or T_{2a}, with a Gleason score of 2 through 6, and a PSA of less than 10 ng/mL (10 mcg/L) may be managed by expectant management, radiation, or radical prostatectomy (Table 139–5). As patients with asymptomatic early-stage disease generally have an excellent 10-year survival, immediate morbidities of treatment must be balanced with the lower likelihood of dying from prostate cancer. In general, more aggressive treatments of early-stage prostate cancer are reserved for younger men, although patient preference is a major consideration in all treatment decisions. In a patient with a normal life expectancy of less than 10 years, expectant management or radiation therapy may be offered. In those with a normal life expectancy of equal to or greater than 10 years, either expectant management, radiation (external beam or brachytherapy), or radical prostatectomy with a pelvic lymph node dissection may be offered. Radiation and radical prostatectomy therapy are generally considered therapeutically equivalent for localized prostate cancer, although neither has been proven to be better than observation alone.[38,39] Wilt and colleagues conducted a systematic review of 18 randomized trials and 473 observational studies to compare the effectiveness and

TABLE 139-5 Management of Prostate Cancer with Low and Intermediate Recurrence Risk

Recurrence Risk	*Expected Survival*	*Initial Therapy*
Low	Less than 10	Expectant management or radiation therapy
T_1–T_{2a} and Gleason 2–6 and PSA less than 10 ng/mL (10 mcg/L) and less than 5% tumor in specimen	Greater than or equal to 10	Expectant management or radical prostatectomy with or without pelvic lymph node dissection or radiation therapy
	Less than 10	Expectant management or radical prostatectomy with or without pelvic lymph node dissection or radiation therapy with or without 4–6 months of androgen deprivation therapy
Intermediate		
T_{2b}–T_{2c} or Gleason 7 or PSA 10–20 ng/mL (10–20 mcg/L)	Greater than or equal to 10	Radical prostatectomy with or without pelvic lymph node dissection or radiation therapy with or without 4–6 months of androgen deprivation therapy

potential complications from treatment options from prostate cancer. This study showed that superiority between radiation, radical prostatectomy, and androgen deprivation therapy could not be determined because of the paucity of high-quality evidence available for analysis. Side effect profiles were found to be similar, although severity varied among the treatments.[40] Complications from radical prostatectomy include blood loss, stricture formation, incontinence, lymphocele, fistula formation, anesthetic risk, and impotence. Nerve-sparing radical prostatectomy can be performed in many patients; 50% to 80% regain sexual potency within the first year. Although a recent prospective study found that even in patients with good preoperative sexual health, many do not return to baseline after surgery even with the assistance of erectile dysfunction treatments.[41] Acute complications from radiation therapy include cystitis, proctitis, hematuria, urinary retention, penoscrotal edema, and impotence (30% incidence).[27] Chronic complications include proctitis, diarrhea, cystitis, enteritis, impotence, urethral stricture, and incontinence.[27] In addition to possibly intensifying these problems, androgen deprivation can also cause cognitive impairment, mood disturbances, and lack of initiative.[40] Since radiation and prostatectomy have significant and immediate mortality when compared with expectant management alone, many patients may elect to postpone therapy until symptoms develop.

Individuals with T_{2b} and T_{2c} disease or a Gleason score of 7 or a PSA ranging from 10 to 20 ng/mL (10 to 20 mcg/L) are considered at intermediate risk for prostate cancer recurrence.[37] Individuals with less than a 10-year expected survival may be offered expectant management, radiation therapy, or radical prostatectomy with or without a pelvic lymph node dissection, and those with a greater than or equal to 10-year life expectancy may be offered either radical prostatectomy with or without a pelvic lymph node dissection or radiation therapy (Table 139–6).

TABLE 139-6 Management of Prostate Cancer with High and Very High Recurrence Risk

Recurrence Risk	Initial Therapy
High	
T_{3a}, Gleason 8–10, PSA greater than 20 ng/mL (20 mcg/L)	ADT (2–3 years) and radiation therapy, or short-term ADT and radiation therapy for those with a single high risk factor or radical prostatectomy with or without pelvic lymph node dissection
Locally Advanced, Very High	
T_{3b}–T_4	ADT (2–3 years) or radiation therapy + ADT (4–6 months) or radical prostatectomy
Very High	
Any T, N_1	ADT (2–3 years) or radiation therapy + ADT (4–6 months)
Very High	
Any T, Any N, M_1	ADT 2–3 years

ADT= androgen deprivation therapy to achieve serum testosterone levels less than 50 ng/dL (1.7 nmol/L)
LHRH agonist (medical castrations or surgical are equivalent)

The treatment of patients at high risk of recurrence (stage T_3, a Gleason score ranging from 8 to 10, or a PSA value greater than 20 ng/mL [20 mcg/L]) should be treated with androgen ablation for 2 to 3 years combined with radiation therapy (see Table 139–6). Select individuals with a low tumor volume may receive a radical prostatectomy with or without a pelvic lymph node dissection.

Patients with T_{3b} and T_4 disease have a very high risk of recurrence and are not candidates for radical prostatectomy because of extensive local spread of disease.[37] 4 Androgen deprivation therapy with a LH-RH agonist plus an antiandrogen should be used prior to radiation therapy for patients with locally advanced prostate cancer to improve outcomes over radiation therapy alone. Recent evidence suggests that androgen ablation should be instituted at diagnosis rather than waiting for symptomatic disease or progression to occur. In a randomized clinical trial enrolling 500 men with locally advanced prostate cancer who were randomized to either immediate initiation of androgen ablation with either orchiectomy or androgen ablation, or deferred hormonal therapy, individuals with immediate therapy had a median actuarial cause-specific survival duration of 7.5 years for immediate treatment and 5.8 years for deferred treatment.[42]

5 Androgen deprivation therapy, with either orchiectomy, an LH-RH agonist alone, or an LH-RH agonist plus an antiandrogen (combined androgen blockade), can be used to provide palliation for patients with advanced (stage D_2) prostate cancer. Estrogens were once widely used, but the primary estrogen, diethylstilbestrol (DES), was withdrawn from the U.S. market in 1997 due to increased cardiovascular risk. Secondary hormonal manipulations, cytotoxic chemotherapy, or supportive care is used for the patient who progresses after initial therapy.[43]

NONPHARMACOLOGIC THERAPY

Expectant Management

Expectant management, also known as observation or watchful waiting, involves monitoring the course of disease and initiating treatment if the cancer progresses or the patient becomes symptomatic. A PSA and DRE are performed every 6 months, with a repeat biopsy at any sign of disease progression. The advantages of expectant management are avoiding the adverse effects associated with definitive therapies such as radiation and radical prostatectomy, and minimizing the risk of unnecessary therapies. The major disadvantage of expectant management is the risk that the cancer progresses and requires a more intensive therapy.[37]

Orchiectomy

Bilateral orchiectomy, or removal of the testes, is a form of androgen deprivation therapy that rapidly reduces circulating androgens to castrate levels (less than 50 ng/dL [1.7 nmol/L]).[22] However, many patients are not surgical candidates owing to their advanced

age, and other patients find this procedure psychologically unacceptable.[26] Orchiectomy is the preferred initial treatment in patients with impending spinal cord compression or ureteral obstruction.

Radiation

The two commonly used methods for radiation therapy are external beam radiotherapy, and brachytherapy.[37] In external beam radiotherapy, doses of 70–75 Gy (7000–7500 rad) are delivered in 35–41 fractions in patients with low-grade prostate cancer and 75–80 Gy (7500–8000 rad) for those with intermediate or high-grade prostate cancer. Brachytherapy involves the permanent implantation of radioactive beads of 145 Gy (14500 rad) ^{125}Iodine or 124 Gy (12400 rad) of ^{103}Palladium and is generally reserved for individuals with low-risk cancers. Radiation therapy may also be given after surgery in patients with localized disease. In a recent study in men with early-stage prostate cancer, radiation therapy administered after radical prostatectomy was found to reduce the risk of prostate cancer by 29% with a 28% increase in survival.[44]

Radical Prostatectomy

Complications from radical prostatectomy include blood loss, stricture formation, incontinence, lymphocele, fistula formation, anesthetic risk, and impotence. Nerve-sparing radical prostatectomy can be performed in many patients; 50% to 80% regain sexual potency within the first year. Acute complications from radiation therapy include cystitis, proctitis, hematuria, urinary retention, penoscrotal edema, and impotence (30% incidence).[16] Chronic complications include proctitis, diarrhea, cystitis, enteritis, impotence, urethral stricture, and incontinence.[26] Since radiation and prostatectomy have significant and immediate mortality when compared with observation alone, many patients may elect to postpone therapy until symptoms develop.

PHARMACOLOGIC THERAPY

Drug Treatments of First Choice

Luteinizing Hormone-Releasing Hormone Agonists Luteinizing hormone–releasing hormone (LH-RH) agonists are a reversible method of androgen ablation and are as effective as orchiectomy in treating prostate cancer.[45] Currently available LH-RH agonists include leuprolide, leuprolide depot, leuprolide implant, treptorelin depot, treptorelin implant, and goserelin acetate implant. Leuprolide acetate is administered once daily, whereas leuprolide depot and goserelin acetate implant can be administered either once monthly, once every 12 weeks, or once every 16 weeks (leuprolide depot, every 4 months). The leuprolide depot formulation contains leuprolide acetate in coated pellets. The dose is administered intramuscularly, and the coating dissolves at different rates to allow sustained leuprolide levels throughout the dosing interval. Goserelin acetate implant contains goserelin acetate dispersed in a plastic matrix of D, L-lactic and glycolic acid copolymer and is administered subcutaneously. Hydrolysis of the copolymer material provides continuous release of goserelin over the dosing period. A recently approved leuprolide implant is a mini-osmotic pump that delivers 120 mcg of leuprolide daily for 12 months. After 12 months the implant is removed, and a different implant can be placed. Triptorelin LA is administered as an intramuscular injection of 11.25mg every 84 days. Triptorelin depot is 3.75 mg once every 28 days.

Several randomized trials have demonstrated that leuprolide, goserelin, and triptorelin are effective agents when used alone in patients with advanced prostate cancer.[30] Response rates around 80% have been reported, with a lower incidence of adverse effects compared with estrogens.[30] The currently available LH-RH agonists or the dosage formulations have not been directly compared in clinical trials, but a recent meta-analysis showed no significant differences in efficacy or toxicity between leuprolide and goserelin. Triptorelin is a more recent addition but is generally considered equally effective. Therefore the choice between the three agents is usually made based on cost and patient and physician preference for a dosing schedule.

The most common adverse effects reported with LH-RH agonist therapy include a disease flare-up during the first week of therapy, hot flashes, erectile impotence, decreased libido, and injection-site reactions.[30] The disease flare-up is caused by an initial induction of LH and FSH by the LH-RH agonist leading to an initial phase of increased testosterone production, and manifests clinically as either increased bone pain or increased urinary symptoms.[30] This flare reaction usually resolves after 2 weeks and has a similar onset and duration pattern for the depot LH-RH products.[46,47] Initiating an antiandrogen prior to the administration of the LH-RH agonist and continuing for 2 to 4 weeks is a frequently employed strategy to minimize this initial tumor flare.[31]

LH-RH agonist monotherapy can be used as initial therapy, with response rates similar to those for orchiectomy. The incidence of cardiovascular-related adverse effects is lower with LH-RH therapy than with estrogen administration. Patients should be counseled to expect worsening symptoms during the first week of therapy. Appropriate pain and symptom management is required during this period, and a short course of concomitant antiandrogen therapy may need to be considered prior to initiating the LHRH agonist. Caution should be exercised if initiating LH-RH agonist therapy in patients with widely metastatic disease involving the spinal cord or having the potential for ureteral obstruction because irreversible complications may occur.

Another potentially serious complication of androgen deprivation therapy (ADT) is a resultant decrease in bone-mineral density leading to an increased risk for osteoporosis, osteopenia, and an increased risk for skeletal fractures. During initial therapy, bone mineral density of the hip and spine decreases by 2% to 3%.[48] Additionally, ADT has been associated with a 21% to 45% relative increase in fracture risk.[49–51] Therefore, most clinicians recommend that men starting long-term ADT should have a baseline bone mineral density and be initiated on a calcium and vitamin D supplement.[31,37]

Several agents are being tested in clinical trials to prevent bone loss and fractures during ADT therapy. Zoledronic acid, an intravenous bisphosphonate, has been studied in patients receiving ADT at a dose of 4 mg every 3 weeks for 1 year in several randomized trials. Although the use of this agent increases bone mineral density in the spine (3.3% to 5.6%) and hip (0.7% to 1.6%), long-term data regarding the impact on reducing the incidence of fractures are lacking.[52] A promising agent is denosumab, a human monoclonal antibody targeted against receptor activator of nuclear factor-κB ligand (RANKL). In previous studies, denosumab increased bone mineral density at multiple skeletal sites in breast cancer patients receiving aromatase inhibitor therapy.[53] In a large randomized trial, nonmetastatic prostate cancer patients on ADT therapy received denosumab 60 mg subcutaneously every 6 months versus placebo. The results revealed that denosumab increased bone mineral density at all sites and reduced new vertebrae fractures at 36 months (1.5% vs 3.9% with placebo).[54]

ADT has also been associated with a higher incidence of metabolic effects. In a landmark population-based trial, patients treated with ADT and a GnRH agonist were found to have a greater risk of new-onset diabetes, coronary artery disease, and myocardial infarctions.[55] A subsequent study found that concomitant use of ADT and a GnRH agonist was associated with cardiovascular

mortality. However, retrospective studies have shown conflicting results.[56–61] Based on these results, screening for and interventions to prevent and standard medical management to treat cardiovascular disease and diabetes are recommended for patients receiving ADT.[37]

Gonadotropin-Releasing Hormone (GnRH) Antagonists An alternative to LH-RH agonists is the recently approved GnRH antagonist, degarelix. Degarelix works by binding reversibly to GnRH receptors in the pituitary gland, reducing the production of testosterone to castrate levels. The major advantage of degarelix over LH-RH agonists is the rapidity at which it can reduce testosterone levels; castrate levels are achieved in 7 days or less with degarelix, as compared with 28 days with leuprolide, eliminating the tumor flare seen and the need for antiandrogens, with LH-RH agonists.

In a trial of 610 men with advanced prostate cancer, degarelix was shown to be equivalent to leuprolide in lowering testosterone levels for up to 1 year and is FDA-approved for the treatment of advanced prostate cancer. Degarelix is available as a 40 mg/mL and a 20 mg/mL vial for subcutaneous injection, and the starting dose is 240 mg followed by 80 mg every 28 days. The starting dose should be split into two 120 mg injections.[62] Degarelix has not been studied in combination with antiandrogens, and routine use of the combination cannot be recommended.

The most frequently reported adverse reactions were injection site reactions, including pain (28%), erythema (17%), swelling (6%), induration (4%), and nodule (3%). Most were transient and mild to moderate, leading to discontinuation in less than 1% of study subjects. Other adverse effects included elevations in lever function tests, which occurred in approximately 10% of study subjects. Like other methods of androgen supplementation therapy, osteoporosis may develop and calcium and vitamin D supplementation should be considered.[62]

Like degarelix, abarelix is a GnRH antagonist, with the same advantage of reducing testosterone to castrate levels rapidly and avoiding the tumor flare associated with LH-RH agonists. Unfortunately, abarelix is also associated with severe allergic reactions, including syncope and hypotension, which occur in approximately 1% of initial doses and an increased frequency with repeat doses, for an incidence approaching 5% overall. Therefore, abarelix is available only through a restricted distribution program (Plenaxis PLUS Program) and is only indicated for men with advanced prostate cancer who can not tolerate LH-RH agonist therapy and who refuse surgical castration and have one or more of the following: (1) risk of neurological compromise due to metastases, (2) ureteral or bladder outlet obstruction due to local encroachment or metastatic disease, or (3) severe bone pain from skeletal metastases persisting on narcotic analgesia. The recommended dose of abarelix is 100 mg administered intramuscularly to the buttock on days 1, 15, 29 (week 4), and every 4 weeks thereafter.

Antiandrogens Three antiandrogens, flutamide, bicalutamide,[46] and nilutamide,[45] are currently available (Table 139–7). Cyproterone is another agent with antiandrogen activity, but it is not available in the United States. Antiandrogens have been used as monotherapy in previously untreated patients, but a recent meta-analysis determined that monotherapy with antiandrogens is less effective than LH-RH agonist therapy.[47] Therefore, for advanced prostate cancer, all currently available antiandrogens are indicated only in combination with androgen-ablation therapy; flutamide and bicalutamide are indicated in combination with an LH-RH agonist, and nilutamide is indicated in combination with orchiectomy.[43]

The most common antiandrogen-related adverse effects are listed in Table 139–7. In the only randomized comparison of bicalutamide plus an LH-RH agonist versus flutamide plus an LH-RH agonist, diarrhea was more common in flutamide-treated patients. Antiandrogens can reduce the symptoms from the flare phenomenon associated with LH-RH agonist therapy.[31]

TABLE 139-7 Antiandrogens

Antiandrogen	Usual Dose	Adverse Effects
Flutamide	750 mg/day	Gynecomastia Hot flushes Gastrointestinal disturbances (diarrhea) Liver function test abnormalities Breast tenderness Methemoglobinemia
Bicalutamide	50 mg/day	Gynecomastia Hot flushes Gastrointestinal disturbances (diarrhea) Liver function test abnormalities Breast tenderness
Nilutamide	300 mg/day for first month then 150 mg/day	Gynecomastia Hot flushes Gastrointestinal disturbances (nausea or constipation) Liver function test abnormalities Breast tenderness Visual disturbances (impaired dark adaptation) Alcohol intolerance Interstitial pneumonitis

Combined Androgen Blockade Although up to 80% of patients with advanced prostate cancer will respond to initial hormonal manipulation, almost all patients will progress within 2 to 4 years after initiating therapy.[26] Two mechanisms have been proposed to explain this tumor resistance. The tumor could be heterogeneously composed of cells that are hormone-dependent and hormone-independent, or the tumor could be stimulated by extratesticular androgens that are converted intracellularly to DHT. The rationale for combination hormonal therapy is to interfere with multiple hormonal pathways to completely eliminate androgen action. In clinical trials, combination hormonal therapy, sometimes also referred to as maximal androgen deprivation or total androgen blockade, or *combined androgen blockade (CAB)*, has been used. The combination of LH-RH agonists or orchiectomy with antiandrogens is the most extensively studied combined androgen blockade approach.

Many studies comparing CAB with conventional medical or surgical castration have been performed.[35,63,64] In studies with LH-RH agonists, the results have varied, with no consistent benefit demonstrated for CAB. A recently completed National Cancer Institute Intergroup trial involving 1,387 evaluable stage D_2 prostate cancer patients failed to show any significant survival benefits for the combination of orchiectomy plus flutamide over orchiectomy alone.[65] Like other studies of CAB, overall survival was longest in patients with minimal disease. Diarrhea, elevated liver function tests, and anemia were more common in those patients who received flutamide.

A meta-analysis of 27 randomized trials in 8,270 patients (4,803 treated with flutamide, 1,683 treated with nilutamide, and 1,784 treated with cyproterone) comparing CAB with conventional medical or surgical castration showed a small survival benefit at 5 years for those treated with flutamide or nilutamide (27.6%) compared to those with castration alone (24.7%; $P = .0005$).[63]

In one of the few combination androgen-deprivation studies comparing two different antiandrogens (bicalutamide vs. flutamide), the time-to-treatment failure (the main study end point), time-to-progression (as defined by appearance of new or worsening

bone or extraskeletal lesions), and time-to-death were equivalent, suggesting that the two treatments are equally effective.[66]

Although some investigators now consider CAB to be the initial hormonal therapy of choice for newly diagnosed patients, the clinician is left to weigh the costs of combined therapy against potential benefits in light of conflicting results in the randomized trials[43] and the modest benefit seen in the meta-analysis.[63] For those trials that did show an advantage for CAB, whether these effects are specific to the testosterone-deprivation method (orchiectomy vs. leuprolide vs. goserelin), the antiandrogen, the duration of therapy, or patient selection is not clear. Until further carefully designed studies that use survival, time to progression, quality of life, patient preference, and cost as end points are conducted, it is appropriate to use either LH-RH agonist monotherapy or CAB as initial therapy for metastatic prostate cancer. CAB may be most beneficial for improving survival in patients with minimal disease and for preventing tumor flare, particularly in those with advanced metastatic disease. All other patients may be started on LH-RH monotherapy, and an antiandrogen may be added after several months if androgen ablation is incomplete.

CLINICAL CONTROVERSY

The use of CAB is controversial. Meta-analysis shows a small survival advantage when comparing combined androgen blockade to orchiectomy or LH-RH agonist alone. However, this modest benefit is achieved at significant financial cost and with additional toxicities.

It is not clear when to start hormonal-deprivation therapy in patients with advanced prostate cancer.[30] The original recommendation to start therapy when symptoms appeared was based on the Veterans Administration Cooperative Urologic Research Group (VACURG) trials, in which no overall survival difference was demonstrated in patients who either started DES initially or crossed over to active treatment when symptoms appeared; the excess mortality was attributed to estrogen administration.[66] Because LH-RH agonists and antiandrogens are viable therapies with less cardiovascular toxicity, it is not clear whether delaying therapy is justified with these agents. Reanalysis of the original VACURG data[67] and recent combined androgen-deprivation trials[67,68] demonstrate a survival advantage for young, good-performance-status, minimal-disease patients treated initially with hormonal therapy, suggesting that early intervention before symptoms appear may be appropriate.[67] The issue of when best to start hormonal therapy is the subject of several ongoing clinical trials.[67]

CLINICAL CONTROVERSY

Older data, using DES, showed that initiation of hormonal therapy at symptom onset yielded equivalent survival to starting hormonal therapy at initial diagnosis. With equivalent survival, decreased costs, and decreased toxicity from DES, the standard of practice was to delay initiation of hormonal therapy until symptoms developed. The favorable toxicity profile of LH-RH agonists led to the re-evaluation of the starting time for therapy; current research shows that younger men with a good performance status may benefit from initiation of hormonal therapy at diagnosis, rather than waiting for symptoms to develop.

Alternative Drug Treatments

Secondary or salvage therapies for patients who progress after their initial therapy depend on what was used for initial management.[37] For patients initially diagnosed with localized prostate cancer, radiotherapy can be used in the case of failed radical prostatectomy. Alternatively, androgen ablation can be used in patients who progress after either radiation therapy or radical prostatectomy.

Secondary Hormonal Manipulations In patients treated initially with one hormonal modality, secondary hormonal manipulations may be attempted. This may include adding an antiandrogen to a patient who incompletely suppresses testosterone secretion with an LH-RH agonist. In patients that have progression while receiving CAB, withdrawing antiandrogens, or using agents that inhibit androgen synthesis may be attempted. Supportive care, chemotherapy, or local radiotherapy can be used in patients who have failed all forms of androgen-ablation manipulations because these patients are considered to have hormone-refractory prostate cancer.

For patients who initially received an LH-RH agonist alone, castration testosterone levels should be documented. Patients with inadequate testosterone suppression (greater than 20 ng/dL [0.7 nmol/L]) can be treated by adding an antiandrogen or performing an orchiectomy. If castration testosterone levels have been achieved, the patient is considered to have androgen-independent disease, and palliative androgen-independent salvage therapy can be used.

6 Antiandrogen withdrawal, for patients having progressive disease while receiving combined hormonal blockade with an LH-RH agonist plus an antiandrogen, can provide additional symptomatic relief. Mutations in the androgen receptor have been documented that cause antiandrogen compounds to act like receptor agonists.

If the patient initially received combined androgen blockade with an LH-RH agonist with an antiandrogen, then androgen withdrawal is the first salvage manipulation.[37] Objective and subjective responses have been noted following the discontinuation of flutamide,[67] bicalutamide,[68] or nilutamide[69] in patients receiving these agents as part of combined androgen ablation with an LH-RH agonist. Mutations in the androgen receptor have been demonstrated that allow antiandrogens such as flutamide, bicalutamide, and nilutamide (or their metabolites) to become agonists and activate the androgen receptor.[70] Patient responses to androgen withdrawal manifest as significant PSA reductions and improved clinical symptoms. Androgen withdrawal responses lasting 3 to 14 months have been noted in up to 35% of patients, and predicting response seems to be most closely related to longer androgen exposure times.[66] Incomplete cross-resistance has been noted in some patients who received bicalutamide after they had progressed while receiving flutamide.[71] Adding an agent that blocks adrenal androgen synthesis, such as aminoglutethimide, at the time that androgens are withdrawn may produce a better response than androgen withdrawal alone.[70] Because of the potential for response immediately after antiandrogen withdrawal, a sufficient observation and assessment period (usually 4 to 6 weeks) is usually required before a patient can be enrolled on a clinical trial evaluating a new agent or therapy for advanced prostate cancer.

Androgen synthesis inhibitors, such as aminoglutethimide or ketoconazole, can provide symptomatic relief for a short time in approximately 50% of patients with progressive disease despite previous androgen-ablation therapy.[43] Adverse effects during aminoglutethimide therapy occur in approximately 50% of patients.[43] Central nervous system effects that include lethargy, ataxia, and dizziness are the major adverse reactions. A generalized morbilliform, pruritic rash has been reported in up to 30% of patients treated. The rash is usually self-limiting and resolves within 5 to 8 days with continued

TABLE 139-8 First-Line Chemotherapy Regimens for Metastatic Hormone-Independent Prostate Cancer

Regimen	Usual Dose	Adverse Effects	Dose Adjustments
Docetaxel	75 mg/m^2 every 3 weeks	Fluid retention, alopecia, mucositis, myelosuppression, hypersensitivity	Hepatic Aspartate transaminase/Alanine transaminase greater than 1.5 times the upper limit of normal and alkaline phosphatase greater than 2.5 times the upper limit of normal do not administer Hematologic Assure complete blood count recovered
Estramustine	280 mg three times daily days 1–5	Edema, gynecomastia, leucopenia, increased risk of thromboembolic events	Hematologic Assure complete blood count recovered

therapy. Adverse effects from ketoconazole include gastrointestinal intolerance, transient rises in liver and renal function tests, and hypoadrenalism. Ketoconazole is combined with replacement doses of hydrocortisone to prevent symptomatic hypoadrenalism.[43]

Supportive Care After all hormonal manipulations are exhausted, the patient is considered to have androgen-independent disease, also known as hormone-refractory prostate cancer. At this point, either chemotherapy or palliative supportive therapy is appropriate. Palliation can be achieved by pain management, using radioisotopes such as strontium-89[72] or samarium-153 lexidronam[73] for bone-related pain, analgesics, corticosteroids, bisphosphonates,[74] or local radiotherapy.[37]

Skeletal metastases from hematogenous spread are the most common sites of distant spread of prostate cancer. Typically, the bone lesions are osteoblastic or a combination of osteoblastic and osteolytic. Bisphosphonates or denosumab may prevent skeletal-related events and improve bone mineral density. A randomized, controlled trial of zoledronic acid at a dose of 4 mg every 3 weeks reduced the incidence of skeletal-related events by 25% ($P = 0.021$) compared with placebo.[75] The usual dose of pamidronate is 90 mg every month and the usual dose of zoledronic acid is 4 mg every 3 to 4 weeks. Renal function should be monitored as bisphosphonates should not be administered to patients with a CrCl < 30 mL/min (0.5 mL/s).[37] A trial of pamidronate or zoledronic acid can be initiated in prostate cancer patients with bone pain; if no benefit is observed, the drug may be discontinued.[74]

Chemotherapy 7 Chemotherapy with docetaxel and prednisone improves survival in patients with hormone-refractory prostate cancer. Patients with hormone-refractory prostate cancer should be considered for entry into clinical trials investigating new therapies for prostate cancer.

Docetaxel 75 mg/m^2 every 3 weeks combined with prednisone 5 mg twice a day improves survival in hormone-refractory metastatic prostate cancer.[76] The most common adverse events reported with this regimen are nausea, alopecia, and bone marrow suppression. Other adverse effects of docetaxel include fluid retention and peripheral neuropathy. Docetaxel is hepatically eliminated; patients with hepatic impairment may not be eligible for treatment with docetaxel because of an increased risk for toxicity.

The combination of estramustine (280 mg three times a day, days 1–5) and docetaxel 60 mg/m^2 on day 2, every 3 weeks also improves survival in hormone refractory metastatic prostate cancer.[77] Estramustine causes a decrease in testosterone and a corresponding increase in estrogen; therefore, the adverse effects of estramustine include an increase in thromboembolic events, gynecomastia, and decreased libido (Table 139–8). Estramustine is an oral capsule and should be refrigerated. Calcium inhibits the absorption or estramustine. While both the docetaxel/prednisone and the docetaxel/estramustine regimens are effective in hormone refractory prostate cancer, most clinicians prefer the docetaxel/prednisone regimen because of the cardiovascular adverse effects associated with estramustine. In addition, androgen ablation is usually continued when chemotherapy is initiated.[37]

The regimen of mitoxantrone plus prednisone has been shown to be effective in reducing pain from bone metastasis. The effectiveness of mitoxantrone after failure of docetaxel-based therapy has not been evaluated. Many clinicians will treat patients with radiation therapy for palliation of symptoms after failure of docetaxel-based chemotherapy.[37] Cabazitaxel, a new taxane, recently received FDA approval for use with prednisone in the treatment of patients with hormone-refractory metastatic prostate cancer after failure of doxetaxel-based chemotherapy.

Immunotherapy Sipuleucel-T is a novel autologous cellular immunotherapy that was FDA-approved in April 2010 for the treatment of asymptomatic or minimally symptomatic metastatic hormone-refractory prostate cancer. Each patient undergoes leukapheresis on day 1 to collect peripheral blood mononuclear cells, the cellular fraction that includes immune effector cells. These cells are incubated with a prostatic acid phosphatase - granulocyte-macrophage colony-stimulating factor (PAP-GM-CSF) fusion protein; PAP is the specific tumor antigen and GM-CSF is the immune cell activator. The cellular product is then infused intravenously into the patient on day 3 or 4, providing an autologous infusion of activated cells. Each course of sipuleucel-T consists of three infusions of activated cells, given every 2 weeks. In the pivotal trial, sipuleucel-T prolonged median survival by 4.1 months and reduced the risk of death by 22% (HR = 0.78, 95% CI, 0.61-0.98; $P = 0.03$).[78] Adverse effects related to sipuleucel-T were generally mild and nearly all patients were able to receive the entire course (i.e. 3 infusions). A course of sipuleucel-T costs about $93,000, and some insurers have questioned the value of the therapy.

PHARMACOECONOMIC CONSIDERATIONS

The main economic concerns for prostate cancer focus on prostate cancer screening for asymptomatic men, initial therapy of clinically localized disease, surgical vs. medical castration, and the use of combined hormonal blockade as treatment for advanced disease. Unfortunately, the paucity of high-quality evidence to determine the most appropriate therapy reduces the usefulness of economic modeling.

Prostate cancer screening remains highly controversial because the survival benefits and the associated costs are not well defined. Krahn and collegues[79] determined that annual screening of all eligible Canadian men would cost 45 million Canadian dollars, or 0.15% of total health care expenditures. Available cost-utility studies estimate that the cost per crude or quality-adjusted life-year gained from prostate cancer screening ranges from $3,000 to $729,000.[78–82] Since the cost-effectiveness of prostate cancer screening cannot be determined until the benefits are documented, it is important to incorporate economic analysis into the large ongoing screening studies.

Treatment options for clinically localized prostate cancer include radiation therapy, surgery, or watchful waiting. There is currently no evidence to suggest which therapy is the most clinically effective, and treatment choice is often made by patient or physician preference. However, there are large economic differences in the therapies, with the cost of a radical prostatectomy $12,000 more expensive than watchful waiting, and radiation therapy $15,000 more expensive than watchful waiting.[82]

Surgical castration (by removal of the testes) and medical castration with LH-RH agonists yield similar clinical results, although the majority of patients prefer medical castration. In two economic analysis comparisons, the primary cost of the surgical castration was hospital length of stay and medical castration drug costs. Both analyses found that in patients surviving 18 to 24 months, a surgical castration was more cost effective.[81]

Table 139–9 lists the costs for the initial hormonal therapies for stage D_2 prostate cancer. Using a societal perspective and data from the original leuprolide plus flutamide versus leuprolide alone trial to calculate the incremental cost per life-year gained, Hillner and colleagues[80] concluded that CAB has an incremental cost-effectiveness ratio of $25,300 per life-year gained, which is within current accepted benchmarks. The cost dropped to $13,700 per life-year gained in patients with minimal disease.

In a follow-up study, this same group used physician focus group estimates to generate quality-of-life factors and incorporated these factors into an economic model.[82] The incremental cost per quality-adjusted life-year gained seemed reasonable when data from the original CAB were used: $25,000 for patients with minimal disease and $18,000 for patients with severe disease. However, these incremental costs increased dramatically to $53,700 for patients with minimal disease and $41,000 for patients with severe disease when the same model was applied to survival data from a meta-analysis.

Because there is considerable debate about the value of using CAB for advanced prostate cancer, continued economic assessments of this therapy will be crucial to help policymakers and clinicians decide on the most appropriate therapy. It will also become very important to incorporate economic analyses into chemotherapy trials because these efforts move toward including clinical benefit response as a main end point.

A cost report from the United Kingdom National Institute for Health and Clinical Excellence estimated the cost of docetaxel plus prednisone to be approximately $16,800 compared with $8,900 for patients treated with mitoxantrone. Based on the median survival advantage provided by docetaxel, they estimated an incremental cost of $40,000 per life-year gained.[83]

TABLE 139-9 Comparative Costs of Hormonal Therapy for Advanced Prostate Cancer

Drug	Dose	Average Wholesale Price per Month of Therapy
Leuprolide depot	7.5 mg/mo	$781.90
Leuprolide depot	22.5 mg/12 wk	$781.89
Leuprolide depot	30 mg/16 wk	$781.89
Goserelin implant	3.6 mg every 28 days	$451.19
Goserelin implant	10.8 mg/12 wk	$451.19
Flutamide	750 mg/day	$390.79
Bicalutamide	50 mg/day	$523.92
Nilutamide	300 mg/day for first mo then 150 mg/day	$830.28 then $415.14
Combined Androgen Blockade		**Average Wholesale Price per 3 Months of Therapy**
Leuprolide depot 22.5 mg/12 wk		
+ flutamide	750 mg/day	$3,518.03
+ bicalutamide	50 mg/day	$3,917.42
+ nilutamide	150 mg/day	$3,591.08 ($3,175.94 1st month)
Goserelin depot 10.8 mg/12 wk		
+ flutamide	750 mg/day	$2,525.95
+ bicalutamide	50 mg/day	$2,925.34
+ nilutamide	150 mg/day	$2,599.00 ($2,183.86 1st month)

EVALUATION OF THERAPEUTIC OUTCOMES

Monitoring of prostate cancer depends on the stage of the cancer.[33] When definitive, curative therapy is attempted, objective parameters to assess tumor response include assessment of the primary tumor size, evaluation of involved lymph nodes, and the response of tumor markers such as PSA to treatment. PSA may continue to rise before declining, leading to an interruption or discontinuation of therapy. Therefore, treatment decisions are often difficult, and more research about end points is needed to facilitate prostate cancer treatment, continued enrollment in clinical trials, and drug development.[84] Following definitive therapy, the PSA level is checked every 6 months for the first 5 years, then annually. Local recurrence in the absence of a rising PSA may occur, so the DRE is also performed. In the metastatic setting, clinical benefit responses can be documented by evaluating performance status changes, weight changes, quality of life, and analgesic requirements, in addition to the PSA or DRE at 3-month intervals.

ABBREVIATIONS

ACS: American Cancer Society
ADT: Androgen deprivation therapy
AUS: American Urologic System
BPH: benign prostatic hyperplasia
CAB: combined androgen blockade
DES: diethylstilbestrol
DHT: dihydrotestosterone
DRE: digital rectal examination
EGF: epidermal growth factor
FSH: follicle-stimulating hormone
IGF-1: insulin-like growth factor
LH: luteinizing hormone
LH-RH: luteinizing hormone–releasing hormone
NCCN: National Comprehensive Cancer Network
NCI: National Cancer Institute
PCPT: Prostate Cancer Prevention Trial
PSA: prostate-specific antigen
TRUS: transrectal ultrasound
VACURG: Veterans Administration Cooperative Urologic Research Group

CHAPTER 140

Lymphomas

ALEXANDRE CHAN AND GARY C. YEE

KEY CONCEPTS

1. Patients with Hodgkin lymphoma present with a painless, rubbery lymph node, which most commonly resides in the neck (cervical or supraclavicular nodes).
2. Patients with early-stage Hodgkin lymphoma should be treated with combination chemotherapy with or without involved-field radiation
3. Combination chemotherapy with doxorubicin (Adriamycin), bleomycin, vinblastine, and dacarbazine (ABVD) is the primary treatment for patients with advanced-stage Hodgkin lymphoma. Patients with advanced unfavorable disease may be treated with more aggressive regimens that have greater activity, but are associated with a higher risk of secondary malignancies.
4. Some patients with Hodgkin lymphoma will be refractory to initial therapy or will have a recurrence following a complete remission. Response to salvage therapy depends on the extent and site of recurrence, previous therapy, and duration of initial remission. High-dose chemotherapy and autologous hematopoietic stem cell transplantation should be considered in patients with refractory or relapsed disease.
5. The current classification system for non-Hodgkin lymphoma is the World Health Organization classification system, which is based on the principle that non-Hodgkin lymphomas can be classified into specific disease entities, defined by a combination of morphology, immunophenotype, genetic features, and clinical features.
6. As compared with Hodgkin lymphoma, the clinical presentation of non-Hodgkin lymphoma is more variable because of disease heterogeneity and more frequent extranodal involvement.
7. The Ann Arbor staging system correlates poorly with prognosis in non-Hodgkin lymphoma because the disease does not spread through contiguous lymph nodes and often involves extranodal sites.
8. Several prognostic models have been developed to estimate prognosis in patients with non-Hodgkin lymphoma. The International Prognostic Index (IPI) score is a well-established model for patients with aggressive non-Hodgkin lymphoma. The Follicular Lymphoma International Prognostic Index (FLIPI) is a similar model used for patients with follicular and other indolent lymphomas.
9. The clinical behavior and degree of aggressiveness can be used to categorize non-Hodgkin lymphoma into indolent and aggressive lymphomas. Patients with an indolent lymphoma usually have a relatively long survival, with or without aggressive chemotherapy. Although these lymphomas respond to a wide range of therapeutic approaches, few if any of these patients are cured of their disease. In contrast, aggressive lymphomas are rapidly growing tumors and patients have a short survival if appropriate therapy is not initiated. Most patients with aggressive lymphomas respond to intensive chemotherapy and many are cured of their disease.
10. Patients with localized follicular lymphoma can be cured with radiation therapy alone. Advanced follicular lymphoma is not curable, and there are many treatment options, including watchful waiting, extended-field radiation therapy, single-agent alkylating agents, anthracycline-containing combination chemotherapy, purine analogs, interferon-α, anti-CD20 monoclonal antibodies, and high-dose chemotherapy with hematopoietic stem cell transplantation.
11. Patients with localized aggressive lymphomas can be cured with several cycles of R-CHOP (rituximab, cyclophosphamide, doxorubicin, Oncovin, prednisone) chemotherapy and involved-field irradiation. Patients with bulky stage II, stage III, or stage IV aggressive lymphomas can be cured of their disease with R-CHOP chemotherapy.
12. Conventional-dose salvage therapy can induce responses in patients with aggressive lymphomas who relapse, but long-term survival and cure is uncommon. Some patients with aggressive lymphoma who relapse and respond to salvage therapy can be cured with high-dose chemotherapy and autologous hematopoietic stem cell transplantation.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Lymphomas are a heterogeneous group of malignancies that arise from malignant transformation of immune cells that reside predominantly in lymphoid tissues. They most commonly present as a solid tumor, but can sometimes present as circulating tumor cells in peripheral blood. The differing histology of lymphoma cells has led to classification of Hodgkin lymphoma (Reed–Sternberg cells) or non-Hodgkin lymphoma (B- or T-cell lymphocyte markers). Non-Hodgkin lymphomas (NHLs) are further classified into distinct clinical entities, which are defined by a combination of morphology, immunophenotype, genetic features, and clinical

features. Chemotherapy is the mainstay of treatment in patients with lymphoma, especially those with widespread disease. Overall cure rates are high for many subtypes of lymphomas, even when patients present with advanced disease.

HODGKIN LYMPHOMA

Hodgkin lymphoma is a form of lymphoma, named after Thomas Hodgkin who first described seven cases of a mysterious disease of the lymph system over 150 years ago. Hodgkin lymphoma is fatal in more than 90% of the patients who are untreated for two to three years, and the cause is still unknown. The prognosis with treatment is generally good, but is not well predicted by stage alone. The International Prognostic Score was created to better predict an individual's risk of recurrence, which in turn influences treatment decisions. Patients with Hodgkin lymphoma can be categorized into four prognostic groups: early favorable disease, early unfavorable disease, advanced favorable disease, and advanced unfavorable disease. These groups are defined by patient age, gender, tumor size and spread (tumor stage), presence or absence of systemic symptoms, and laboratory test results. When appropriate therapy is given, more than 75% of all newly diagnosed Hodgkin lymphoma patients can be cured. However, the success of treatment has not been without cost. The treatment programs are intense, technically demanding, and associated with considerable acute toxicity and long-term complications. The long-term effects, particularly secondary malignancies, account for a higher cumulative mortality than Hodgkin lymphoma 15 to 20 years after treatment. Long-term toxicities with standard chemotherapy regimens have been more fully documented in recent years and are shaping future therapies.[1–3]

EPIDEMIOLOGY AND ETIOLOGY

Hodgkin lymphoma represents less than 1% of all known cancers in the United States. It is estimated that 8,490 new cases of Hodgkin lymphoma will be diagnosed in the United States in 2010, and there will be 1,320 deaths associated with Hodgkin lymphoma during this same period.[4] This disease occurs slightly more frequently in males than in females. Once thought to be a disease of the young, it is now recognized that Hodgkin lymphoma exhibits bimodal distribution in industrialized countries. The first peak occurs in the third decade of life, with a small peak occurring after age 50.[2,3] The five-year overall survival for all stages of Hodgkin lymphoma is approximately 85%.[5] Death rates as a consequence of recurrent Hodgkin lymphoma are less than those from other causes 15 years after treatment.[6]

The etiology of Hodgkin lymphoma is currently unknown but there is laboratory evidence to support infectious exposure as a potential cause.[7,8] Studies suggest an increased risk of Hodgkin lymphoma in patients who have been infected with the Epstein-Barr virus (EBV); and many patients experience EBV activation even before the onset of Hodgkin lymphoma. EBV is found in approximately 40% of all classical Hodgkin lymphoma cases, and it is frequently observed in cases of mixed cellularity and lymphocyte-depleted Hodgkin lymphoma.[9] Reed–Sternberg cells (large, bilobate, multinuclear cells), the malignant cells in Hodgkin lymphoma, are linked to EBV. Immunosuppressed individuals are also at much higher risk to develop Hodgkin lymphoma. Such individuals include patients with congenital immunosuppression, solid-organ transplantation recipients, and human immunodeficiency virus (HIV)-infected patients. Although the risk of developing Hodgkin lymphoma is approximately sevenfold greater in patients with HIV, the level of CD4 may vary depending on the subtype of Hodgkin lymphoma.[8]

Genetic factors are also shown to be associated with an increased risk of Hodgkin lymphoma. The strongest evidence suggesting that genes are important in the etiology of Hodgkin lymphoma comes from identical twin studies, which show that the unaffected identical twin has almost a 100-fold increase in risk.[10]

PATHOPHYSIOLOGY

Hodgkin lymphoma is a clonal malignant lymphoid disease of transformed lymphocytes. The malignant cell in Hodgkin lymphoma is known as the *Reed–Sternberg* cell named after Drs. Dorothy Reed and Carl Sternberg, who were credited with the first definitive microscopic description of Hodgkin lymphoma.[2,3,11] Procedures to isolate and analyze Reed–Sternberg cells remain a challenge to scientists, due to the relatively small percentage (1% to 2%) of Reed–Sternberg cells that are found in the Hodgkin lymphoma mass.[9] Fortunately, new laboratory techniques have led to significant progress in identifying the origin of the Reed–Sternberg cell. Single-cell polymerase chain reaction and DNA microarray analyses indicate that nearly all classic Hodgkin lymphoma cases and all nodular lymphocyte-predominant Hodgkin lymphomas have immunoglobulin gene rearrangements, which indicates a germinal center or postgerminal center B-cell origin (Table 140–1).[9,12] Interestingly, nearly all Reed–Sternberg cells fail to express B-cell specific cell surface proteins.

B-cell transcriptional processes are disrupted during malignant transformation, which prevents B-cell surface marker expression and production of immunoglobulin messenger ribonucleic acid. The normal cellular consequence of failure to express immunoglobulin is apoptosis, but because of alterations in the normal apoptotic pathways, cell survival and proliferation are favored. Reed–Sternberg cells overexpress nuclear factor-κB, which is associated with cell proliferation and antiapoptotic signals. Infections with viral and bacterial pathogens upregulate nuclear factor-κB and consequently are hypothesized to be involved with the etiology of Hodgkin lymphoma.[2,9,12] This hypothesis is supported by the presence of EBV in many Hodgkin lymphoma tumors, but it is important to note that not all tumors are associated with EBV. Another signaling pathway, Janus Kinase–signal transduction and transcription (JAK–STAT), has also been found to be active in Hodgkin lymphoma.[2,9] As molecular techniques continue to improve, our understanding of the pathophysiology of Hodgkin lymphoma will also improve.

The histopathologic classification of Hodgkin lymphoma has undergone numerous changes over the last three decades. The

current classification system is the 2008 World Health Organization (WHO) classification (Table 140–2).[13] This classification divides Hodgkin lymphoma into two major groups: classical Hodgkin lymphoma and nodular lymphocyte-predominant Hodgkin lymphoma, which constitute approximately 95% and 5% of cases, respectively. Classic Hodgkin lymphoma is further divided into four subtypes: nodular sclerosis, mixed cellularity, lymphocyte-depletion, and lymphocyte-rich. The subtypes in these classifications are based on characteristics of the Reed–Sternberg cell, the surrounding cells, and the connective tissue. Nodular sclerosis has features that make it distinct from the other three subtypes, which represent a continuum of background cellularity, with lymphocyte-predominance being the most cellular and lymphocyte-depletion being the least cellular. Nodular lymphocyte-predominant Hodgkin lymphoma is separated because of its distinct immunophenotype: $CD15^-$, $CD20^+$, $CD30^-$, and $CD45^+$ (the opposite of classical Hodgkin lymphoma). With the introduction of extensive staging, sophisticated radiotherapy, and effective combination chemotherapy, the prognostic value of these subtypes is becoming less clear. The true value of understanding these subtypes is likely tied to the pathogenesis of the disease and its potential prevention in the future.

CLINICAL PRESENTATION

1 Most patients with Hodgkin lymphoma present with a painless, rubbery, enlarged lymph node in the supradiaphragmatic area and commonly have mediastinal nodal involvement.[14] Hodgkin lymphoma is occasionally diagnosed in an asymptomatic patient who has a mediastinal mass found with chest radiography or another imaging procedure. Asymptomatic adenopathy of the inguinal and axillary regions may be present at diagnosis but is less common (Fig. 140–1).[2] Patients can also present with constitutional symptoms (B symptoms) before the discovery of lymph node enlargement, and these symptoms include fever, drenching night sweats, and weight loss. At diagnosis, these symptoms may appear in approximately 25% of all patients and up to 50% of patients with advanced disease. Patients may also experience other nonspecific symptoms including pruritus, fatigue, and development of pain after alcohol consumption at sites where nodes are involved.[3] Extranodal manifestations, such as bowel and hepatic involvements, are much less common in Hodgkin lymphoma than non-Hodgkin lymphoma.[2]

DIAGNOSIS, STAGING, AND PROGNOSTIC FACTORS

Diagnostic and staging procedures are based on recommendations made at the Ann Arbor and Cotswolds conferences and new scientific advances, as described in the National Comprehensive Cancer Network (NCCN) guidelines.[15] The diagnosis and pathologic classification of Hodgkin lymphoma can only be made by review of a biopsy (preferably an excisional biopsy) of the enlarged node by an expert hematopathologist.

In addition to a careful physical examination and routine laboratory tests, chest radiography and computed tomography (CT) scans of the chest, abdomen, and pelvis are routinely performed.

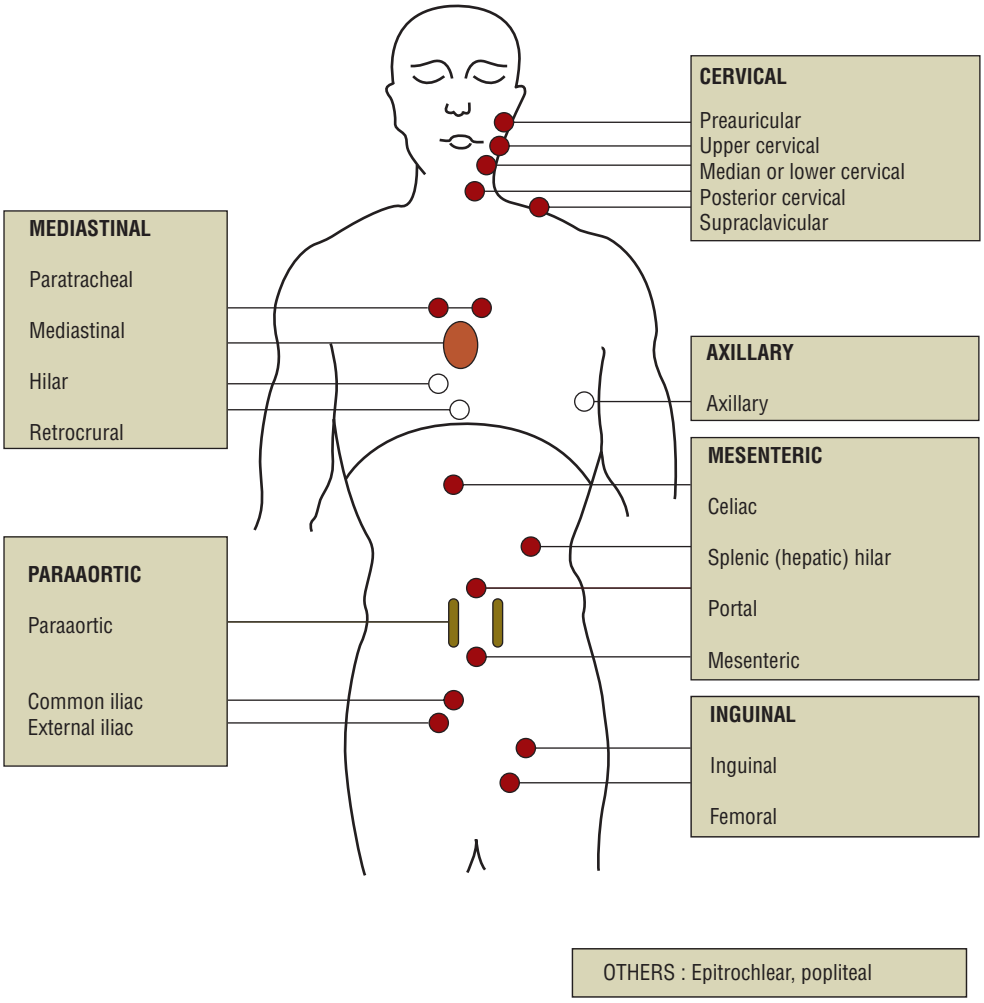

FIGURE 140-1. Areas of lymph nodes used in the staging of Hodgkin and non-Hodgkin lymphoma. Each rectangle corresponds to a nodal area. *(This research was originally published and modified from Blood. Solal-Celigny P, Roy P, Colombat P, et al. Follicular lymphoma international prognostic index. Blood 2004;104:1258–1265. Copyright © American Society of Hematology.)*

Furthermore, positron emission tomography (PET) plays an important role in the initial staging of Hodgkin lymphoma, as it has shown high sensitivity and specificity in the staging of the disease.[16] The use of integrated PET-CT has further improved the staging of Hodgkin lymphoma given that it can provide more sensitive and specific imaging as compared with each imaging alone. Currently, the NCCN guideline recommends either an integrated PET-CT scan (preferred) or a PET scan with diagnostic CT for initial staging.[15] Bone marrow biopsy is also recommended in patients with advanced-stage disease.

Staging can be based on clinical or pathologic findings. The clinical stage is based on all non-invasive procedures (history, physical examination, laboratory tests, and radiologic findings), whereas the pathologic stage is based on the biopsy findings of strategic sites (muscle, bone, skin, spleen, and abdominal nodes) with an invasive procedure such as a laparoscopy or laparotomy. Patients with extranodal disease (muscle, skin, bone, or Waldeyer ring) contiguous to involved nodes are classified with the subscript "E" in the Cotswolds staging system.[3,15] As a result of improved imaging techniques, pathologic workup and staging that can be associated with toxicity is rarely performed.

The Ann Arbor staging classification, which was developed at the 1970 Ann Arbor conference, has proven to be a good workable scheme. At the Cotswolds meeting in 1989, the Ann Arbor classification was modified to account for new diagnostic techniques (e.g., CT and magnetic resonance imaging), and the understanding that prognosis is associated with the bulk of the disease and the number of involved nodal sites (Table 140–3).[3] After careful staging, about one

TABLE 140-3 The Cotswolds Staging Classification of Hodgkin Lymphoma

Stage I	Involvement of a single lymph node region or structure (I) or of a single extralymphatic organ or site (I_E)
Stage II	Involvement of two or more lymph node regions on the same side of the diaphragm (II) or localized involvement of an extralymphatic organ or site and of one or more lymph node regions on the same side of the diaphragm (II_E). The number of nodal regions involved should be indicated by a subscript (e.g., II_2)
Stage III	Involvement of lymph node regions on both sides of the diaphragm (III), which may also be accompanied by localized involvement of an extralymphatic organ or site (III_E) or by involvement of the spleen (IIIS) or both ($IIIS_E$). III_1: with or without splenic, hilar, celiac, or portal node involvement. III_2: with paraaortic, iliac, or mesenteric node involvement
Stage IV	Diffuse or disseminated involvement of one or more extralymphatic organs or tissues with or without associated lymph node enlargement
	A–No symptoms
	B–Fever, night sweats, weight loss (>10%)
	X–Bulky disease
	>One-third the width of the mediastinum
	>10 cm maximal dimension of nodal mass
	E–Involvement of extralymphatic tissue on one side of the diaphragm by limited direct extension from an adjacent, involved lymph node region
	S–Involvement of the spleen
	CS–Clinical stage
	PS–Pathologic stage

half of patients have localized disease (stages I, II, and II$_E$) and the remainder have advanced disease (stage III or IV). Approximately 10% to 15% present with metastatic disease (stage IV). It is important to note that Hodgkin lymphoma appears to follow a predictable pattern of nodal spread that is not seen with the NHLs.[14,15]

Patient prognosis is predominately driven by age and tumor stage. Patients older than ages 65 to 70 have a lower cure rate than younger patients. The difference in cure rates may be related to the high rate of comorbid diseases and decreased organ function, which impairs the patient's ability to tolerate intensive chemotherapy.[17] Stage is the other dominant factor in predicting survival; patients with limited-stage disease (stages I to II) have a 90% to 95% cure rate, whereas those with advanced disease (stages III to IV) have only a 60% to 80% cure rate.[3,15]

Seven adverse prognostic factors with similar impact on survival (each factor reduced survival by 7% to 8% per year) have been identified through an international collaborative effort. These factors can be combined to generate an International Prognostic Score (IPS) that can be used to predict progression-free and overall survival (Table 140–4).[18]

TREATMENT

Hodgkin Lymphoma

The current goal in the treatment of Hodgkin lymphoma is to maximize curability while minimizing short- and long-term treatment-related complications. According to the SEER database, the five-year age-adjusted relative survival is greater than 80%.[5] Therefore, the treatment goal of all stages of Hodgkin lymphoma should be cure.

Although multiple treatment modalities are used to treat Hodgkin lymphoma, surgery has a limited therapeutic role regardless of stage. It is, however, important for diagnosis (excisional biopsy), and on certain occasions, such as placement of a central line.

Combination chemotherapy is the primary treatment modality for most patients with Hodgkin lymphoma. In general, patients with early-stage Hodgkin lymphoma are treated with combination chemotherapy and radiation, whereas patients with advanced-stage disease are treated with combination chemotherapy with or without radiation therapy. For patients with refractory or recurrent disease, salvage therapy consists of multiagent chemotherapy with or without high-dose chemotherapy and autologous hematopoietic stem cell transplantation (HSCT), which can be curative.[2,3,19]

Radiation is often an integral part of the treatment plan. Selected patients with early-stage disease (usually nodular lymphocyte-predominant histology) can receive radiation as the only treatment modality, whereas most patients will receive chemotherapy and radiation. Although radiation is a local therapy, many patients with advanced disease will also receive radiation therapy to residual or bulky disease sites after chemotherapy. The major concern with radiation therapy is its long-term effects, such as cardiovascular disease and secondary malignancies, which commonly occur in the lung, breast, gastrointestinal tract, and connective tissue.[20] To avoid these toxicities, several studies have been completed and others are ongoing to determine the optimal extent (radiation field) and dose of radiation.[21] Radiation to a single field that contains Hodgkin lymphoma is called *involved-field radiation*; radiation to the involved field and a second uninvolved area is termed *extended-field radiation* or *subtotal nodal irradiation*; and radiation of all areas is called *total nodal irradiation*.[22] When given with chemotherapy (the most common scenario), involved-field radiation is usually used to avoid the increased toxicity associated with extended-field radiation.[21] The following sections review treatment of early-stage favorable disease, early-stage unfavorable disease, advanced-stage favorable disease, advanced-stage unfavorable disease, and salvage therapy.

TREATMENT OF EARLY-STAGE FAVORABLE DISEASE

Patients with early-stage favorable disease have stage IA or IIA disease and no adverse risk factors (extranodal disease, bulky disease, three or more sites of nodal involvement, or an erythrocyte sedimentation rate of ≥50 mm/h [≥13.9 µm/s]). In the past, extended-field radiation was considered to be the treatment of choice for stages IA and IIA disease. This treatment strategy produces disease-free survival rates ranging from 65% to 85% and overall survival rates ranging from 75% to 93%. However, there is a potential for long-term toxicities due to large radiation fields, such as increased risk for heart disease, pulmonary dysfunction, and secondary malignancies.[3,23]

In an effort to avoid the long-term effects of extended-field radiation and improve treatment results, several studies have evaluated a combined modality approach that involves the use of short-duration chemotherapy and involved-field radiation. Based on favorable results of these studies, most patients with early-stage favorable disease are no longer treated with radiation alone.[21,23,24]

Clinical trials comparing radiation alone to radiation plus chemotherapy show lower relapse rates in patients treated with combined modality therapy (radiation and chemotherapy), but no change in overall survival.[21] Current trials focus on questions such as the optimal number of chemotherapy cycles and the volume of radiation that must be used to obtain optimal patient outcomes. Emerging data also suggests that as few as two cycles of chemotherapy followed by involved-field radiation is sufficient in favorable, early-stage disease patients. Different combination chemotherapy regimens have been used in these studies, and no one regimen is clearly superior to another.[21,23]

The current NCCN guidelines recommend that patients with early-stage favorable disease be treated with two cycles of the Stanford V regimen (doxorubicin, vinblastine, mechlorethamine, etoposide, vincristine, bleomycin, and prednisone) or four cycles of the ABVD (doxorubicin [Adriamycin], bleomycin, vinblastine, and dacarbazine) regimen, followed by consolidative involved-field radiation.[15] With this approach, five-year progression-free and overall survival rates of >90% can be achieved.

Nodular lymphocyte-predominant Hodgkin lymphoma has been described as more indolent in nature, and better prognosis can be achieved when compared with classic Hodgkin lymphoma. The use of radiation alone for nodular lymphocyte-predominant Hodgkin lymphoma patients who choose to omit chemotherapy, or who cannot tolerate chemotherapy, does not appear to adversely affect survival.[15] The disadvantage of radiation therapy alone as compared with combination chemotherapy and radiation is the higher relapse rate. The lack of difference in survival rates is a result of the fact that patients who relapse after radiation alone (20% to 25%) can be successfully salvaged with chemotherapy. If the decision is made to use radiation alone, extended-field radiation appears to be superior to involved-field radiation.[25] It is shown that more extensive radiation reduces the risk of treatment failure at ten years (31% vs. 43%), although it does not improve ten-year overall survival. However, the risk of long-term complications (such as secondary malignancies) is increased with the use of extended-field radiotherapy when compared with less extensive radiation fields.

TREATMENT OF EARLY-STAGE UNFAVORABLE DISEASE

Patients with early-stage disease who have certain features associated with a poor prognosis (B symptoms, extranodal disease, bulky disease, three or more sites of nodal involvement, or an erythrocyte sedimentation rate >50 mm/h [≥13.9 μm/s]) are defined as having unfavorable disease. Current guidelines recommend combined modality therapy (combination chemotherapy and involved-field radiation) to reduce the relapse rate and avoid the toxicity associated with extended-field radiation.[15]

2 Although randomized trials show that combined modality therapy reduces the relapse rate in patients with early-stage unfavorable disease, questions concerning the appropriate radiation volume, most effective chemotherapy regimen, and number of chemotherapy cycles remain.[23] A number of studies have compared extended-field radiation to involved-field radiation. In one large trial conducted by the German Hodgkin Study Group (GHSG), patients with early-stage unfavorable Hodgkin lymphoma treated with chemotherapy and involved-field radiation had similar freedom from treatment failure and overall survival as those treated with the same chemotherapy regimen and extended-field radiation.[26] Because toxicity was greater with extended-field radiation, the accepted standard is chemotherapy and involved-field radiation.

Different chemotherapy regimens and number of chemotherapy cycles were also compared in clinical trials. Mechlorethamine, vincristine, procarbazine, and prednisone (MOPP) was one of the first highly effective regimens introduced to treat Hodgkin lymphoma. MOPP or MOPP-like regimens were then given alternately or hybridized with a combination of ABVD. In advanced disease, ABVD was found to be less toxic than alternating MOPP/ABVD, and both were found to be superior to MOPP alone. Consequently, ABVD has now become the standard regimen used to treat patients with early-stage unfavorable disease. It has established effectiveness in patients with advanced-stage disease and a favorable toxicity (both acute and chronic) profile.

Despite excellent results from treatment with ABVD and radiation, approximately 5% of patients do not respond to initial treatment and another 15% of patients will relapse following an initial response. Several studies have evaluated more aggressive regimens or more cycles of therapy. However, none of these regimens has proven to be more effective than ABVD, and each is associated with more toxicity. The current NCCN guideline lists the Stanford V regimen as an acceptable option, which also uses more drugs than the ABVD regimen.[15]

In summary, most patients with early-stage disease will be treated with two to four cycles of ABVD chemotherapy and involved-field radiation. The number of cycles administered is based on the classification of favorable versus unfavorable disease. For patients who have unfavorable disease, six cycles of ABVD are recommended when radiation is completely omitted.[15] Although this approach results in excellent outcomes, studies are still ongoing to maximize the efficacy in this regimen while minimizing acute and long-term toxicity.

TREATMENT OF ADVANCED-STAGE DISEASE

Advanced-stage disease consists of stages III and IV disease. In some studies, stage IIB with a large mediastinal mass or extranodal disease is also considered advanced-stage disease (Table 140–3). By definition, patients with stages III and IV disease have tumors on both sides of the diaphragm, which almost always precludes the use of radiation alone as a therapeutic modality. Intensive combination chemotherapy is the mainstay of treatment, although some patients will benefit from radiation following chemotherapy. The prognosis of advanced-stage disease is excellent with five-year overall survival rates ranging from less than 56% to 90%. Prognostic factors have been identified and standardized to provide a more accurate individual prognosis (Table 140–4).[18]

Combination Chemotherapy

One of the initial combination chemotherapy regimens introduced in the early 1960s that was shown to cure advanced Hodgkin lymphoma was the MOPP regimen (Table 140–5). MOPP chemotherapy was a mainstay of treatment for patients with stages III and IV advanced Hodgkin lymphoma. It produced complete remissions in 84% of patients and has a ten-year cure rate of 54%.[27]

Ever since MOPP therapy was introduced and its efficacy confirmed, researchers have tried to modify the regimen in an attempt to improve efficacy and decrease toxicity.[19] Some MOPP variations, including MVPP (vinblastine substituted for vincristine), CVPP (cyclophosphamide substituted for mechlorethamine), and ChlVPP (chlorambucil substituted for mechlorethamine, and vinblastine substituted for vincristine) were attractive alternatives to MOPP because they offered equal efficacy and differing or less severe toxicities.

3 The development of ABVD by Bonnadonna et al. at the Milan Cancer Institute approximately a decade later represents the next important step in the evolution of therapy for Hodgkin lymphoma (Table 140–5). ABVD was initially shown to be effective in treating MOPP failures and was later compared directly to MOPP in advanced disease, where it produced an 82% complete response rate, as compared to a 67% complete response rate with MOPP. Improved failure-free survival was demonstrated with ABVD, but no significant differences in five-year overall survival were noted.[28] Since ABVD was less toxic and provided similar or better outcomes than MOPP, it eventually replaced MOPP as the standard regimen for advanced-stage Hodgkin lymphoma.[3]

In the early 1980s, the Goldie–Coldman hypothesis proposed that chemotherapy resistance was related to spontaneous mutation rates and the development of resistant clones. To test that hypothesis, researchers designed several clinical trials to evaluate the efficacy of alternating non–cross-resistant drug combinations in patients with Hodgkin lymphoma.[29] The initial approach adopted by investigators was to alternate or combine the MOPP and ABVD regimens. When MOPP and ABVD (or ABV) are combined in a monthly cycle, it is referred to as a hybrid regimen. Besides a potential benefit in efficacy, another potential benefit of alternating or

TABLE 140-5 Combination Chemotherapy Regimens for Hodgkin Lymphoma

Drug	Dosage (mg/m²)	Route	Days
MOPP			
Mechlorethamine	6	IV	1, 8

hybrid regimens is the decreased risk of long-term toxicities. In the alternating MOPP/ABVD regimen, the cumulative doses of procarbazine and mechlorethamine are reduced by 50% and the cumulative doxorubicin dose is reduced by 50%. In the hybrid regimen, the cumulative doxorubicin dose is reduced by 33% and the cumulative bleomycin dose is reduced by 50%.

Several clinical trials have been performed to evaluate the efficacy of alternating or hybrid MOPP/ABVD regimens. The results of these trials show that alternating and hybrid regimens are superior to MOPP but not to ABVD.[28] Another approach adopted by researchers was the administration of sequential cycles of MOPP and ABVD (MOPP → ABVD). Results of an intergroup trial showed sequential MOPP and ABVD to be inferior to the MOPP/ABV hybrid regimen in terms of response and survival.[30] In another randomized comparison trial of the MOPP/ABV hybrid regimen and ABVD, the complete remission rate, failure-free survival, and overall survival were similar between the two regimens.[31] The latter trial was closed prematurely because of an increased number of treatment-related deaths and secondary malignancies in the patients who received the MOPP/ABV hybrid regimen.

More aggressive regimens such as Stanford V and BEACOPP have been evaluated as alternatives to MOPP or ABVD.[19] The Stanford V regimen generated significant interest because of the results of

phase II trials.[23,32] Stanford V, ABVD, and a MOPP/ABV hybrid-like regimen (MOPPEBVCAD) were compared in a randomized trial to determine the best regimen to support a reduced radiotherapy program.[33] Five-year failure-free and progression-free survival were significantly worse for the Stanford V regimen as compared to the other two regimens. However, no significant differences in projected five-year progression-free and overall survival were observed between Stanford V and ABVD in a recently published randomized trial of patients with advanced Hodgkin lymphoma.[34] The investigators speculated that differences in the application of radiotherapy may explain the divergent results in the two randomized trials. More pulmonary toxicity occurred in the ABVD group, but other toxicities occurred more frequently in the Stanford V group.

The GHSG developed the BEACOPP regimens based on principles of dose density, dose intensity, and mathematical modeling. BEACOPP uses similar drugs as in the COPP/ABVD regimen (a combination of bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone), but rearranges the drugs in a shorter three-week cycle. Several different versions of BEACOPP have been developed: standard-dose BEACOPP, escalated-dose BEACOPP, and dose-dense BEACOPP (BEACOPP-14).[35] Granulocyte colony-stimulating factor support is required for the escalated-dose BEACOPP and BEACOPP-14 regimens.

Several randomized trials have compared BEACOPP to other regimens.[3,19] The GHSG conducted a randomized comparison of COPP/ABVD (alternating), BEACOPP, or an escalated-dose BEACOPP regimen in 1,201 patients with advanced Hodgkin lymphoma.[36] Most patients had advanced favorable disease and after chemotherapy, all patients received radiation to sites of bulky or residual disease. Escalated-dose BEACOPP appears to be the best regimen in this study with ten-year freedom from treatment failure at 82% and overall survival at 86%, but this regimen also appeared to be more toxic.[37] Despite filgrastim support, 90% of patients in the escalated-dose BEACOPP group had grade IV leukopenia, as compared with 19% in patients in the COPP/ABVD arm and 37% in the standard-dose BEACOPP arm. The higher rate of acute toxicity did not translate into a difference in acute treatment-related fatalities (<2% for all three regimens). The risk of toxic deaths due to sepsis or acute cardiac events was higher in elderly patients receiving BEACOPP.[38] Furthermore, the higher rates of leukemia among patients receiving escalated-dose BEACOPP (2.5% at 5 years follow up, and 3% at 10 years followup) as compared with those in the COPP/ABVD arm (0.4%) are of concern. Some experts recommend that these more intensive regimens should only be considered in patients with high-risk disease because of the potentially higher risk of secondary malignancies.

In a recently published study, the HD2000 trial compared three regimens in the treatment of advanced Hodgkin lymphoma: ABVD, BEACOPP, and CEC (cyclophosphamide, lomustine, vindesine, melphalan, prednisone, epirubicin, vincristine, procarbazine, vinblastine, bleomycin).[39] In this study, 370 patients were randomized to receive six cycles of ABVD, six cycles of CEC, or four cycles of escalated-dose BEACOPP with two cycles of standard-dose BEACOPP. The results of this trial showed that BEACOPP was superior to ABVD for five-year failure-free survival (78% vs. 65%, $P = 0.036$) and progression-free survival (81% vs. 68%, $P = 0.038$). However, five-year overall survival was not significantly different between ABVD and BEACOPP. It appears that BEACOPP may be superior to ABVD in patients with high-risk advanced Hodgkin lymphoma (IPS ≥3). Higher rates of neutropenia and severe infections were observed with BEACOPP as compared with ABVD. Further data is needed to determine whether BEACOPP is superior to ABVD in the treatment of advanced Hodgkin lymphoma.

CLINICAL CONTROVERSY

Some clinicians believe that escalated-dose BEACOPP is superior to ABVD in the treatment of patients with advanced-stage Hodgkin lymphoma. Escalated-dose BEACOPP has been shown to be superior to COPP/ABVD, which is similar to MOPP/ABVD. Other experts believe that ABVD is still the treatment of choice because escalated-dose BEACOPP has not been tested directly against it. They also express concern over the long-term toxicity with escalated-dose BEACOPP.

Risk-Adapted Therapy

Patients with advanced-stage Hodgkin lymphoma can be classified into two groups based on the number of prognostic factors present from the International Prognostic Index (Table 140–4). Advanced-stage patients with three or fewer poor prognostic factors are considered to have favorable disease and an approximately 60% likelihood of being failure-free at five years with traditional combination chemotherapy.[31] Advanced-stage patients with four or more poor prognostic factors are considered to have unfavorable disease and a less than 50% likelihood of being failure-free at five years with traditional combination chemotherapy. Due to the high treatment failure rate, the therapeutic goal for this group of high-risk patients is to improve antitumor control.

One recently published study has reported the feasibility of a risk-adapted treatment approach based on the IPS, with the goal of reducing cumulative doses of chemotherapy in patients with low-risk Hodgkin lymphoma.[40] Patients at low risk with early unfavorable disease and standard-risk patients with IPS of 2 or less were treated with two cycles of standard-dose BEACOPP, and high-risk patients with an IPS of 3 or higher were treated with two cycles of escalated-dose BEACOPP. After an interim gallium or PET/CT scan, patients with positive disease were given escalated-dose BEACOPP while patients who had negative disease were given standard-dose BEACOPP. For all patients, the complete remission rate, five-year event-free survival, and overall survival were 97%, 85%, and 90%, respectively. Although this was not a randomized study, the results suggested the feasibility of using a risk-adapted treatment modality in the treatment of advanced-stage Hodgkin lymphoma.

Currently, the NCCN guidelines suggest that escalated-dose BEACOPP be considered for patients with unfavorable disease because of the increase in efficacy. It is recommended that patients in advanced-stage disease with an IPS less than 4 should be treated with ABVD because of less-acute toxicity, the absent of sterility, and a low risk of secondary acute myeloid leukemia/myelodysplastic syndrome.[15]

Radiation

The role of low-dose consolidative radiation when added to chemotherapy for the treatment of advanced-stage Hodgkin lymphoma is controversial.[23] The rationale for its use is based on the radiosensitivity of Hodgkin lymphoma, a 20% to 40% relapse rate, and the tendency of Hodgkin lymphoma to relapse at sites of initial involvement.[41] Many clinical trials have been conducted to evaluate the benefit of additional radiation in patients who have a complete response to combination chemotherapy. The results of these studies are inconsistent, and a meta-analysis of 14 randomized trials showed a modest improvement in disease control at ten years, but no difference in overall survival.[42] In one study, patients with advanced disease were randomized to receive either involved-field radiation after MOPP/ABV hybrid chemotherapy or no further therapy. Eight-year event-free survival reported for patients achieving a complete response randomized to receive radiation, no

radiation, and a group of partial responders who received radiation were 73%, 77% and 76%, respectively. These results suggest that radiation provides no benefit for patients who achieve a complete remission with chemotherapy. Furthermore, radiation was also associated with a higher risk of secondary cancers (12.9% vs. 5.6% in the radiation and no radiation arms, respectively). It does, however, show a significant role for consolidative radiation in patients who have a partial response after chemotherapy.[43]

Summary

In summary, the standard treatment of advanced-stage favorable Hodgkin lymphoma is six to eight cycles of ABVD chemotherapy. BEACOPP should be considered for patients with unfavorable disease. This risk-adapted approach should result in approximately 70% to >90% of patients achieving a complete remission and approximately 60% to 80% of patients being cured of their disease. No further treatment is needed for patients attaining a complete remission. Patients achieving a partial remission should receive consolidative radiation to residual sites of disease.

TREATMENT OF REFRACTORY OR RELAPSED DISEASE

4 The goal of salvage therapy is cure regardless of the site(s) of recurrence or primary therapy. With the increasing use of chemotherapy with or without radiation, regardless of disease extent, the rate of primary refractory disease is decreasing. Patients who do not achieve a complete remission with the initial regimen are considered to have primary refractory disease. These patients have a poor prognosis when treated with salvage chemotherapy, and therefore should be offered autologous HSCT as a treatment option.[44,45]

Patients who relapse after an initial complete response can be treated with the same regimen, a different potentially non–cross-resistant regimen, radiation, or high-dose chemotherapy and autologous HSCT (often preceded by conventional-dose chemotherapy). There is no data available from randomized trial comparing the cytoreductive regimens that are utilized before transplantation. However, as most patients are now treated with ABVD, doxorubicin should be avoided in salvage chemotherapy regimens if the cumulative dose has reach >400 mg/m^2, particularly in those patients who have received mediastinal radiotherapy because they are at much higher risk of cardiotoxicities.

The response to salvage therapy depends on the extent and site of recurrence, previous therapy, and duration of initial remission. Patients who relapse after radiation therapy alone have a good chance of being cured with combination chemotherapy, although fewer patients are being treated with radiation alone. High response rates (60% to 87%) have been observed with salvage chemotherapy regimens.[19,46] Other patient groups who have a favorable prognosis following salvage therapy include patients who experience a local recurrence in a nonirradiated location and those who relapse more than 1 year after completion of their initial chemotherapy. Patients who experience late relapses can be cured with retreatment with the same chemotherapy regimen, treatment with a different, potentially non–cross-resistant regimen, or high-dose chemotherapy and autologous HSCT.

Patients who have an early relapse (less than one year after treatment) generally respond poorly to standard-dose salvage chemotherapy. High-dose chemotherapy and autologous HSCT is more effective, but also produces a higher risk of treatment-related mortality. Therefore, the choice of salvage treatment should consider the patient's tolerance for a particular set of chemotherapeutic agents and treatment approach (standard-dose chemotherapy vs. high-dose chemotherapy and autologous HSCT).[45]

High-dose therapy should be considered in patients who relapse within 12 months of initial remission and in those who are refractory to first-line chemotherapy.[45] Although no single preparative regimen has been shown to be superior to another, most regimens do not include total-body irradiation because of its potential pulmonary toxicity. Most patients are already at higher risk for pulmonary toxicity because of previous exposure to one or more of the following: bleomycin, thoracic radiation, and nitrosoureas. Long-term effects of high-dose chemotherapy and autologous HSCT were elucidated in a recent study. Among 218 Hodgkin lymphoma patients who were treated with high-dose chemotherapy and autologous HSCT, 70% survived over two years. A total of 15 patients were diagnosed with a second malignancy and the median time from autologous HSCT to secondary malignancy diagnosis was nine years. The risk of secondary malignancy is possibly caused by high-dose etoposide in the rescue regimen, as well as those patients who were initially treated with MOPP chemotherapy.[47] Chapter 148 provides more details about high-dose chemotherapy and HSCT.

LONG-TERM COMPLICATIONS

A variety of acute and chronic toxicities may occur as a result of treatment for Hodgkin lymphoma. Long-term complications of radiation therapy, chemotherapy, and combined modality therapy have become more evident as the curability and long-term survival of Hodgkin lymphoma patients has improved.[2,3] Gonadal dysfunction (including sterility and hypothyroidism), secondary malignancies, and cardiopulmonary diseases have become important considerations in the treatment of this malignancy. Almost all men and up to 50% of premenopausal women treated with six cycles of regimens containing alkylating agents become sterile. This appears to be a dose-related phenomenon. For men, even a single dose of nitrogen mustard or chlorambucil can cause sterility, so if fertility is a major concern, ABVD may be the best alternative.[48]

The risk of secondary malignancies is increased about threefold in long-term survivors of Hodgkin lymphoma. The risk of developing leukemia carries the highest increase in risk and is seen with radiotherapy, chemotherapy, and chemoradiotherapy. Solid tumors, including breast cancers, gastrointestinal cancers and lung cancers are also likely to develop more than 10 years after the completion of treatment.[49–51] However, studies that evaluate the risk of secondary malignancies (and other complications) must be interpreted cautiously because many factors probably contribute to the development of secondary malignancies.[52] In addition, much of the long-term complication data is derived from patients who were treated with older regimens and extensive field radiotherapy, which are no longer commonly used in clinical practice. Furthermore, as minimal data is currently available on the appropriate follow-up duration and procedures to monitor for long-term effects, many of the recommendations in the NCCN guideline are based on clinical practice but not evidence-based information. Nonetheless, follow-up schedule should be personalized and patient-specific, after assessing a patient's potential risks for long-term complications.[15]

NON-HODGKIN LYMPHOMA

The NHLs are a heterogeneous group of lymphoproliferative disorders that affect individuals from early childhood to late adulthood. Advances in molecular biology techniques and our understanding of the human immune system have led to major progress in understanding the pathogenesis and treatment of the lymphomas. NHLs are classified into distinct clinical entities that are defined by a combination

of morphology, immunophenotype, genetic features, and clinical features. These differences influence the natural history, and approach and response to treatment. The use of extensive combination chemotherapeutic regimens shows dramatic improvement in survival and cure in patients with a disease that was once considered incurable. The five-year survival rate for patients with NHL has increased from 48% to 71% over the past 25 years, and the mortality rate actually *declined* from 1997 to 2004.[4,5] Further improvement in survival is anticipated with the continued expansion of our therapeutic armamentarium, including high-dose chemotherapy and biologic therapy.

EPIDEMIOLOGY AND ETIOLOGY

NHL is the fifth most common cause of newly diagnosed cancer in the United States and accounts for approximately 4% of all cancers. An estimated 65,540 new cases will be diagnosed in 2010, and it is estimated that 20,210 people will die from NHL during this same period.[4] Although the average age of patients at the time of diagnosis is about 67 years, NHL can occur at any age. The incidence rate generally increases with age, and is higher in men than in women and in whites than in blacks.[5] The age-adjusted incidence rate of NHL increased by more than 80% in the United States since the early 1970s, from about 11 cases per 100,000 in 1975 to approximately 20 cases per 100,000 in 2003 and 2004.[5] The incidence of NHL increased by 3% to 4% from 1975 to 1991, but appears to have stabilized since reaching its peak in 1994. The increased incidence of NHL over the past three decades is second only to melanoma and has been referred to as an epidemic of NHL. Although the increase has been noted particularly among the elderly and patients with acquired immune deficiency syndrome (AIDS), much of it cannot be explained by known risk factors.

The etiology of NHL is unknown, although several genetic diseases, environmental agents, and infectious agents are associated with the development of NHL.[53–55] An increased incidence of NHL is seen in many congenital and acquired immunodeficiency states, supporting the role of immune dysregulation in the etiology of NHL.[54] Patients with congenital immunodeficiency disorders such as Wiskott-Aldrich syndrome and ataxia telangiectasia, acquired immunodeficiency disorders such as AIDS, and those receiving chronic pharmacologic immunosuppression in the setting of solid-organ transplantation are predisposed to the development of NHL. Autoimmune diseases (Hashimoto thyroiditis, Sjögren's syndrome) cause chronic inflammation in the mucosa-associated lymphoid tissue (MALT), which predisposes patients to subsequent lymphoid malignancies. Other autoimmune diseases, such as systemic lupus erythematosus and rheumatoid arthritis, are also associated with the development of NHL, but the use of immunosuppressive agents in these diseases makes the pathologic cause less clear.

Certain infections are associated with the development of lymphoma.[53,55] EBV was discovered in cell lines from tumors of patients with African (endemic) Burkitt lymphoma, and EBV DNA is associated with nearly all cases of endemic Burkitt lymphoma. However, EBV is associated with sporadic Burkitt lymphoma in 15% to 85% of cases. EBV is also associated with posttransplant lymphoproliferative disorders and some lymphomas in patients with AIDS or congenital immunodeficiencies. The human T-cell lymphotropic virus type 1 was the first human retrovirus associated with a malignancy. Infection with human T-cell lymphotropic virus type 1, especially in early childhood, is strongly associated with an aggressive form of T-cell lymphoma, known as adult T-cell leukemia/lymphoma. Human T-cell lymphotropic virus type 1 is endemic in parts of southern Japan, Africa, South America, and the Caribbean. In endemic areas, more than 50% of all NHL cases are adult T-cell leukemia/lymphoma. A third virus associated with NHL is human herpes virus 8 (also referred as Kaposi sarcoma–associated herpesvirus [KSHV]). This virus was originally isolated from Kaposi sarcoma lesions in AIDS patients. Gastric infection with *Helicobacter pylori*, a gram-negative bacteria that leads to chronic gastritis, is associated with gastric MALT lymphomas. Finally, hepatitis C virus has been associated with splenic and nodal marginal zone lymphomas.

A number of physical agents are also associated with the development of NHL.[53,54] Exposure to herbicides, particularly phenoxyl herbicides, is associated with the development of NHL. These observations may explain why certain occupations, such as farmers, forestry workers, and agricultural workers, are associated with a higher risk of NHL. Exposure to lawn-care pesticides is also increasing in the general population. A higher risk of NHL is also associated with exposure to other chemical solvents and dyes, exposure to radiation from nuclear explosions, and high intake of meats and dietary fats. Smoking or alcohol consumption is not strongly associated with an increased risk of NHL.

MOLECULAR ABNORMALITIES

Chromosomal translocations have become a hallmark of many lymphoid malignancies.[56,57] The presence of these specific translocations can be helpful in the diagnosis and classification of lymphoid malignancies. The mechanisms leading to the translocations are unknown, but they usually involve the antigen receptor loci. In contrast to most myeloid and some lymphoid leukemias, NHLs usually place a structurally intact cellular protooncogene under the regulatory influence of highly expressed immunoglobulin or T-cell receptor genes, leading to effects on cell growth, cellular differentiation, or apoptosis. The most common chromosomal translocations involve t(8;14), t(14;18), and t(11;14); each translocation involves the immunoglobulin heavy-chain gene locus on chromosome 14 at 14q32. The translocation t(8;14) that involves c-*MYC*, a well-characterized oncogene clearly associated with malignancy, is implicated in nearly all cases of Burkitt lymphoma. The translocation t(14;18) that involves *BCL*-2, one of several putative B-cell lymphoma–associated oncogenes, is found in approximately 90% of cases of follicular B-cell lymphomas. The translocation t(11;14) that involves *BCL*-1 is found in about 70% of patients with mantle cell lymphoma. Another putative B-cell lymphoma–associated oncogene, *BCL*-6, is found in about one third of diffuse large B-cell lymphomas.

Although mutations in the *p53* tumor suppressor gene have been recognized in many human neoplasms, such mutations have not been consistently found in patients with lymphoma, which suggests that it may occur late in malignant evolution.

Because of their role in the pathogenesis of lymphoma, oncogenes are attractive molecular targets for the development of new and novel therapies.[58]

PATHOLOGY AND CLASSIFICATION

NHLs are neoplasms derived from the monoclonal proliferation of malignant B or T lymphocytes and their precursors. Approximately 85% to 90% of NHLs in the United States are of B-cell origin.[54] Proliferation of malignant cells results in the replacement of the normal cells and architecture of lymph nodes or bone marrow with a relatively uniform population of lymphoid cells. The classification of NHLs has evolved over the last five decades, as advances in immunology and genetics have allowed scientists to recognize a number of previously unrecognized subtypes of NHLs (Table 140–6).[11,59] The current classification schemes characterize the NHLs according to the cell of origin (B cell vs. T cell), clinical features, and morphologic features. Additional immunohistochemical markers, cytogenetic features, and genotypic characteristics may also be of help to further classify NHL into subtypes.

TABLE 140-6 Evolution in the Classification of Non-Hodgkin Lymphomas

Time	Classification System	Basis for Classification
1950s–1960s	Rappaport	Morphology
1970s–1980s	Luke–Collins	Morphology and immunophenotype
1970s–1980s	Kiel	Morphology and immunophenotype
1980s–1990s	International Working Formulation	Morphology and clinical behavior
1990s	REAL	Disease entities
2001	WHO	Disease entities

REAL, Revised European–American Classification of Lymphoid Neoplasms developed by the International Lymphoma Study Group; WHO, World Health Organization.

Morphology

The macroscopic and microscopic appearance of the involved tissue remains one of the most important factors in the diagnosis and classification of NHLs.[11,59] In the 1950s, Rappaport et al. proposed a morphologic classification of malignant lymphomas based on two features: that the malignant cell would disrupt the nodal architecture in a *nodular* or *diffuse* manner, and that lymphomas of histiocytic origin existed. The Rappaport classification gained rapid acceptance in the United States because of its precision, simplicity, and prognostic significance. Application of the system divided NHLs into those with large (i.e., incorrectly called "histiocytes") or small cells, with or without a nodular (i.e., follicular) growth pattern.

Immunology

In the 1970s, it became apparent that NHLs were tumors of the immune system and were derived from B or T lymphocytes. The availability of techniques using antibodies to antigens on the surface of lymphoid cells (i.e., immunophenotype) and cytochemical assays led to the following conclusions: most NHLs were of B-cell origin; all follicular or nodular lymphomas were of follicle center cell origin; and most lymphomas previously classified as reticulum cell sarcoma, clasmatocytic lymphoma, or histiocytic lymphoma had the immunologic characteristics of transformed lymphocytes. Using this new information, expert pathologists independently developed new classification schemes for NHL in the 1970s and 1980s.[11,59] The Kiel classification was based primarily on the work of Lennert in Germany and became widely used in Europe. In North America, the Lukes and Collins classification scheme was used briefly, but was soon superseded by the Working Formulation. Like the Rappaport classification, divisions within the Working Formulation were based largely on cell size (large [histiocytic] vs. small [lymphocytic]), cell shape (round vs. not round), and growth pattern (follicular [nodular] vs. diffuse). Both the Kiel and Working Formulation classification schemes considered the histologic grade of the tumor, but only the Working Formulation considered actual survival curves of patients with the various subtypes of NHL. *Low-grade* indicated longer median survival (i.e., indolent) whereas *intermediate-grade* and *high-grade* indicated shorter median survival (i.e., aggressive). In the 1980s and early 1990s, the Working Formulation became the most widely used classification scheme in North America, whereas the Kiel classification was widely used in Europe and Asia. It was based on the premise that NHL was a single disease with a range of histologic grades and clinical aggressiveness.

New Disease Entities

In the 1980s and early 1990s, rapid advances in immunology and genetics allowed scientists to recognize a number of previously unrecognized subtypes of NHLs. Cytogenetic and molecular genetic analyses identified the presence of many chromosomal translocations, oncogenes, and their gene products in patients with NHL (see Molecular Abnormalities later in this chapter). In addition, diseases that would have been lumped together as low-grade or intermediate/high grade in the Working Formulation showed marked differences in survival, which prompted scientists to reevaluate lymphoma classification schemes.

Information from these studies allowed scientists to further classify B-cell lymphomas as malignant expansions of cells from the germinal center, mantle zone, or marginal zone of normal lymph nodes (Table 140–1).[11,60,61] Germinal centers are complex structures that form in the spleen and lymph nodes in response to antigenic challenge. In addition to B cells, germinal centers contain antigen-presenting cells and helper T cells that cooperate in mediating the B-cell changes that result in a more potent secondary immune response. Malignant transformation often occurs or is initiated in germinal center B cells. Follicular, Burkitt, and most large cell lymphomas are believed to be tumors of germinal center B cells. Three histologically distinct microenvironments have been described within the germinal center: a mantle zone surrounding interior, dark, and light zones. The mantle zone contains small resting B cells that have not been exposed to antigens (naïve). Tumors of cells from the mantle zone are usually clinically indolent and histologically low grade. Antigen-triggered activation of the densely packed B cells of the dark zone causes cells to proliferate and subjects genomic DNA to somatic hypermutation. Surviving clones from within the dark zone then enter the light zone where proliferation slows and affinity selection occurs. During affinity selection, only cells with surface immunoglobulin receptors with high affinity for the antigen survive. Antigen-specific B cells generated in the germinal center reaction leave the follicle and reappear in the outer mantle zone, to form a marginal zone. Marginal zones are particularly prominent in mesenteric lymph nodes, Peyer patches, and the spleen. These post-germinal center B cells include memory B cells of the marginal zone and plasma cells. Marginal cell B-cell lymphomas tend to be indolent and may be either extranodal or nodal; extranodal marginal cell B-cell lymphomas are also referred to as MALT lymphomas.

T-cell lymphomas can be classified on the basis of antigen expression as either precursor (thymic) or mature (peripheral) in origin. These classifications clinically translate to precursor lymphoblastic lymphomas or to a heterogeneous group of peripheral T-cell lymphomas. Tumors of natural killer or natural killer-like T cells are uncommon.

The International Lymphoma Study Group, an informal group of 19 hematopathologists from the United States, Europe, and Asia, adopted a new approach to lymphoma classification in 1993. Because it represented a revision of current or prior European and American lymphoma classifications, it was called the Revised European–American Classification of Lymphoid Neoplasms (REAL). The REAL classification system is based on the principle that a classification is a list of "real" disease entities, which are defined by a combination of morphology, immunophenotype, genetic features, and clinical features.[11,59] The relative importance of each of these criteria for both definition and diagnosis differs among different diseases. Morphology is always important, and some diseases are primarily defined by morphology alone (e.g., follicular lymphoma), although immunophenotype can be helpful in difficult cases. Some diseases have a specific immunophenotype (e.g., mantle cell lymphoma, small lymphocytic lymphoma) that is virtually diagnostic of that disease. A specific genetic abnormality is important in some lymphomas—t(11;14) in mantle cell lymphoma, t(8;14) in Burkitt lymphoma, and t(14;18) in follicular lymphoma—whereas other lymphomas lack specific genetic abnormalities (e.g., MALT lymphoma, diffuse large B-cell lymphoma). Finally, other lymphomas consider clinical features (e.g., extranodal vs. nodal presentation in marginal zone lymphoma and peripheral T-cell lymphoma).

Since 1995, members of the European and American Hematopathology societies have worked to develop a new WHO classification of hematologic malignancies. The final classification was published in 2001 and revised in 2008.[13] The WHO classification uses an updated version of the REAL classification and expands the principles of the REAL classification to the classification of myeloid and lymphoid malignancies.

5 The 2008 WHO classification categorizes lymphoid malignancies into two major categories: B-cell lymphomas and T-cell (and natural killer cell) lymphomas (Table 140–2).[11,13,59] B-cell lymphomas represent about 85% to 90% of all NHLs. Lymphomas within each category can be divided into malignancies of precursor or mature cells. Hodgkin lymphoma and multiple myeloma are now recognized as mature B-cell neoplasms. The WHO classification uses the term *grade* to refer to histologic parameters such as cell and nuclear size, density of chromatin, and proliferation fraction, and the term *aggressiveness* to denote clinical behavior of a tumor. This classification scheme includes both lymphomas and lymphoid leukemias because there is no distinction between the solid and circulating forms of these diseases. The WHO classification includes several previously unrecognized types of lymphomas, and new entities not specifically recognized in the Working Formulation account for approximately 20% to 25% of the cases.

The WHO classification has broad clinical implications. The WHO Clinical Advisory Committee has agreed that clinical groupings of lymphoid neoplasms into prognostic categories are neither necessary nor desirable because such arbitrary groupings are of no practical value and may be misleading.[62] Treatment of a specific patient should be determined not by the broad prognostic group into which the patient's neoplasm falls but by the specific type of neoplasm, with the addition of grade *within* the tumor type (if applicable), and clinical prognostic factors.

CLINICAL PRESENTATION

6 Patients with NHL present with a wide variety of symptoms, depending on the site of involvement and whether tumor involvement is nodal or extranodal.[63] Sites of involvement and dissemination of the malignant cells can sometimes be predicted based on the cell of origin and the tendency of tumors to frequently disseminate to areas where the normal counterparts of the lymphoma cells are located. For example, B-cell lymphomas involve areas of the lymphoid system normally populated by B-lymphocytes, such as lymph nodes, spleen, and bone marrow. T-cell lymphomas commonly disseminate to various extranodal sites, such as the skin and lungs.

Most patients present with peripheral lymphadenopathy.[63] The lymphadenopathy may be either localized or generalized, and the involved nodes are often painless, rubbery, and discrete, and usually located in the cervical and supraclavicular regions as in Hodgkin lymphoma (Fig. 140–1). Rapid and progressive lymphadenopathy is more characteristic of aggressive lymphomas. Waxing and waning of lymph nodes, including their complete disappearance and reappearance, is more characteristic of indolent lymphomas. Massive lymphadenopathy can sometimes lead to organ dysfunction. For example, patients with NHL may present with acute renal failure from retroperitoneal adenopathy causing ureteral obstruction or from metabolic abnormalities such as hyperuricemia with uric acid nephropathy.

Approximately 40% of patients with NHL present with fever (temperature >38°C [100.4°F]), weight loss (unexplained weight loss of 10% of body weight over the past 6 months), or night sweats (drenching night sweats). If one or more of these symptoms is present, the patient is noted to have B symptoms, and a B is added to the stage of disease (discussed in the Diagnosis, Staging, and Prognostic Factors section under Hodgkin Lymphoma earlier in this chapter). B symptoms are more commonly observed in patients with aggressive NHLs.

CLINICAL PRESENTATION OF NON-HODGKIN LYMPHOMA

General

- Patients with NHL present with a wide variety of symptoms, depending on the site of involvement and whether tumor involvement is nodal or extranodal.

Symptoms

- Approximately 40% of patients present with fever, night sweats, and weight loss (i.e., B symptoms).
- Fatigue, malaise, and pruritus.

Signs

- More than two thirds of patients present with peripheral lymphadenopathy.

Laboratory Tests

- A complete blood count, tests of renal and liver function, and serum electrolytes should be obtained.
- Serum β_2-microglobulin and lactate dehydrogenase levels may be useful as prognostic factors and for monitoring response to therapy.

Other Diagnostic Tests

- Varies depending on sites of involvement.

Patients with Hodgkin lymphoma rarely present with extranodal (i.e., extralymphatic) disease, but 10% to 35% of patients with NHL have primary extranodal disease at the time of diagnosis.[63] The frequency of extranodal presentation varies dramatically among different subtypes. The most common extranodal sites are the gastrointestinal tract followed by the skin. The liver or spleen may be enlarged in patients with generalized adenopathy. Patients with mesenteric or gastrointestinal involvement may present with signs and symptoms of nausea, vomiting, obstruction, abdominal pain, a palpable abdominal mass, or gastrointestinal bleeding. Patients with bone marrow involvement may have symptoms related to anemia, neutropenia, or thrombocytopenia. Other sites of extranodal disease include the testes and bone. The incidence of solitary brain lymphoma is increasing, especially in patients with AIDS.

DIAGNOSIS, STAGING, AND PROGNOSTIC FACTORS

As with Hodgkin lymphoma, the diagnosis of NHL must be established by pathologic review of tissue obtained by biopsy.[63] The preferred procedure is an excisional biopsy, where the entire involved lymph node is removed for review by an experienced hematopathologist. This procedure should be done carefully to prevent distortional artifact of the architecture, which could lead to an inaccurate diagnosis. Needle biopsy of the node can sometimes provide adequate tissue for pathologic diagnosis, if an excisional biopsy cannot be performed. When adenopathy is not present, diagnosis may be established by biopsy of cutaneous lesions, bone marrow biopsy and aspiration in patients with unexplained myelosuppression, liver biopsy in patients with hepatomegaly or elevated liver function tests, or biopsy of involved extranodal organs, such as bone, Waldeyer ring, lung, and testis.

After the diagnosis is established, further workup is required to determine the extent of involvement.[56,63,64] Clinical staging always begins with a thorough history and physical examination. Patients should be questioned about the presence or absence and extent of fever, night sweats, and weight loss. A detailed history of lymphadenopathy should also be obtained, including when and where the lymph nodes were first noted, and their rate of growth. A complete physical examination is performed to assess the extent

TABLE 140-7 Clinical Characteristics of Patients with Common Types of Non-Hodgkin Lymphomas

Disease	Median Age (Years)	Frequency in Children	% Male	Stage I/II vs. III/IV (%)	B Symptoms (%)	BM Involvement (%)	GI Tract Involvement (%)	% Surviving 5 years
B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma	65	Rare	53	9 vs. 91	33	72	3	51
Mantle cell lymphoma	63	Rare	74	20 vs. 80	28	64	9	27
Extranodal marginal zone B-cell lymphoma of MALT type	60	Rare	48	67 vs. 33	19	14	50	74
Follicular lymphoma	59	Rare	42	33 vs. 67	28	42	4	72
Diffuse large B-cell lymphoma	64	≈25% of childhood NHL	55	54 vs. 46	33	16	18	46

of disease involvement, with special attention given to all nodal areas (Fig. 140–1). All patients should have a complete blood count, serum chemistries including liver and renal profiles, a chest radiograph, and bone marrow aspiration and biopsy. The likelihood of bone marrow involvement varies among the different histologic types of lymphoma (Table 140–7). Lumbar puncture to evaluate the cerebrospinal fluid is recommended in patients who have histologic types of lymphoma that often spread to the CNS.

Imaging studies are usually important in the staging workup.[63,64] CT scanning can identify both nodal and extranodal sites of disease, and has largely replaced lymphangiography for the evaluation of retroperitoneal lymphadenopathy. The abdominal and pelvic CT scan can identify mesenteric and retrocrural node involvement. CT scans can also detect tumor involvement of organs, including the kidneys, ovary, spleen, and liver. PET is currently not used routinely for staging of NHL.[64,65] Magnetic resonance imaging is of limited usefulness in the staging of NHL. Gallium scans are sometimes used as part of the staging work up. Other tests, such as liver–spleen scan, bone scan, upper gastrointestinal series, and intravenous pyelogram, are sometimes useful in patients with organ symptomatology or serum chemistry abnormalities.

Although staging laparotomy was widely used in the late 1960s and 1970s as part of the staging workup in patients with lymphoma, it is rarely used today because of technical improvements in imaging studies and the morbidity and potential mortality associated with the procedure.

The Ann Arbor staging classification developed for the clinical staging of Hodgkin lymphoma is also used to stage patients with NHL (see Table 140–3). After completion of the staging workup, most patients will be found to have advanced disease (stages III and IV). The frequency of localized disease at the time of diagnosis varies depending on the histologic type of lymphoma (Table 140–7). Stage is a more important prognostic factor in Hodgkin lymphoma than in NHL.

7 The Ann Arbor system emphasizes the distribution of nodal disease sites because Hodgkin lymphoma usually spreads through contiguous lymph nodes and does not involve extranodal sites. But NHL is a disease with tremendous heterogeneity that does not spread through contiguous lymph nodes and that often involves extranodal sites. As a result of these clinical differences between Hodgkin lymphoma and NHL, Ann Arbor stage correlates poorly with prognosis.

8 This lack of accuracy with the Ann Arbor staging system in NHL has led to several international projects to develop prognostic models for the most common types of NHLs—diffuse large B-cell lymphomas and follicular lymphomas. The International Non-Hodgkin Lymphoma Prognostic Factors Project was based on more than 2,000 patients with diffuse aggressive lymphomas treated with an anthracycline-containing combination chemotherapy regimen in the United States, Europe, and Canada.[66] The Project identified five risk factors that correlated with low response to chemotherapy and poor survival: age >60 years, reduced performance status ≥2, abnormal serum lactate dehydrogenase (LDH) levels, two or more extranodal sites of disease, and advanced tumor stage (Ann Arbor stages III or IV) (Table 140–8). In patients ≤60 years old, three risk factors correlated with low response to chemotherapy and poor survival: reduced performance status, abnormal serum LDH levels, and Ann Arbor stage. It is unclear whether the effect of serum LDH level is related to a tumor or a host event. LDH likely measures cellular catabolism (the enzyme is released from injured cells), or the product of tumor

TABLE 140-8 Risk Factors and Survival According to the International Non-Hodgkin Lymphoma Prognostic Factors Project

All Patients	Patients ≤ 60 Years of Age
Age >60 years	Abnormal LDH level
Abnormal LDH level	Performance status ≥2
Performance status ≥2	Ann Arbor stage III or IV
Ann Arbor stage III or IV

burden and proliferation. Because each of the factors has about the same impact (e.g., relative risk) on prognosis, the number of adverse risk factors is summed to provide the International Prognostic Index (IPI). Patients could, therefore, have a score of 0 to 5. Table 140–8 shows the correlation between four risk groups based on the IPI score and complete response rate and five-year survival. For patients ≤60 years old, a simplified IPI score can be developed based on Ann Arbor stage, serum LDH level, and performance status.

As prognosis improves as a result of more effective therapy, it is important to reevaluate prognostic factors. The IPI was based on patients treated from 1982 to 1987 with anthracycline-based combination chemotherapy; none of the patients received rituximab. In a reexamination of the IPI in a cohort of patients treated with rituximab-containing chemotherapy, Sehn et al. found that the IPI remained predictive but it only identified two, rather than four, risk groups.[67] When the number of risk factors is redistributed, three risk groups are identified that correlate with prognosis. This revised IPI score may more accurately predict prognosis in patients treated with rituximab-containing combination chemotherapy, but needs to be validated in a larger group of patients.

Although the IPI is often used to predict prognosis in patients with other NHL subtypes, the IPI has several shortcomings when applied to patients with indolent lymphomas. Because only patients with diffuse aggressive lymphomas were used to develop the IPI system, some important prognostic factors may have been missed. Furthermore, the IPI system has limited discriminating power in follicular lymphoma because only approximately 10% of patients are categorized as high-risk in the IPI system. To address these concerns, an international cooperative study was designed to develop a prognostic model similar to the IPI in patients with follicular lymphoma. The results of that study, which was based on more than 4,000 patients with follicular lymphoma diagnosed between 1985 and 1992, were recently published.[68] Five factors were identified that correlated with poor survival: age >60 years, advanced tumor stage (Ann Arbor stage III or IV), low hemoglobin level (<12 g/dL [<120 g/L; 7.45 mmol/L]), five or more nodal sites of disease (Fig. 140–1), and an abnormal serum LDH level. Analogous to the IPI, the number of adverse risk factors is summed to provide the Follicular Lymphoma International Prognostic Index (FLIPI). Three prognostic groups were identified: low-risk (0 to 1 factors), intermediate-risk (2 factors), and high-risk (≥3 factors). The new system appeared to have higher discriminating power among groups as compared with the IPI system. Table 140–9 shows the correlation between the FLIPI score and overall survival. The survival data may not reflect current figures because none of the patients used to derive the FLIPI were treated with rituximab.

TABLE 140-9 Risk Factors and Survival According to the Follicular Lymphoma International Prognostic Index

All Patients

Age >60 years
Ann Arbor stage III or IV
Number of nodal sites ≥5
Abnormal lactate dehydrogenase level
Hemoglobin <12 g/dL [<120 g/L; 7.45 mmol/L]

Risk Group (% of Patients)	Number of Risk Factors	5-Year Overall Survival (%)	10-Year Overall Survival (%)
Low (36)	0–1	91	71
Intermediate (37)	2	78	51
High (27)	≥3	53	36

Although IPI and FLIPI are clinically useful tools to estimate prognosis, the factors used to calculate these scores probably represent clinical surrogates for the biologic heterogeneity among NHLs and many researchers are interested in determining the prognostic importance of certain phenotypic and molecular characteristics of NHLs. For example, markers of apoptosis, cell-cycle regulation, cell lineage, and cell proliferation are being evaluated as potentially clinically useful prognostic factors.[69]

Gene expression profiling with microarrays may also correlate with survival. Using gene expression profiling, investigators identified at least two molecularly distinct forms of diffuse large B-cell lymphomas based on gene expression patterns indicative of different stages of B-cell differentiation: germinal center B-cell–like (GCB) and activated B-cell–like (ABC).[70] The GCB subtype of diffuse large B-cell lymphoma probably arises from normal germinal center B-cells while the ABC subtype may arise from post-germinal center B-cells. Many oncogenic pathways are different for the GCB and ABC subtypes, and these differences may lead to the development of targeted therapies for each subtype.[61] Patients with the germinal center B-cell profile had significantly better overall survival independent of IPI score after treatment with CHOP (cyclophosphamide, doxorubicin, Oncovin, prednisone) or CHOP-like chemotherapy. In a recently published study of patients with diffuse large B-cell lymphoma treated with either CHOP or rituximab and CHOP (R-CHOP), Lenz et al. identified several gene expressions signatures that predicted survival in both CHOP and R-CHOP cohorts: GCB, stromal-1, and stromal-2.[71] The GCB and stromal-1 signatures were associated with a favorable prognosis while the stromal-2 signature was associated with an unfavorable prognosis. The stromal-1 signature reflects extracellular matrix deposition and histiocytic infiltration whereas the stromal-2 signature reflects tumor blood vessel density. The authors speculated that diffuse large B-cell lymphomas that express the stromal-2 signature may respond to antiangiogenic agents.

Two molecularly distinct profiles of follicular lymphoma also have been identified; the first included genes encoding for T-cell markers and genes highly expressed in macrophages, and the second included genes that are preferentially expressed in macrophages, dendritic cells, or both.[72] Patients with the first molecular signature had a more favorable outcome than those with the second signature. These results suggest that molecular classification of tumors on the basis of gene expression may allow identification of clinically significant subtypes of cancer.

TREATMENT

Non-Hodgkin Lymphoma

GENERAL TREATMENT PRINCIPLES

The primary goals in the treatment of NHL are to relieve symptoms, cure the patient of the disease whenever possible, and minimize the risk of serious toxicities. The treatment strategy depends on many factors, including the patient's age, concomitant disease, disease type, stage of disease, site of disease, and patient preference.

9 Historically, both the clinical behavior and degree of aggressiveness are often used to describe NHLs. Indolent lymphomas, which make up approximately 25% to 40% of all NHLs, are characterized by their slow-growth behavior. Patients with an indolent lymphoma usually have a relatively long survival (measured in years), with or without aggressive chemotherapy. Although these lymphomas respond to a wide range of therapeutic approaches, there is no convincing evidence of a survival plateau, which indicates that patients are rarely cured of their disease. In contrast,

aggressive lymphomas, which make up approximately 60% to 75% of all NHLs, are characterized by rapid growth rate and short survival (measured in weeks to months), if appropriate therapy is not initiated. Despite their more aggressive nature, many patients with aggressive lymphomas who respond to chemotherapy can experience prolonged disease-free survival and some are cured of their disease. Therefore, the terminology for the NHLs represents a paradox, where "indolent" is bad and "aggressive" is good in terms of the likelihood for cure.

Therapeutic approaches to NHL include radiation therapy, chemotherapy, and biologic agents. The role of radiation therapy in the treatment of NHL differs from its role in the treatment of Hodgkin lymphoma. Although the disease responds to radiation therapy, only a small percentage of patients with NHL present with truly localized disease that can be treated with local or regional radiation therapy. Radiation therapy is used more commonly in advanced disease, primarily as a palliative measure to control local bulky disease.

Effective chemotherapy for NHL ranges from single-agent therapy in indolent lymphomas to aggressive, complex chemotherapy regimens in aggressive lymphomas. The most active agents used in the treatment of NHL include the alkylating agents (e.g., cyclophosphamide, chlorambucil), bleomycin, doxorubicin, purine analogs, etoposide, methotrexate, vincristine, and corticosteroids (e.g., prednisone, dexamethasone). The most aggressive chemotherapy approaches are dose-dense chemotherapy or high-dose chemotherapy followed by autologous or allogeneic HSCT.

B-cell lymphomas have served as a model for immunotherapy with monoclonal antibodies for more than 20 years, beginning with the successful use of custom-made monoclonal antibodies targeted against the idiotype present on the patient's cancer cells.[73,74] These encouraging results lead to the development of monoclonal antibodies against a more generic target, a molecule on the surface of B cells that would be present on tumor cells. One potential target, the CD20 molecule, is present only on cells in the B-lymphocyte lineage. It is expressed on the surface of both normal and malignant B cells, but not on other normal tissues. Rituximab (Rituxan®) is a chimeric monoclonal antibody directed at the CD20 molecule. Its antitumor activity is mediated through complement-dependent cytotoxicity, antibody-dependent cytotoxicity, and induction of apoptosis.[74] Since rituximab was approved in November 1997 to treat relapsed or refractory indolent or follicular $CD20^+$ lymphomas, it has become one of the most widely used therapies for NHL. More recently, two radiolabeled monoclonal antibodies (i.e., radioimmunoconjugates) targeted against the CD20 antigen were approved. With the availability of monoclonal antibodies and radioimmunoconjugates for the therapy of lymphoma, nearly all patients with NHL will receive one or more biologic agents during the course of their disease.

Objective response to therapy for NHL should be defined according to the International Workshop to Standardize Response Criteria for Non-Hodgkin Lymphoma, which was recently updated to incorporate the results of newer tests to monitor response such as PET, immunohistochemistry, and flow cytometry.[65] The revised guidelines describe criteria for response (e.g., complete response, partial response, and stable disease) and survival (e.g., overall, disease-free, event-free, progression-free).

Appropriate therapy for NHL depends on the patient's age, histologic type, stage of disease, site of disease, and presence of adverse prognostic factors (as measured by IPI or FLIPI score), and patient preferences. In general, treatment of lymphoma can be divided into limited disease and advanced disease. Limited disease includes those patients with localized disease (Ann Arbor stages I and II). Advanced disease is defined as all Ann Arbor stage III or IV patients, and also frequently includes Ann Arbor stage II patients with poor prognostic features (Tables 140–8 and 140–9).[66,68]

The following section discusses the clinical characteristics and therapy of the most common disease entities.

INDOLENT LYMPHOMAS

Follicular Lymphomas

The combined group of follicular lymphomas makes up the second most common histologic type of NHL in the United States, comprising approximately 20% of all NHLs worldwide and up to 70% of indolent lymphomas reported in American and European clinical trials.[75] The WHO classification includes criteria for grading follicular lymphoma based on the number of centroblasts per high-power field: grade 1 to 2 (0 to 15 centroblasts/high-power field) and grade 3 (>15 centroblasts/high-power field).[13] The clinical behavior and treatment outcome of grades 1 and 2 follicular lymphoma are similar, and they are usually treated as indolent lymphomas. In contrast, grade 3 follicular lymphoma is synonymous with what is often referred to as follicular large cell lymphoma and is usually treated as an aggressive lymphoma.

Follicular lymphomas tend to occur in older adults, with a slight female predominance (Table 140–7). Most patients have advanced disease at diagnosis, but approximately 25% to 33% of patients have localized disease (clinical stage I or II) at diagnosis.[76] Extranodal disease, bulky disease, and B symptoms are uncommon features at diagnosis. Most patients with follicular lymphoma have the chromosomal translocation t(14;18) at the time of diagnosis.

The clinical course is generally indolent, with median survivals of eight to ten years. But the natural history of follicular lymphoma can be unpredictable. Spontaneous regression of objective disease has been noted in as many as 20% to 30% of patients.[77] There is also a high conversion rate of follicular lymphoma to a more aggressive histology over time that steadily increases after diagnosis and reaches approximately 30% at ten years.[78] At autopsy, most patients with follicular lymphoma have some evidence of diffuse large B-cell lymphoma. Patients with transformed indolent lymphoma should be treated in the same way as patients with an aggressive lymphoma.

Most patients have dramatic responses to initial therapy, and their disease course is characterized by multiple relapses, with responses to salvage therapy becoming progressively shorter after every relapse, eventually leading to death from disease-related causes.[77] This pattern of constant relapses over time without evidence of a survival plateau and the failure of randomized controlled trials to show a survival benefit with aggressive chemotherapy led to the conclusion that therapy does not prolong overall survival and patients are not cured of their disease. However, several recently published studies suggest that the use of biologic agents, particularly rituximab, has changed the natural history of the follicular lymphoma. In a study of patients enrolled in Southwest Oncology Group (SWOG) trials over a period of more than 20 years, patients treated with CHOP and a monoclonal antibody had a significantly longer four-year overall survival than those treated with CHOP alone (91% vs. 69%).[79] Similar results were reported in patients treated over a 30-year period at the M.D. Anderson Cancer Center.[80] That study also showed an apparent plateau in the failure-free survival curve.

Certain subsets of patients with follicular lymphoma have a much better or worse prognosis.[69] Some studies suggest that the natural history of follicular large cell lymphoma (i.e., grade 3 follicular lymphoma) is similar to that of other aggressive lymphomas and that treatment with intensive combination chemotherapy regimens may result in long-term disease-free survival, including a possible plateau in the survival curve.[75] The recent development of the FLIPI prognostic model should help clinicians to identify patients in different prognostic groups based on disease characteristics at the time of diagnosis.[68] Patients who are predicted to have a poor prognosis

(i.e., high-risk) could then be offered aggressive or experimental therapy, whereas those who are predicted to have a good prognosis (i.e., low-risk) would be treated with standard therapy, avoiding unnecessary toxicity.

Treatment of Localized Disease (Stages I and II) Radiation therapy is the standard treatment for early-stage follicular lymphoma. Involved-field, extended-field, and total nodal irradiation have been used. Carefully staged patients with either stage I or contiguous stage II disease treated with radiation therapy alone can achieve disease-free survival rates of 40% to 50% and overall survival rates of 60% to 70% at ten years.[75] Late relapses are uncommon; only 10% of patients who reached ten years without relapse subsequently experienced a recurrence.

Chemotherapy is not usually given in most patients with localized follicular lymphoma, but it may be helpful in some patients with high-risk stage II disease (e.g., multiple sites of involvement or bulky disease).[81]

10 Approximately 40% to 60% of patients with clinical stage I or II follicular lymphoma are cured of their disease with radiation therapy alone.[75] Most centers use radiation at a dose of 30 to 40 Gy (3000 to 4000 rad) to either involved (i.e., local) or regional fields, which would consist of irradiation to the involved nodal region plus one additional uninvolved region on each side of the involved nodes. Extended-field irradiation is not usually used because of the absence of a survival benefit and possible increased risk of secondary malignancies. In addition, previous use of extended-field irradiation compromises the ability of that patient to receive subsequent chemotherapy. The current NCCN guidelines state that locoregional radiation therapy is preferred for most patients with early-stage follicular lymphoma.[64] Immunotherapy (i.e., rituximab) with or without chemotherapy or radiation therapy is also listed as an option (category 2B).

Treatment of Advanced Disease (Stages III and IV) 10 The management of stages III and IV indolent lymphomas remains controversial because until recently, no therapeutic approaches had been shown to prolong overall survival despite the high complete remission rates to initial therapy. However, the results of recently published studies suggest that the initial use of biologic therapy such as rituximab is associated with longer overall survival.[79,80] More than 80% of patients with stage III or IV follicular lymphoma are alive at five years, and the median survival ranges between seven and ten years.

Therapeutic options for these patients are diverse and include watchful waiting, radiation therapy, single-agent chemotherapy, combination chemotherapy, biologic therapy, radioimmunotherapy, and combined-modality therapy.[75,82] Although complete remission can be achieved in 50% to 80% of patients with various treatments, the median time to relapse is usually only 18 to 36 months. Approximately 20% of patients who have a complete response remain in remission for longer than ten years. After relapse, patients are retreated, and high remission rates can be achieved. Unfortunately, response rates and duration of response both decrease with each retreatment.

Several different approaches can be used to treat follicular lymphoma. Carefully selected patients may receive no initial therapy followed by single-agent chemotherapy, rituximab, or radiation therapy when treatment is needed. Candidates for the conservative approach are usually older, asymptomatic, and have minimal tumor burden. Patients with symptoms, extensive extranodal involvement, bulky disease, cytopenia due to bone marrow involvement, or impaired end-organ function at the time of diagnosis are not candidates for conservative treatment. Alternatively, patients can be treated aggressively with combination chemotherapy, with or without rituximab, or radioimmunotherapy early in the disease course. Both conservative and aggressive approaches are listed as possible options in the current NCCN guidelines, but the guidelines recommend that initial therapy should include rituximab unless contraindicated.[64] Patients who respond to induction therapy may receive maintenance therapy with single-agent rituximab.

A recently published observational study of 2,728 patients with newly diagnosed follicular lymphoma treated in the United States from March 2004 to March 2007 showed that approximately two thirds of patients were treated with rituximab, either alone (14%) or combined with chemotherapy (52%).[83] Approximately 18% of patients were treated with observation.

At the time of relapse, many of the same treatment options are available, and the following factors must be considered: age, symptomatic status of the patient, tumor burden, rate of regrowth (based on previous assessment of active disease sites), presence or absence of characteristics suggesting transformation or biologic progression, prior therapy, degree and duration of response to prior therapy, availability of clinical trials, and patient preferences.[64,75]

No Initial Therapy. Because there are no convincing data that standard treatment approaches have improved survival, some clinicians have adopted a "watch-and-wait" approach for asymptomatic patients where therapy is delayed until the patient experiences systemic symptoms or disease progression such as rapidly progressive or bulky adenopathy, anemia, thrombocytopenia, or disease in threatening sites such as the orbit or spinal cord.[82] The median time until treatment is required is 3 to 5 years, and approximately 20% of patients do not require therapy for up to ten years. The ten-year survival is 73%, which is not significantly different from patients who received therapy at the time of diagnosis. In a randomized study of asymptomatic patients with indolent lymphomas (mostly follicular), patients who underwent watchful waiting had similar cause-specific and overall survival as compared with those who received immediate chlorambucil.[84] With a median length of followup of 16 years, approximately 17% of patients who were randomized to the watchful waiting group died of other causes without receiving chemotherapy and an additional 9% are alive and have not yet had chemotherapy. As described above, patients with follicular lymphoma who are followed without therapy sometimes have spontaneous regressions that can be complete while the disease in other patients can convert to a more aggressive histology. If the watchful waiting approach is chosen, the patient should be evaluated at least every 2 months for the first year and quarterly thereafter, so that intervention can occur before serious problems occur.

Chemotherapy. Oral alkylating agents, given either alone or combined with prednisone, have been the mainstay of treatment for follicular lymphoma. More intensive chemotherapy has not been shown to improve patient outcome. In a randomized trial of oral chlorambucil, oral cyclophosphamide, or CVP (cyclophosphamide, vincristine, and prednisone) in patients with indolent lymphoma, no significant difference in overall survival or freedom-from-relapse between the three groups was observed.[77] In a more recently published randomized trial of single-agent cyclophosphamide vs. CHOP-B (CHOP and bleomycin), no significant difference in overall time-to-failure or overall survival was observed at ten years.[85] The dosage of single-agent chlorambucil or cyclophosphamide is usually adjusted to maintain a platelet count above 100,000 cells/mm^3 (100×10^9/L) and a white blood cell count above 3,000 cells/mm^3 (3×10^9/L). Although single-agent alkylating agents have a high initial complete remission rate, the time required to achieve a complete response is slow (median time is 9 to 12 months). Complete responses occur more rapidly with combination chemotherapy, particularly with doxorubicin-containing regimens. Many clinicians will therefore give CHOP or CHOP-like chemotherapy when a rapid response is necessary. The development of the CHOP regimen is described in more detail in the Aggressive Lymphomas section later in this chapter. Table 140–10 shows the CHOP

TABLE 140-10 CHOP Regimen

Drug	Dose (mg/m²)	Route	Treatment Days
Cyclophosphamide	750	IV	1
Doxorubicin	50	IV	1
Vincristine	1.4	IV	1
Prednisone	100	Oral	1–5

One cycle is 21 days

Another name for doxorubicin is hydroxydaunorubicin.

regimen that is widely used in the treatment of NHL. In those who achieve a complete response, the duration of response is relatively short (about 2.5 years). There is no benefit of maintenance therapy with chemotherapy. After the "best" response is achieved, many experts will discontinue therapy and observe.

Both single-agent alkylating agents and CVP are well tolerated by most patients. The advantages of oral chlorambucil are no hair loss, little or no nausea, and minimal myelosuppression. Because of its mild side effect profile, oral chlorambucil is usually recommended for older patients who are minimally symptomatic or who have other comorbidities. There are some concerns with the risk of secondary acute leukemia in patients receiving continuous exposure to alkylating agents.

Bendamustine. Bendamustine is an alkylating agent with structural similarities to both alkylating agents and purine analogs.[86] The mechanism of action of bendamustine appears to be different from other alkylating agents and it does not show cross-resistance to other alkylating agents. When used as a single agent, bendamustine shows antitumor activity in relapsed or refractory indolent lymphomas. Overall and complete response rates of 70% to 80% and 30% to 35% have been reported, respectively, in phase II trials. Bendamustine received FDA approval for relapsed or refractory indolent NHL in October 2008.

Purine Analogs. Several studies report encouraging results with two adenosine analogs, fludarabine phosphate and cladribine (2-chlorodeoxyadenosine), in previously untreated and relapsed advanced follicular lymphoma.[87] The mechanism of action for both drugs is not well understood, but both agents accumulate in lymphocytes and are resistant to adenosine deaminase. In patients with relapsed or refractory indolent lymphoma, single-agent fludarabine has an overall response rate of almost 50% and a complete response rate of 10% to 15%. Response rates are higher in previously untreated patients, with overall and complete response rates of 70% and almost 40%, respectively. The median time to progression is less than 6 months for relapsed disease and more than 12 months for previously untreated patients. Although the response rates to 2-chlorodeoxyadenosine in previously untreated patients is similar to those with fludarabine, the duration of response appears to be shorter with 2-chlorodeoxyadenosine.

Combination regimens that include one of these purine analogs are also being investigated.[87] Fludarabine and mitoxantrone (FN) and fludarabine, mitoxantrone, and dexamethasone (FND), given with or without rituximab, are examples of fludarabine-containing regimens that show encouraging results in patients with indolent lymphoma. Fludarabine plus rituximab and FND plus rituximab are listed as acceptable first-line options for follicular lymphoma (Category 2A).[64]

Purine analogs usually do not cause nausea and vomiting or hair loss, but they are associated with cumulative and prolonged myelosuppression and profound immunosuppression, which increases the risk of opportunistic infections, such as fungal infections, *Pneumocystis jiroveci* pneumonia, and viral infections. Because the use of fludarabine-based regimens may impair stem cell mobilization and collection, some experts avoid fludarabine-based regimens for patients who are potential candidates for autologous HSCT.

Interferon-α. Single-agent interferon-α (IFN-α) is active in the treatment of follicular lymphoma, but is not curative. Several randomized controlled trials have evaluated the potential benefit of adding IFN-α to combination chemotherapy. Based on the results of one of these trials, IFN-α_{2b} (Intron® A) was granted FDA approval as initial treatment for patients with clinically aggressive follicular lymphoma and a large tumor burden, in combination with an anthracycline-containing regimen. Its approval was based on the Groupe d'Etude des Lymphomes Folliculaires (GELF) trial, which compared CHVP (cyclophosphamide, doxorubicin, teniposide, and prednisone) to CHVP and IFN-α_{2b}.[88] CHVP was given monthly for six cycles, then every two months for six more cycles, whereas IFN-α_{2b} was given at a dose of 5 million units three times a week for 18 months. Patients who received concurrent IFN-α_{2b} had a significantly higher response rate (85% vs. 69%), which translated into significant differences in median progression-free survival (2.9 years vs. 1.5 years) and overall survival (not reached vs. 5.6 years).

At least 10 randomized controlled trials in the United States and Europe have evaluated the role of IFN-α either during induction, as maintenance therapy, or in both settings. The results of these trials have been inconsistent.[89] In a meta-analysis of more than 1,500 newly diagnosed patients from the various randomized trials, the efficacy of IFN-α depended on the intensity of the initial chemotherapy regimen and the IFN-α dose.[90] The major conclusion of the meta-analysis was that IFN-α was probably beneficial in patients receiving relatively intensive initial chemotherapy (anthracycline or anthracene-containing regimen) and at a dose of ≥5 million units ($\geq 36 \times 10^6$ units per month).

In the most recent randomized controlled trial, 571 patients with stage III or IV indolent NHL (mostly follicular) were studied as part of a SWOG trial. Patients who responded to intensive chemotherapy that consisted of six to eight cycles of prednisone, methotrexate, doxorubicin, cyclophosphamide, and etoposide/mechlorethamine, vincristine, procarbazine, and prednisone (ProMACE-MOPP) or chemotherapy plus irradiation therapy were randomized to receive either consolidation IFN-α_{2b} (2 million units/m² given subcutaneously three times weekly) for two years or observation.[91] With a median follow-up of more than six years, no difference in progression-free or overall survival was observed.

The reasons for the divergent results cannot be easily explained.[89] Based on these negative results, the significant cost and toxicities associated with this agent and the recent availability of other treatment options, most clinicians no longer use IFN-α in patients with indolent lymphomas.

Rituximab. The approval of rituximab is arguably the most important recent development in the treatment of NHL. Its initial approval in 1997 was based on an open-label multicenter study that enrolled 166 patients with relapsed or recurrent indolent lymphoma.[92] Rituximab, given intravenously at a dose of 375 mg/m² weekly for four weeks, resulted in an overall response of 48% (complete response: 6%, partial response: 42%). Median time to progression for responders was 13.2 months and median duration of response was 11.6 months. Other studies of single-agent rituximab in patients with relapsed or refractory indolent NHL have reported overall response rates of 40% to 60% and complete response rates of 5% to 10%.[93]

Based on the activity of rituximab in relapsed or refractory patients, it is currently being used as first-line therapy, either alone or in combination with chemotherapy.[74,83,93,94] When given as a single agent to patients with previously untreated indolent NHL, the overall response rate is 60% to 70% and the complete response rate is 20% to 30%. It is interesting to note that many of these patients remain

in molecular remission (i.e., polymerase chain reaction–negative) at 12 months. Single-agent rituximab is listed as an acceptable option for first-line therapy of follicular lymphoma, particularly for patients who cannot tolerate more intensive chemotherapy regimens.[64]

The rationale for the use of rituximab in combination with conventional agents is based on clinical activity of both agents/regimens, non–cross-resistant mechanisms of action, nonoverlapping toxicities, and synergistic antitumor activity in vitro. Many clinical trials have evaluated the use of rituximab in combination with other chemotherapy agents. In a phase II trial of six courses of R-CHOP, the overall and complete response rate in 40 patients with previously untreated or relapsed indolent lymphoma was 95% and 55%, respectively.[95] More than 70% of patients were progression-free after 4 years of followup. In an updated analysis, median time-to-progression was reached at 82 months.[96] Based on these encouraging results, several randomized controlled trials have evaluated rituximab in combination with various chemotherapy regimens in first-line therapy for follicular or other indolent lymphomas.[74,94] In the R-CHOP vs. CHOP trial, patients who were randomized to receive R-CHOP as initial therapy had significantly higher overall response rates (96% vs. 90%), reduced risk for treatment failure (relative risk 0.4), and longer time-to-treatment failure and overall survival.[97] In another randomized trial of R-CHOP versus CHOP in relapsed or resistant follicular lymphoma, patients treated with R-CHOP had higher overall and complete response rates (85% vs. 72% and 30% vs. 16%, respectively) and lower risk of treatment failure (hazard ratio [HR] 0.65), but no significant difference in overall survival was observed.[98] Similar results were reported when rituximab was added to other combination regimens.[74,94] In a meta-analysis of all randomized controlled trials, patients with indolent lymphoma treated with rituximab and chemotherapy had a significantly higher overall response rate and reduced risk of treatment failure (HR 0.62) and death (HR 0.65).[99] In 2006, rituximab was FDA-approved for first-line therapy for follicular lymphoma in combination with CVP chemotherapy. R-CHOP is listed as an acceptable option for first-line therapy of follicular lymphoma (Category 1).[64]

Rituximab and CHOP chemotherapy can be combined in many different ways.[100] In the R-CHOP regimen developed by Czuczman et al., two doses of rituximab are given before the start of CHOP therapy; two more doses are given in the middle of the six cycles of CHOP; and two additional doses are given at the end of CHOP therapy.[95] However, in most NHL protocols and in clinical practice, rituximab is given on day 1 of CHOP chemotherapy.[100] In some protocols, rituximab is given on the day before chemotherapy (i.e., day 0) or rituximab is given on day 1 and the other drugs are given on day 3.

Although R-CHOP is the most commonly used chemoimmunotherapy regimen, other regimens may have similar antitumor activity. Bendamustine and rituximab (BR) has been evaluated in rituximab-refractory NHL. In a phase II trial, the overall and complete response rate to BR was 92% and 55%, respectively.[101] In a randomized controlled trial of first-line therapies for advanced indolent NHL, patients who received BR had a higher complete response rate (40% vs. 30%) and longer median progression-free survival (55 vs. 35 mos) as compared with those who received R-CHOP.[102] The BR regimen was tolerated better than R-CHOP. Based on these results, BR is listed as an acceptable option for first-line therapy of follicular lymphoma (Category 2A).[64]

In patients who respond to rituximab, either alone or combined with chemotherapy, maintenance therapy with single-agent rituximab is often given to prolong the duration of remission. In a phase II study, patients with indolent lymphoma who responded to first-line single-agent rituximab received maintenance rituximab, given at a dose of 375 mg/m^2 weekly for 4 weeks every 6 months, in an attempt to improve the initial therapeutic response and prolong duration of remission.[103] With continued maintenance therapy, the final response rate increased to 73%, with 37% complete responses. Median progression-free survival was 34 months. Based on these encouraging results, several randomized controlled trials were initiated in previously untreated or chemotherapy-treated patients with indolent lymphoma.[74,82,94] Patients in these trials received induction therapy with either single-agent rituximab or combination chemotherapy with or without rituximab. Several different maintenance rituximab schedules have been used in these trials: 375 mg/m^2 weekly for 4 weeks every 6 months for 2 years; 375 mg/m^2 weekly × 4 in months 3 and 9 following induction therapy; 375 mg/m^2 every 2 to 3 months for 1 to 2 years; and 375 mg/m^2 every 2 months for 8 months.[74,94,100] Administration every 2 to 3 months is supported by the observation that therapeutic rituximab levels are maintained for about 3 months.[100] A meta-analysis of five randomized controlled trials of maintenance rituximab showed that the effect on overall survival depended on the treatment setting.[104] Patients with refractory or relapsed follicular lymphoma who received maintenance rituximab had a significant improvement in overall survival (hazard ratio 0.58, 95% CI [confidence interval] 0.42 – 0.79) while patients with previously untreated disease had no significant overall survival benefit.[104]

CLINICAL CONTROVERSY

Maintenance rituximab is often used in patients with indolent lymphoma who respond to induction chemoimmunotherapy. While maintenance rituximab has been shown to prolong overall survival in patients with refractory or relapsed disease, no consistent survival benefit has been observed in newly diagnosed patients. Various dosing schedules have been used.

Although rituximab is FDA approved as maintenance therapy for patients with stable disease or who achieve a partial or complete response following induction chemotherapy, its use in patients with newly diagnosed follicular lymphoma is controversial.[105,106] The FDA approval was based on a randomized controlled trial in previously untreated patients with advanced-stage follicular lymphoma treated with maintenance rituximab after CVP chemotherapy.[107] Three-year progression-free survival was significantly longer in the maintenance rituximab group as compared with the observation group (68% vs. 33%). However, only approximately 3% of patients with newly diagnosed follicular lymphoma are treated with chemotherapy alone in the United States.[83] No consistent overall survival benefit has been observed with maintenance rituximab and none of the trials used rituximab combined with CHOP (or CHOP-like) as induction therapy. Furthermore, maintenance rituximab is expensive and associated with adverse effects, including an increased risk of grades 3 or 4 infections.[104] The NCCN guideline lists rituximab maintenance as an option in both first- and second-line therapy, but the strength of the recommendation depends on the treatment setting.[64] The recommendation in refractory or relapsed patients (i.e., second-line therapy) is considerably stronger (category 1, based on high-level evidence) than the recommendation in previously untreated patients (i.e. first-line therapy [category 2B, based on lower-level evidence]).

Most of the adverse effects of rituximab are infusion-related, particularly after the first infusion, and consist of fever, chills, respiratory symptoms, fatigue, headache, pruritus, and angioedema.[94] Premedication with oral acetaminophen 650 mg and diphenhydramine 50 mg is usually given 30 minutes before rituximab infusion. Reactivation of hepatitis B has been reported in patients receiving chemotherapy, either alone or combined with rituximab.[108] Hepatitis B testing is recommended in patients who are considering rituximab therapy.[64]

Radioimmunotherapy. The recent approval of the anti-CD20 radioimmunoconjugates—^{131}I-tositumomab (Bexxar) and ^{90}Y-ibritumomab tiuxetan (Zevalin)—has provided clinicians with a novel treatment option for patients with indolent NHLs.[74,109,110] Both ^{131}I-tositumomab and ^{90}Y-ibritumomab tiuxetan are mouse antibodies linked to a radioisotope, either iodine-131 (^{131}I) or yttrium-90 (^{90}Y). Indolent lymphomas are known to be responsive to radiation therapy (i.e., radiosensitive), and the rationale of radioimmunotherapy is that the antibody will act as a guided missile to deliver its payload (i.e., radiation) to its target (i.e., lymphoma cells that express the CD20 antigen). The specificity of the monoclonal antibody allows delivery of the radiation selectively to the tumor (and adjacent normal tissues).

Radioimmunoconjugates have some advantages and disadvantages over unlabeled ("naked") monoclonal antibodies such as rituximab. Tumor cell kill following rituximab depends on binding of the antibody to the tumor cell and the host immune system. Therefore, tumor cells that do not express the target antigen are not accessible to the antibody, or those that are resistant to immune-mediated attacks may escape treatment. Radioimmunoconjugates, because of their ability to deliver radiation over a distance from a source, can not only kill tumor cells that are in contact with the antibody, but also adjacent tumor cells which may not have been in contact with the antibody or may not express the target antigen. This effect is sometimes referred to as the relevant bystander or crossfire effect. However, one disadvantage of radioimmunotherapy is that it can also damage adjacent normal tissues, such as bone marrow cells.

Both ^{131}I-tositumomab and ^{90}Y-ibritumomab tiuxetan have shown activity in relapsed and refractory patients with indolent or transformed lymphomas.[109,110] In patients who respond to radioimmunotherapy, the duration of remission can be more than several years. Although radioimmunotherapy is usually reserved for second-line therapy of follicular lymphoma, some clinicians consider radioimmunotherapy earlier in the disease course, including for patients with previously untreated disease. In a phase II study, patients with previously untreated follicular lymphoma were treated with six cycles of CHOP chemotherapy followed 4 to 8 weeks later by ^{131}I-tositumomab.[111] The overall response rate to the entire treatment regimen was 91%, including 69% complete remissions, and the five-year progression-free survival is estimated to be 67%. Similar results were reported in a phase II trial of ^{131}I-tositumomab given without induction CHOP chemotherapy in previously untreated patients with advanced-stage follicular lymphoma.[112] A current multicenter cooperative group study (SWOG S0016) randomizes previously untreated patients with advanced indolent lymphomas to either CHOP or rituximab (given concurrently, based on the Czuczman regimen[95]) or CHOP and ^{131}I-tositumomab (given sequentially).

Radioimmunotherapy is generally well-tolerated. The major acute toxicities with both radioimmunoconjugates are infusion-related reactions and myelosuppression. ^{131}I-tositumomab can also cause thyroid dysfunction. The primary concern with radioimmunotherapy is the development of treatment-related myelodysplastic syndrome or acute myelogenous leukemia.[113]

The decision to use radioimmunotherapy must be made carefully because of the complexity, risks, and costs of the treatment regimen. Because of safety concerns related to delivery of radiation to bone marrow, candidates for radioimmunotherapy usually have limited bone marrow involvement and adequate absolute neutrophil and platelet counts. Although medical oncologists usually select patients for therapy, the radioimmunotherapy regimen must be administered at a radiation oncology or nuclear medicine facility.

Hematopoietic Stem Cell Transplantation. High-dose chemotherapy, followed by autologous or allogeneic HSCT, is another option for patients with relapsed follicular lymphoma.[75,114,115] In patients who are transplanted at the time of initial treatment failure, five-year event-free survival is approximately 40% to 50%. Although the rate of recurrence is lower after allogeneic HSCT as compared with autologous HSCT, that benefit is offset by increased treatment-related mortality after allogeneic HSCT. The presence of a survival plateau after allogeneic HSCT suggests that some patients may be cured of their disease.

A panel of follicular lymphoma experts recently published their recommendations, which stemmed from an evidence-based review.[115] Their recommendations are: (1) autologous HSCT is recommended as salvage therapy based on pre-rituximab data, with a significant improvement in progression-free and overall survival; (2) autologous HSCT is not recommended as consolidation therapy after first-line chemotherapy for most patients because of no significant improvement in overall survival; (3) autologous HSCT is recommended for transformed follicular lymphoma patients; (4) reduced-intensity conditioning before allogeneic HSCT appears to be an acceptable alternative to myeloablative regimens; and (5) an HLA-matched unrelated donor appears to be as effective as an HLA-matched related donor for reduced intensity conditioning allogeneic HSCT. There are insufficient data to make a recommendation on the use of autologous HSCT after rituximab-based salvage therapy.

Rituximab is being evaluated in the setting of autologous HSCT.[93,116] It is given pretransplant as an in vivo purging agent prior to stem cell collection. In other studies, rituximab is given as posttransplant consolidation.

AGGRESSIVE LYMPHOMAS

Diffuse Large B-Cell Lymphoma

Diffuse large B-cell lymphomas (DLBCLs) are the most common lymphoma in the International NHL Classification Project, accounting for approximately 30% of all NHLs.[76,117] DLBCLs are characterized by the presence of large cells, which are similar in size to or larger than tissue macrophages and usually more than twice the size of normal lymphocytes. The median age at the time of diagnosis is in the seventh decade, but DLBCL can affect individuals of all ages, from children to the elderly. Patients often present with a rapidly enlarging symptomatic mass, with B symptoms in approximately 30% to 40% of cases.[63,117] Approximately 30% to 40% of patients with DLBCL present with extranodal disease; common sites include the head and neck, gastrointestinal tract, skin, bone, testis, and CNS. DLBCL is the most common type of diffuse aggressive lymphomas, which are characterized by an aggressive clinical behavior that leads to death within weeks to months if the tumor is not treated. Diffuse aggressive lymphomas are also sensitive to many chemotherapeutic agents, and some patients treated with chemotherapy can be cured of their disease.

Several factors have been shown to correlate with response to chemotherapy and survival in patients with aggressive lymphoma.[69] Because the IPI was originally developed based on patients with aggressive lymphoma, IPI score correlates with prognosis (Table 140–8).[66] As described above, the revised IPI score may more accurately predict prognosis in patients receiving rituximab-containing combination chemotherapy.[67]

Therapy of DLBCL is based on the Ann Arbor stage, IPI (or revised IPI) score, and other prognostic factors.[117] About one half of patients present with localized (stage I or II) disease. However, many patients present with large bulky masses (i.e., larger than 10 cm), and patients with bulky stage II disease are treated with the same approach used for patients with advanced disease (stage III or IV).

Treatment of Localized Disease (Stages I and II) Before 1980, radiation therapy was the primary treatment for patients with localized DLBCL. Five-year disease-free survival with radiation therapy alone was approximately 50% and 20% in patients with stage I and stage II disease, respectively.[117,118] Randomized trials in the 1980s showed that radiation therapy followed by chemotherapy resulted in significantly longer disease-free and overall survival as compared with radiation therapy alone. Other studies reported excellent results with a short course of chemotherapy (three cycles) followed by involved-field radiotherapy or six to eight cycles of CHOP chemotherapy, with or without consolidation radiotherapy. With either of these approaches, five-year progression-free survival was >90% for patients with stage I disease and approximately 70% for patients with stage II disease.[117,118]

Because the more effective approach was not clear, the SWOG performed a randomized trial that compared three cycles of CHOP and involved-field radiotherapy or eight cycles of CHOP in patients with stage I and nonbulky stage II aggressive lymphoma.[119] Patients treated with three cycles of CHOP plus radiotherapy had significantly better 5-year progression-free (77% vs. 64%) and overall (82% vs. 72%) survival than did patients treated with CHOP alone. The incidence of life-threatening toxicity was higher in patients who received CHOP alone. But with longer followup, more patients who received abbreviated chemotherapy experienced late relapses and the differences in progression-free or overall survival were no longer significant between the two arms. Further subgroup analysis of that trial identified several prognostic factors that led to the development of the stage-modified IPI score.[118] Four adverse risk factors comprise the score: nonbulky stage II disease (bulky stage II disease is considered advanced disease), age >60 years, elevated LDH levels, or performance status ≥2.

The stage-modified IPI score is often used to identify patients with localized aggressive NHL who may have a poor prognosis. Based on the results of this trial, the current standard for therapy of most patients with localized nonbulky aggressive lymphoma without any adverse risk factors is three to four cycles of R-CHOP followed by locoregional radiation therapy (30 to 40 Gy [3000 to 4000 rad]).[64,117] Five-year median survival in this favorable group of patients exceeds 90%.[118]

Five-year median survival is reduced to approximately 70% in patients with at least one adverse risk factor in the stage-modified IPI score.[118] Patients in this high-risk subgroup may benefit from more aggressive chemotherapy (six to eight cycles of R-CHOP) followed by locoregional radiation therapy.[64]

Treatment of Advanced Disease (Bulky Stage II, Stages III and IV) It has been known since the late 1970s that intensive combination chemotherapy can cure some patients with disseminated DLBCL.[117] Initial studies with COP (same as CVP) produced a plateau on the survival curve of just 10%, with a median survival of less than one year. Based on the activity of single-agent doxorubicin, McKelvey et al. developed the CHOP regimen (Table 140–10).[120] A few years later, a SWOG study showed that CHOP was more active than COP, and CHOP chemotherapy rapidly became the treatment of choice for patients with aggressive lymphomas.[121] Studies in larger numbers of patients showed that approximately 50% of patients had a complete remission to CHOP chemotherapy, and 50% to 75% of the patients who had a complete response (about one third of all patients) experienced long-term disease-free survival and cure of their disease.

In an effort to improve these results, many investigators used several general approaches to develop second- and third-generation regimens in the 1980s.[117] Results of phase II trials suggested that these second- and third-generation regimens were more active than CHOP, with slightly higher complete response rates and improved disease-free survival rates. However, they were also more difficult to administer, more toxic, and more expensive. Based on these results, many oncologists adopted one of these second- or third-generation combination regimens as their standard regimen for patients with advanced aggressive lymphomas.

Many randomized studies have compared different combination regimens in patients with aggressive lymphoma.[56,117] Although the results of these studies show that no one regimen is clearly superior to another, they demonstrate the superiority of anthracycline-containing regimens over those that do not contain an anthracycline. In the largest and most widely quoted study, the SWOG initiated a randomized trial in 1986 that compared CHOP to three of the most commonly used third-generation regimens in nearly 900 patients with bulky stage II, stage III, or stage IV aggressive NHL. At the time of the initial publication (median followup: 35 months), no differences in disease-free and overall survival were observed between the four groups.[122] Furthermore, no significant differences in disease-free or overall survival were observed in any subgroup of patients. But the risk of treatment-related mortality was higher in patients receiving one of the third-generation regimens. Extended followup of that trial shows that approximately 35% of patients who participated in that trial are probably cured of their disease, regardless of the initial combination chemotherapy regimen.[118] Interestingly, the overall survival is approximately 10% higher than the disease-free survival, which probably reflects the effectiveness of salvage high-dose chemotherapy with autologous HSCT (see the Treatment of Refractory or Relapsed Disease section later in this chapter).

Based on the lack of survival benefit with the newer combination chemotherapy regimens, the less complicated and less expensive CHOP regimen was considered as the treatment of choice for most patients with DLBCL and other aggressive NHLs for many years. Even with CHOP chemotherapy, however, less than 50% of patients with DLBCL were cured of their disease and most patients who relapse after an initial response do so in the first two years. New treatment approaches were clearly needed.

Several studies attempted to improve treatment results by increasing chemotherapy dose (i.e., dose-intensity), shortening the interval between chemotherapy cycles (i.e., dose-density), or both. Because of the increased risk of severe neutropenia, these approaches require growth factor support. Although results of these studies have not consistently shown improved survival, encouraging results from several recently published studies suggest that these approaches be evaluated in future randomized trials.[123,124]

Based on the encouraging results of R-CHOP in indolent lymphomas, several studies evaluated this combination in aggressive lymphomas.[94,118] The first randomized controlled trial that established the efficacy of R-CHOP in advanced-stage DLBCL showed that R-CHOP significantly increased complete response rates and overall survival in elderly (≥60 years old) patients as compared with CHOP alone (discussed in the Treatment of Elderly Patients with Advanced Disease section later in this chapter).[125] Although the results of that study established R-CHOP as standard therapy in older patients, the role of R-CHOP in the treatment of younger patients was not clear. That issue was recently addressed in the MabThera International Trial, which enrolled younger (18 to 60 years old) patients with good-prognosis DLBCL.[126] Patients randomized to receive rituximab plus CHOP-like chemotherapy had significantly higher complete response rates (86% vs. 68%) and longer three-year event-free and overall survival (79% vs. 59% [HR 0.44] and 93% vs. 84% [HR 0.40], respectively). Furthermore, in a population-based study conducted in British Columbia, institution of a policy recommending R-CHOP for all patients with newly diagnosed advanced-stage DLBCL resulted in significant improvements in progression-free and overall survival.[127] Based on these trial results, rituximab received FDA approval for first-line

treatment in combination with CHOP or CHOP-like chemotherapy and R-CHOP is recommended for all patients with advanced-stage DLBCL in the current NCCN guideline.[64]

Treatment outcomes for high-risk patients according to the IPI (or revised IPI) score are unsatisfactory. High-risk groups generally include all patients older than 60 years and those with an IPI score of ≥3 (or an age-adjusted IPI score of ≥2). Because progression-free survival is only approximately 50% in these high-risk patients treated with R-CHOP,[67,128] other more aggressive treatments, preferably as part of a clinical trial, should be considered in these patients. Examples of more aggressive approaches include dose-intense or dose-dense chemotherapy with growth factor support, usually combined with rituximab, or high-dose chemotherapy with autologous HSCT.[117,118,129]

One approach is to give high-dose chemotherapy with autologous HSCT as intensive consolidation in high-risk patients with DLBCL who achieve a remission with standard chemotherapy.[117,130] Several randomized controlled trials have been conducted in patients with aggressive NHLs, and no consistent survival advantage has been reported. A recently published meta-analysis of all randomized controlled trials of autologous HSCT as intensive consolidation in aggressive NHL concluded that there was no evidence that autologous HSCT improved outcomes in good-risk patients.[131] The evidence for high-risk patients was inconclusive.

CLINICAL CONTROVERSY

Because of high relapse rate in patients who have a complete response to R-CHOP, some experts believe that high-dose chemotherapy with autologous HSCT should be considered as consolidation therapy in high-risk patients with aggressive NHLs who have a complete remission to R-CHOP chemotherapy. Other experts, however, believe that the evidence supporting high-dose chemotherapy with autologous HSCT in this setting is inconclusive and that autologous HSCT should be reserved for patients who relapse.

11 In summary, all patients with bulky stage II, stage III, or stage IV disease should be treated with R-CHOP or rituximab and CHOP-like chemotherapy until a complete response is achieved (usually four cycles).[64] Clinicians are encouraged to adopt the revised response criteria proposed by the International Working Group.[65] In patients who have a positive pretreatment PET scan, PET scanning can be useful in response assessment. A rapid response to chemotherapy (i.e., a complete response achieved in the first three treatment cycles) is associated with a more durable remission compared with patients requiring longer treatment cycles. Two or more cycles of chemotherapy should be given following attainment of a complete response (total of six to eight cycles). The use of long-term maintenance therapy following a complete response has not been shown to improve survival. Treatment outcomes for high-risk patients according to the IPI (or revised IPI) score are unsatisfactory and alternative treatment approaches, preferably as part of a clinical trial, should be considered in these patients.[64] High-dose chemotherapy with autologous HSCT should be considered in high-risk patients who respond to standard chemotherapy and are candidates for autologous HSCT.

Treatment of Elderly Patients with Advanced Disease More than one half of patients with NHL are older than 60 years of age at diagnosis, and about one third are older than age 70 years. The International Non-Hodgkin Lymphoma Prognostic Factors Project showed that patients older than 60 years of age had a significantly lower complete response rate and overall survival.[66] The reasons for the poorer outcome in elderly patients are not clear. Older patients do not tolerate intensive chemotherapy as well as younger patients, and some studies report that older patients have a higher risk of treatment-related mortality. As a result, many clinicians treat elderly patients with reduced dose or less-aggressive chemotherapy regimens. In general, these less-intensive regimens have used anthracyclines with less cardiotoxicity than doxorubicin, have substituted mitoxantrone for doxorubicin, or have used short-duration weekly therapy.[117]

Over the past few years, several nonrandomized and randomized trials have evaluated different treatment approaches in older patients with aggressive NHL.[117] The results of these studies suggest that carefully selected elderly patients with good performance status and without significant comorbidities can tolerate aggressive anthracycline-containing regimens as well as younger patients. These patients should be treated initially with full-dose R-CHOP or similar regimens; dosages can be reduced later if severe toxicity occurs. Hematopoietic growth factors may allow elderly patients to maintain dose intensity.

The combination of rituximab and CHOP (R-CHOP) has replaced CHOP as standard treatment for elderly patients with aggressive lymphoma, based on the results of the Groupe d'Etude des Lymphomes de l'Adulte (GELA) study.[125] In that study of 399 elderly patients with DLBCL, patients who were randomized to receive R-CHOP had a significantly higher complete response rate (76% vs. 63%) and longer event-free and overall survival as compared with those who received CHOP. In an updated analysis of that trial, significant differences in five-year event-free survival (47% vs. 29%) and overall survival (58% vs. 45%) were observed between the two treatment groups.[128] In another randomized controlled trial conducted primarily in the United States (Eastern Cooperative Group 4494), elderly (≥ 60 years old) patients who received rituximab, either as induction or maintenance with CHOP chemotherapy, had significantly longer failure-free survival as compared with those not given rituximab during their treatment course.[132] Maintenance therapy with single-agent rituximab did not provide any additional benefit in patients who received R-CHOP as induction therapy. It is important to note that rituximab is given differently in the two studies. In the GELA study, rituximab is given on day 1 (the same day that cyclophosphamide, doxorubicin, and vincristine are administered) with each cycle of CHOP chemotherapy.[125] In the Eastern Cooperative Group 4494 study,[132] R-CHOP was modeled after the regimen developed by Czuczman et al: two doses of rituximab are given before cycle 1, and one dose is given before cycles 3, 5, and 7 (if administered).[95] In most NHL protocols and in clinical practice, rituximab is given on day 1 of CHOP chemotherapy.[100]

Dose-dense CHOP, where the interval between cycles is shortened from three weeks to two weeks, has been evaluated in elderly patients (61 to 75 years old) with advanced-stage aggressive NHL by the German High-Grade NHL Study Group. In the first study, patients who were randomized to receive biweekly CHOP (CHOP-14) had significantly longer five-year event-free and overall survival than patients who received standard CHOP every 21 days (CHOP-21).[133] All patients in the CHOP-14 group received prophylactic growth factors starting from day 4. Toxicity was similar between the two groups. In the next study, the same group of investigators evaluated the addition of rituximab (CHOP-14 vs. R-CHOP-14) and the number of treatment cycles (six vs. eight cycles).[134] Patients who received rituximab did better than those who did not, and eight cycles were not better than six cycles. The addition of rituximab to the CHOP-14 regimen resulted in significantly longer three-year event-free and overall survival (67% vs. 47% and 78% vs. 68%, respectively). A higher risk of *Pneumocystis jirovecii* has been

recently reported in patients treated with R-CHOP-14.[135] Dose-dense R-CHOP (R-CHOP-14) is listed as a first-line option in the NCCN guideline (Category 2B).

Treatment of Refractory or Relapsed Disease Although many patients with aggressive NHL experience long-term survival and cure with intensive chemotherapy, approximately 10% to 20% of patients fail to achieve a complete remission and, of those patients who do achieve a complete remission, approximately 20% to 30% subsequently relapse. Therefore, approximately 30% to 40% of all patients with aggressive NHL will require salvage therapy at some point during their disease course. Response to salvage therapy depends on the initial responsiveness of the tumor to chemotherapy. Patients who achieve an initial complete remission and then relapse generally have a better response to salvage therapy than those who are primarily or partially resistant to chemotherapy.

Many conventional-dose salvage chemotherapy regimens have been used in patients with relapsed or refractory NHL. Many patients who respond to salvage therapy (i.e., chemosensitive relapse) will then receive high-dose chemotherapy with autologous HSCT. In an effort to avoid cross-resistance, most salvage regimens incorporate drugs not used in the initial therapy. Some of the more commonly used salvage regimens include DHAP (dexamethasone, cytarabine, cisplatin), ESHAP (etoposide, methylprednisolone, cytarabine, cisplatin), and MINE (mesna, ifosfamide, mitoxantrone, etoposide), and no one regimen appears to be clearly superior to any other regimen.[116,117] Rituximab is sometimes added to these salvage regimens. With these salvage regimens, approximately 30% to 50% of patients achieve a complete response, with a median duration of remission of 1 to 2 years. Only approximately 5% to 10% of patients will have long-term disease-free survival.

ICE (ifosfamide, carboplatin, and etoposide) chemotherapy is a newer regimen that has been used in patients with refractory disease. Some clinicians believe that ICE is better tolerated than older cisplatin-based regimens, particularly in older patients. The combination of ICE and rituximab (RICE) is currently being evaluated as a salvage regimen, and early results are encouraging.[116] Rituximab is given before the first dose of ICE and then weekly during the regimen.

12 To improve the cure rate, many studies have evaluated high-dose chemotherapy with autologous HSCT as intensive consolidation therapy in patients who respond to salvage therapy.[117,130] In the PARMA study, 215 patients with relapsed aggressive NHL who had a response to DHAP salvage therapy were randomized to receive either high-dose chemotherapy or continued DHAP therapy.[136] Patients who received high-dose chemotherapy had significantly longer five-year disease-free survival (46% vs. 12%) and overall survival (53% vs. 32%) than those treated with conventional salvage therapy. Further analysis of that study showed that patients who relapsed within 12 months of their initial diagnosis were less likely to benefit from high-dose chemotherapy than patients who relapsed after 12 months. Based on a review of the available evidence, including the PARMA study, high-dose chemotherapy with autologous HSCT is considered to be the treatment of choice in younger patients with chemotherapy-sensitive relapse.[64,117] High-dose chemotherapy with autologous HSCT is not recommended in patients with untested or chemotherapy-refractory relapse.

Rituximab is being evaluated in the setting of autologous HSCT.[116,130] It can be given pretransplant as an in vivo purging agent prior to stem cell collection and as posttransplant consolidation.

Other Aggressive Lymphomas

Mantle cell lymphoma (MCL) is one of the new disease entities that was previously unrecognized by other classification systems.[118,137] This histologic type was found in 6% of cases in the International Lymphoma Classification Project.[76] The chromosomal translocation t(11;14) occurs in most cases of MCL. MCL usually occurs in older adults, particularly in men, and most patients have advanced disease at the time of diagnosis (Table 140–7). Extranodal involvement is found in approximately 90% of cases. The course of the disease is moderately aggressive; the median overall survival is about three years, with no evidence of a survival plateau.

Patients with disseminated MCL are usually treated with the same intensive combination chemotherapy regimens that are used in diffuse aggressive lymphomas. One widely used combination regimen is HyperCVAD (cyclophosphamide, vincristine, doxorubicin, dexamethasone alternating with methotrexate and cytarabine) with or without rituximab. Overall response rates to these regimens is approximately 90%, with about two thirds of patients achieving a complete response.[137] Because MCL usually expresses CD20, rituximab, either alone or combined with CHOP, has been used with some success in patients with newly diagnosed and relapsed MCL.[94,118,137] In a meta-analysis of randomized controlled trials, the addition of rituximab to combination chemotherapy was associated with improved overall survival (HR 0.60).[99] Despite the high response rates, MCL is not considered curable with standard chemotherapy. Consequently, younger patients who have an initial response to chemotherapy often undergo autologous or allogeneic HSCT as consolidation therapy.[137] The NCCN guideline recommends that patients with advanced-stage MCL be treated initially with rituximab and combination chemotherapy, followed by autologous HSCT as first-line consolidation therapy.[64] Unfortunately, most patients with MCL eventually relapse and are treated with salvage therapy or enrolled in trials of investigational agents, some of which are aimed at molecular targets. Bortezomib (Velcade®) received FDA approval in 2006 for treatment of relapsed or refractory MCL based on the results of a phase II study that showed a 33% response rate.[138]

NON-HODGKIN LYMPHOMA IN ACQUIRED IMMUNE DEFICIENCY SYNDROME

The risk of NHL for patients with AIDS is increased more than 100-fold as compared with the general population.[139,140] AIDS-related lymphoma arises as a consequence of long-term stimulation and proliferation of B lymphocytes from HIV and the reactivation of prior EBV infection as a consequence of HIV-induced immunosuppression. AIDS-related lymphoma usually occurs late in the course of HIV infection and is the cause of death in approximately 15% of HIV-infected individuals. Although HIV infects T cells, more than 95% of AIDS-related lymphomas are B-cell neoplasms. Most cases of AIDS-related lymphomas are classified as Burkitt or DLBCL.

The clinical presentation is similar to that observed in other immunocompromised states. Most patients with AIDS-related lymphoma present with B symptoms and have advanced-stage (III or IV) disease at the time of diagnosis.[139] Involvement of extranodal sites is common. The clinical course of AIDS-related lymphoma is usually aggressive and has improved with the availability of highly active antiretroviral therapy (HAART). Improved survival has been observed, primarily in patients with DLBCL. Patients with AIDS-related lymphoma treated with intensive therapy have a median survival that is similar to the survival of patients with HIV-negative NHLs.[140] In the post-HAART era, many of the prognostic factors have also changed and only lymphoma-related factors such as the IPI remain as independent predictors of prognosis.

The treatment of patients with AIDS-associated lymphomas is difficult because the immunocompromised state of these patients increases their risk of significant toxicity as a consequence of myelosuppressive therapy. Except for primary CNS lymphoma, AIDS-related lymphoma is never considered truly localized and systemic chemotherapy is indicated. For patients with adequate immune function and without a history of an opportunistic infection,

chemotherapy regimens similar to that used for aggressive lymphomas may be used.[64,139,140] However, many patients with AIDS-related lymphoma were previously treated with less-intensive regimens because of the increased risk of treatment-related toxicity. In the post-HAART era, however, most clinicians believe that standard doses of chemotherapy can be safely administered to patients who achieve a virologic response to HAART.

The results of treatment with standard chemotherapy regimens have been disappointing, particularly in patients with Burkitt lymphoma. In patients with DLBCL, the complete response rate with combination chemotherapy is approximately 40% to 50%, with 5-year overall survival rates of approximately 20% to 30%. Newer approaches, such as the dose-adjusted EPOCH (etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin) regimen developed at the National Cancer Institute, appear promising. The role of rituximab in the treatment of AIDS-related DLBCL is not clear. In a randomized trial of CHOP versus R-CHOP, no significant differences in progression-free and overall survival were observed.[141] However, 14% of patients treated with R-CHOP died of treatment-related infection as compared with only 2% of those in the CHOP group.

The optimal timing for HAART is not clear in patients with AIDS-related lymphoma.[139,140] If HAART is given concurrently with chemotherapy, patients should be monitored closely for possible pharmacokinetic interactions between HAART and chemotherapy. Some experts suggest that HAART should be withheld until the completion of chemotherapy to allow administration of full chemotherapy doses and to avoid the risk of pharmacokinetic interactions. Prophylactic antibiotics should be continued during chemotherapy and intrathecal chemotherapy should be administered to prevent CNS relapses.

EVALUATION OF THERAPEUTIC OUTCOMES

Hodgkin and non-Hodgkin lymphomas tend to respond well to radiation, chemotherapy, and biologic therapy. The goal of therapy for patients with Hodgkin lymphoma and aggressive NHL is long-term survival and cure. The therapeutic goal in patients with indolent NHLs is less clear because of the indolent nature of the disease and the lack of convincing evidence showing that therapy prolongs survival. Therapeutic responses should be evaluated based on physical examination, radiologic evidence, PET/CT scanning, and other positive findings at baseline. Patients with Hodgkin lymphoma and aggressive NHLs are usually evaluated for response at the end of four cycles of therapy or at the end of treatment if fewer than four cycles of therapy are planned. If patients are treated with chemotherapy alone, two additional cycles of chemotherapy are given after the patient has achieved a complete remission. Recent studies have also shown that early interim PET scans may possess prognostic value in patients with advanced Hodgkin lymphoma. The rapidity of response to therapy in patients with indolent NHL depends on the choice of therapy. Responses occur slowly with therapy with oral alkylating agents, but occur much more rapidly with aggressive therapies such as combination chemotherapy with or without rituximab. If radiation alone is used, then a therapeutic evaluation should occur at the end of treatment.

CONCLUSIONS

Several decades ago, lymphomas were considered a fatal disease. Today, most patients with Hodgkin lymphoma and many patients with aggressive NHLs can be cured with radiation therapy, chemotherapy, or a combination of radiation and chemotherapy. Our ability to achieve long-term survival and cure in these patients is the result of many factors, including development of accurate and reproducible classification systems; a more uniform approach to the staging of lymphoma; and advances in treatment strategies, especially the use of intensive combination chemotherapy. The routine use of hematopoietic growth factors allows oncologists to maintain dose intensity, which may be important for the treatment of aggressive lymphomas. The use of high-dose chemotherapy with autologous HSCT as intensive consolidation therapy for selected patients with aggressive NHLs who respond to initial induction therapy or as salvage therapy after relapse for patients with Hodgkin lymphoma or aggressive NHLs has also contributed to increased cure rates.

New treatment approaches are needed, particularly for indolent NHLs. One of the most exciting therapies is biologic therapy with anti-CD20 monoclonal antibodies. The recent approval of radiolabeled anti-CD20 antibodies (i.e., radioimmunoconjugates) provides another therapeutic option for these patients. There is some evidence that these new therapies have changed the natural history of the disease. It is important to better understand how to use these new agents, either alone or combined with standard chemotherapy. Although approximately one half of patients with aggressive lymphomas can be cured of their disease, many patients will relapse and eventually die of their disease. More effective induction chemotherapy regimens are needed for newly diagnosed patients, and more active salvage therapy is needed for patients with relapsed aggressive NHLs.

The goal for the future is to develop treatment modalities to achieve cure in a larger number of patients. But the acute and chronic toxicities associated with treatment must also be considered, particularly in elderly patients and those with significant comorbidities. Consideration of long-term toxicities is of particular concern to patients with Hodgkin lymphoma because of the high cure rate.

Finally, a better understanding of the pathogenesis of NHL through continued research in molecular biology and immunology will hopefully lead to the development of specific therapies aimed at molecular targets. In addition, gene expression profiling may also allow researchers to identify new clinically important subtypes of NHL and to identify subgroups of patients who do respond poorly to standard therapy.

CHAPTER 141

Ovarian Cancer

JUDITH A. SMITH AND JUDITH K. WOLF

KEY CONCEPTS

1. Ovarian cancer is denoted "the silent killer" because of the nonspecific signs and symptoms that contribute to the delay in diagnosis. The few patients who present with disease still confined to the ovary will have a 5-year survival rate greater than 90%, but most patients present with advanced disease and have a 5-year survival rate of 10 to 30%.
2. Ovarian cancer is a sporadic disease with less than 10% of cases of ovarian cancer attributed to heredity. However, a history of two or more first-degree relatives with ovarian cancer increases a woman's risk of developing ovarian cancer by greater than 50%.
3. CA-125 is a nonspecific antigen used as a tumor marker for diagnosis and monitoring epithelial ovarian carcinoma. If CA-125 is positive at the time of diagnosis, changes in CA-125 levels correlate with disease response and progression.
4. Although most patients will achieve a complete response to initial treatment, over 50% will have recurrence within the first 2 years. If recurrence is less than 6 months after completion of chemotherapy, tumor is defined to be platinum-resistant. The antitumor activity of second-line chemotherapy regimens is similar, and the choice of treatment for recurrent platinum-resistant ovarian cancer depends on residual toxicities, physician preference, and patient convenience. Participation in a clinical trial is also a reasonable option for these patients.
5. Ovarian cancer is staged surgically with the International Federation of Gynecology and Obstetrics (FIGO) staging algorithm. Tumor debulking and total abdominal hysterectomy–bilateral oophorectomy surgery are the primary surgical interventions for ovarian cancer. After the completion of the staging and primary surgical treatment, the current standard of care is six cycles of a taxane/platinum-containing chemotherapy regimen.

Ovarian cancer is a gynecologic cancer that usually arises from disruption or mutations in the epithelium of the ovary.[1] It is associated with the highest mortality among the gynecologic cancers, primarily because most patients present with advanced disease. 1 Ovarian cancer is denoted "the silent killer" because of the nonspecific signs and symptoms that often lead to a delay in diagnosis. Ovarian cancers often metastasize via the lymphatic and blood systems to the liver and/or lungs. Common complications of advanced and progressive ovarian cancer include ascites and small bowel obstruction. The few patients who present with disease still confined to the ovary will have a 5-year survival rate greater than 90%, but most patients present with advanced disease and have a 5-year survival rate of 10% to 30%. Primary treatment includes tumor-debulking surgery followed by six cycles of a taxane-platinum chemotherapy regimen. Although 70% of patients achieve an initial complete response to chemotherapy, more than 50% of these patients will have recurrence within the first 2 years from diagnosis.[2]

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

ETIOLOGY AND EPIDEMIOLOGY

It is estimated that 21,880 new cases of ovarian cancer were diagnosed, and 13,850 women died of the disease in 2010.[3] Ovarian cancer is associated with the highest mortality rate among the gynecologic cancers and is the fifth leading cause of cancer-related deaths in women. The mortality rate associated with ovarian cancer has not changed significantly over the past 3 decades. The high mortality rate is related to the insidious onset of nonspecific symptoms and the lack of adequate screening tools, which allows the disease to go undiagnosed until it has progressed beyond the pelvic cavity.

As with many other cancers, the risk of ovarian cancer increases with increasing age. A woman's risk increases from 15.7 to 54 per 100,000 as her age advances from 40 to 79 years, and the median age at diagnosis is 59.[3] Most cases of ovarian cancer are diagnosed during the peri- and postmenopausal phase of women's reproductive life span.[4]

2 Heredity accounts for less than 10% of all ovarian cancer cases. Family history is an important risk factor in the development of ovarian cancer. If one family member has a diagnosis of ovarian cancer, the associated lifetime risk is 9%, but this risk increases to greater than 50% if there are two or more first-degree relatives (e.g., her mother and sister) with a diagnosis of ovarian cancer or multiple cases of ovarian and breast cancer within the same family.[1,2]

BRCA1 and *BRCA2* are the tumor suppressor genes thought to be involved in one or more pathways of DNA damage recognition and repair. The *BRCA1* gene is located on chromosome 17q12–21, and the *BRCA2* gene is located on chromosome 13q12–13. Both *BRCA1* and *BRCA2* mutations are associated with ovarian cancer. However, *BRCA1* is more prevalent, being associated with 90% of inherited and 10% of sporadic cases of ovarian cancer.[5] Patients with *BRCA1*-associated ovarian cancer are usually considerably younger than patients with *BRCA2* mutations, with a mean age

of 54 years.[6] Patients usually present with advanced stage at diagnosis, and the *BRCA1*-linked ovarian cancers are more aggressive tumors that typically are serous histology, moderate to high grade. As *BRCA1* and *BRCA2* are thought to be involved in DNA damage or repair, their inactivation/mutations may be associated with an increased resistance of ovarian cancer cells to cytotoxic agents.

Hereditary breast and ovarian cancer syndrome is one of the two different forms of hereditary ovarian cancer and is associated with germline mutations in *BRCA1* and *BRCA2*.[5,7] The hereditary nonpolyposis colorectal cancer or Lynch syndrome is a familial syndrome with germline mutations causing defects in enzymes involved in DNA mismatch repair, which is associated with up to 12% of hereditary ovarian cancer cases.[5] This syndrome is associated with mutations in DNA mismatch repair genes such as *MSH2, MLH1, PMS1,* and *PMS2* and leads to microsatellite instability.

Hormone exposure, specifically estrogen, and reproductive history are also associated with the risk of developing ovarian cancer. Conditions that increase the total number of ovulations in women's reproductive history, such as nulliparity, early menarche, or late menopause, are associated with an increasing risk for epithelial ovarian cancers.[8,9] Conversely those conditions that limit ovulations are associated with a protective effect. Each time ovulation occurs, the ovarian epithelium is broken, followed by cellular repair. According to the *incessant ovulation hypothesis*, the risk of mutations and, ultimately, cancer increases each time the ovarian epithelium undergoes cell repair.

Finally, ovarian cancer is associated with certain dietary and environmental factors. A diet that is high in galactose, animal fat, and meat may increase the risk of ovarian cancer, whereas a vegetable-rich diet may decrease the risk of ovarian cancer.[7,10] Although controversial, exogenous factors such as asbestos and talcum powder use in the perineal area are also associated with an increased risk of ovarian cancer.[7,10]

PATHOLOGY AND CLASSIFICATION

Ovarian carcinomas can be separated into three major entities: epithelial carcinomas, germ cell tumors, and stromal carcinomas. Most ovarian tumors (85% to 90%) are derived from the epithelial surface of the ovary.[11] The classification of common epithelial tumors has been developed by the World Health Organization and the International Federation of Gynecology and Obstetrics.[12] The nomenclature considers cell type, location of the tumor, and the degree of the malignancy, which ranges from benign tumors to tumors of low malignancy to invasive carcinomas. Epithelial tumors classified as low malignancy ("borderline malignancy") are characterized by epithelial papillae with atypical cell clusters, cellular stratification, nuclear atypia, and increased mitotic activity, and have a much better prognosis than those classified as invasive carcinomas. Malignant tumors are characterized by an infiltrative destructive growth pattern with malignant cells growing in a disorganized manner and dissection into stromal planes.

Invasive epithelial adenocarcinomas are characterized by histologic subtype and grade, which measures the degree of cellular differentiation. Although the histologic type of the tumor is not a significant prognostic factor, with the exception of clear cell, the histopathologic grade is an important prognostic factor. Undifferentiated tumors are associated with a poorer prognosis than those lesions that are considered to be well or moderately differentiated. A universal grading system for ovarian cancer was developed that combines mitotic score, nuclear atypia score, and architectural score based on the histologic pattern.[13]

The histologic subtypes of adenocarcinomas include papillary serous, mucinous, endometrioid, clear cell, mixed epithelial, transition-cell, and undifferentiated.[2,4,13] Papillary serous adenocarcinoma is the most common type of epithelial ovarian cancer and accounts for approximately 46% of cases. The peak age of diagnosis ranges from 45 to 65 years with 63 years as the median age of diagnosis.[14] Serous carcinomas typically display complex papillary and solid patterns and qualify as high-grade carcinomas. Endometrioid carcinomas are seen in women 40 to 50 years of age and comprise approximately 8% of ovarian carcinomas, of which approximately 6% are surface epithelial neoplasms.[14] Endometrioid tumors are usually diagnosed as stage I disease and have a better prognosis than tumors with serous histology. Mucinous carcinomas occur in women between 40 and 70 years of age and account for approximately 36% of all ovarian cancers. The overall prognosis for mucinous carcinoma is better than for serous carcinoma because most patients present with stage I disease. Clear cell carcinoma comprises approximately 3% of ovarian carcinomas in women, with a mean age of 57 years. Although clear cell carcinoma is the least common ovarian neoplasm, it is most commonly associated with paraneoplastic-related hypercalcemia.[14]

Germ cell tumors of the ovary, including malignant teratoma and dysgerminomas, are rare, comprising approximately 2% to 3% of all ovarian cancers in Western countries with an increased incidence in black and Asian women.[15,16] These tumors are highly curable and affect primarily young women. In contrast to epithelial tumors, approximately 60% to 70% of germ cell tumors are stage I at diagnosis, which is related to earlier detection and response to symptoms in this younger patient population.[16] Serum markers (human β-chorionic gonadotropin and α-fetoprotein) are helpful to confirm the diagnosis and monitor response to treatment.

Finally, ovarian sex cord-stromal tumors account for 7% of all ovarian cancers and tend to be diagnosed at stage I.[12] Sex cord-stromal tumors are associated with hormonal effects, such as precocious puberty, amenorrhea, and postmenopausal bleeding. Because these tumors are rare, the optimal treatment of ovarian sex cord-stromal tumors is not clear. The current recommended standard of care is surgery followed by treatment with a platinum-based chemotherapy regimen.

Ovarian cancer is usually confined to the abdominal cavity, but spread can occur to the lung, liver, and, less commonly, the bone or brain. Disease is spread by direct extension, peritoneal seeding, lymphatic dissemination, or bloodborne metastasis. Lymphatic seeding is the most common pathway and frequently causes ascites.

SCREENING AND PREVENTION

SCREENING

Ovarian cancer is an uncommon disease with no known preinvasive component, which has made it difficult to screen patients to detect early disease. In addition, the risk factors for developing ovarian cancer are not well understood, which also makes it difficult to identify a high-risk group of individuals. At the present time, there are no effective screening tools for early detection of ovarian cancer.

Pelvic examinations are noninvasive and well accepted and can detect large tumors with a sensitivity of 67% for detecting all tumors.[15] However, because pelvic examinations cannot detect minimal or microscopic disease, they do not usually detect ovarian cancer until it is in an advanced stage. As a result of these limitations, routine pelvic examinations are not an effective screening tool and do not decrease overall mortality.[15]

Transvaginal ultrasound (TVUS) creates an image of the ovary by releasing sound waves. It can be used to evaluate the size and shape

and to detect the presence of cystic or solid masses or abdominal fluid. TVUS can also evaluate blood flow within an ovarian mass. Normal ovarian size cutoff parameters range from 1.25 cm^2 for women 55 to 59 years of age to 1.0 cm^2 for women older than age 65 to 69 years.[17,18] TVUS is sensitive in identifying ovarian lesions and abnormalities, but its use as a routine screening test is limited by a lack of specificity and an inability to detect peritoneal cancer or cancer in normal-size ovaries.[19,20]

Serum cancer antigen-125 (CA-125) is a nonspecific inflammatory antigen that can be elevated in numerous conditions associated with inflammation in the abdominal cavity. CA-125 has been extensively studied as a potential tumor marker for ovarian cancer based on the observation that CA-125 levels in a woman without ovarian cancer tend to stay the same or decrease over time, whereas levels associated with malignancy tend to gradually increase over time.[19] However, CA-125 is a nonspecific test that can be elevated in a number of benign conditions, including other gynecologic conditions, such as endometriosis, and many nongynecologic conditions, such as diverticulitis and peptic ulcer disease. Because of these limitations, CA-125 levels are not recommended as a routine screening test for detection of ovarian cancer. Numerous other serologic markers such as carcinoembryonic antigen and lipid-associated sialic acid have been evaluated but cannot be recommended for routine screening for ovarian cancer.

The United States Preventive Services Task Force found fair evidence to support screening with CA-125 or TVUS and concluded that earlier detection would likely have a small effect, at best, on mortality from ovarian cancer.[21] Unfortunately, because of the low prevalence of ovarian cancer and the invasive nature of diagnostic testing after a positive screening test, the United States Preventive Services Task Force also found fair evidence that screening could likely lead to important harms. The United States Preventive Services Task Force concluded that the potential harms outweigh the potential benefits and recommended against any form of routine screening with CA-125 or TVUS for ovarian cancer.

In high-risk women, as defined by family history, most clinicians use a multimodality approach for ovarian cancer screening that includes an annual TVUS in combination with a CA-125 blood test every 6 months. Changes in CA-125 are monitored over time, and changes such as a persistent elevation or consistent increases in CA-125 levels in conjunction with TVUS abnormalities are evaluated further.

PREVENTION

It is difficult to make recommendations for prevention for the general population because ovarian cancer is a sporadic disease with no established risk factors. Noninvasive measures, such as chemoprevention, have demonstrated some benefit in decreasing the risk of developing ovarian cancer. Ovulation itself is considered a potential insult to the ovarian epithelium, increasing its susceptibility to damage and, ultimately, to cancer. Interventions or reproductive conditions associated with decreasing the number of ovulations, including multiparity, may have a protective effect for the prevention of ovarian cancer. However, the more invasive prevention interventions, such as prophylactic surgery and genetic screening, should be reserved for those women identified to be at high risk based on their heredity for developing ovarian cancer.

Chemoprevention

Although a number of agents have been investigated as chemoprevention of ovarian cancer, including oral contraceptives, aspirin, nonsteroidal antiinflammatory agents, and retinoids, none of these agents is currently accepted as standard treatment for the prevention of ovarian cancer. Oral contraceptives inhibit ovulation, which reduces the opportunity for potential for damage to the ovarian epithelium. Oral contraceptives decrease the relative risk to less than 0.4 in women who used oral contraceptives for longer than 10 years.[22,23] Because oral contraceptive use is associated with an increased risk of breast cancer, women with a family history of breast cancer are not candidates for this use of oral contraceptives as chemoprevention of ovarian cancer.[22,23]

Nonsteroidal antiinflammatory drugs, aspirin, and acetaminophen also have been suggested for use in the chemoprevention of different cancers, especially hereditary nonpolyposis colon cancer.[24] Although the results of observational studies show that the use of nonsteroidal antiinflammatory drugs, aspirin, and acetaminophen reduces the risk of ovarian cancer, these findings have not been confirmed in prospective clinical studies. The proposed mechanism of these agents is the antiinflammatory effect on normal ovulation and inhibition of ovulation.[24,25]

Prophylactic Surgery

Prophylactic surgical interventions for the prevention of ovarian cancer are reserved for patients with a significant family history and/or with known genetic mutations such as *BRCA1* and should be postponed until after childbearing is completed. The goal is to remove healthy, at-risk organs before any carcinogenic activity is initiated, ultimately reducing the risk of developing cancer. These surgeries include prophylactic oophorectomy or bilateral salpingo-oophorectomy and tubal ligation. These procedures will cause surgical menopause, which can be associated with severe hot flashes, vaginal dryness, sexual dysfunction, and increased risk for development of osteoporosis and heart disease in these women. Because of the potential impact on quality of life and increased health risks, prophylactic surgery is not recommended as a general prevention intervention for the general population.

Although prophylactic surgical interventions are associated with significant reduction in risk of developing ovarian cancer, patients who choose to have a prophylactic oophorectomy/bilateral salpingo-oophorectomy completed need to be informed that complete protection is not guaranteed.[15,23,26] Although a 67% risk reduction has been shown, a potential 2% to 5% risk of primary peritoneal cancer remains.[27,28] Primary peritoneal cancers have identical histology of ovarian tumors with diffuse involvement of peritoneal surfaces. Often primary peritoneal cancers can result from "seeding" during the prophylactic surgery. It is recommended for peritoneal washings to be completed during the prophylactic surgery to check for presence of peritoneal surfaces. If positive, then prophylactic surgery would change to staging and treatment surgery to determine extent of disease and remove any other possible lesions.

Tubal ligation is another procedure that can potentially reduce the risk for developing ovarian cancer. In a case-control study, Narod et al. reported that tubal ligation in *BRCA*-positive women was associated with a 63% reduction in risk of developing ovarian cancer.[29] However, it is not recommended as a sole procedure in prophylaxis. The mechanism for its protective effect is not clear, but it has been proposed that tubal ligation may limit exposure of the ovary to environmental carcinogens.

GENETIC SCREENING

Genetic screening should be considered for those women with a significant family history of ovarian cancer. Patients should be evaluated for the presence of genes such as *BRCA1*, *BRCA2*, or other genes such as those associated with hereditary nonpolyposis colorectal cancer or the hereditary breast ovarian cancer (hereditary breast and ovarian cancer syndrome) syndrome.[29–32] Prior to genetic screening, appropriate patient/family counseling and genetic counseling should be available to help women prepare and deal with the health and psychosocial implications of the genetic screening results.

CLINICAL PRESENTATION

Patients with early ovarian cancer are often asymptomatic and the ovarian mass is often detected incidentally during their annual pelvic examinations. Patients with ovarian cancer often present with nonspecific, vague symptoms such as abdominal bloating, indigestion, or change in bowel movements.[2,4,33] These symptoms can easily be confused with symptoms of common benign gastrointestinal disorders. Patients will often not seek medical attention until these symptoms become unrelenting and bothersome, which allows the disease to progress undetected. Patients with advanced disease may report symptoms such as pain, abdominal distension, and ascites.[2,33]

Several groups have partnered together to educate women about early signs and symptoms of ovarian cancer. Goff et al. recently developed a symptom index, based on a comparison of symptoms experienced in patients with ovarian cancer and a matched control group.[34] Symptoms that were correlated with ovarian cancer were persistent or recurrent bloating, pelvic or abdominal pain, difficulty eating or feeling full quickly, and urinary symptoms (either urgency or frequency). The Gynecologic Cancer Foundation, Society of Gynecologic Oncologists, and American Cancer Society recommend that women who have any of those problems nearly every day for more than 2 or 3 weeks should see a gynecologist, especially if the symptoms are new and quite different from her usual state of health.

CLINICAL PRESENTATION OF OVARIAN CANCER

GENERAL

- Ovarian cancer is sometimes referred to as "the silent killer" because of the vague nonspecific signs and symptoms that contribute to the delay in diagnosis.

SYMPTOMS

- The patient may complain of abdominal discomfort, nausea, dyspepsia, flatulence, bloating, fullness, early satiety, urinary frequency, change in bowel function (diarrhea or constipation), weight change, and digestive disturbances.

SIGNS

- Abdominal or pelvic mass may be palpable.
- Lymphadenopathy may be present.
- Vaginal bleeding may be irregular.
- Patient may have signs of ascites (abdominal distension, shifting, and dullness to percussion—may present like "pregnant abdomen").

LABORATORY TESTS

- CA-125 may be elevated (normal level is less than 35 units/mL [35 kU/L]).
- Abnormalities in liver function tests may suggest hepatic involvement.
- Abnormalities in renal function tests may suggest compression of the renal system by the tumor.

DIAGNOSIS

The diagnostic workup for suspected ovarian cancer includes a careful physical examination including a Papanicolaou (Pap) smear and a pelvic and rectovaginal examination.[7] The presence of a pelvic mass that is unilateral or bilateral, solid, irregular, fixed, or nodular is highly suggestive of ovarian cancer. Unfortunately, by the time a pelvic mass can be palpitated on physical exam, the disease is already advanced beyond the pelvic cavity. A detailed family history should be taken, especially noting the number and pattern of first-degree relatives with malignancies.

A complete blood count, chemistry profile (including liver and renal function tests), and CA-125, carcinoembryonic antigen, and CA19–9 levels should be performed. 3 Although CA-125 is a nonspecific antigen, it is the best current tumor marker for epithelial ovarian carcinoma. A normal CA-125 value is less then 35 units/mL (35 kU/L). If CA-125 is elevated at the time of diagnosis, changes in CA-125 levels correlate with tumor burden. Rising CA-125 levels are often associated with disease progression, but CA-125 can be elevated in various other conditions such as different phases of the menstrual cycle, diverticulitis, endometriosis, as well as other nongynecologic cancers. When a patient presents with an abdominal mass, it is important to rule out other cancers in the abdominal cavity. Carcinoembryonic antigen and CA19–9 are markers for other gastrointestinal cancers and may be helpful in the differential diagnosis.

Other diagnostic tests should include a transvaginal or abdominal ultrasonography, chest radiography, computed tomography, magnetic resonance imaging, or positron emission tomography scan. An upper GI series, intravenous pyelogram, cystoscopy, proctoscopy, or barium enema is sometimes indicated to confirm diagnosis and extent of disease.

TREATMENT

Ovarian Cancer

4 A multimodality approach that includes comprehensive surgery and chemotherapy is used for the initial treatment of ovarian cancer with curative intent. Although most patients will initially achieve a complete response, more than 50% will recur within the first 2 years.[2,35] A clinical complete response to treatment is defined as no evidence of disease by physical examination or diagnostic tests and a normal CA-125 level.

Chemotherapy regimens for ovarian cancer have evolved over the past few decades. Treatment regimens began with single-agent melphalan followed by single-agent cyclophosphamide. Shortly after cisplatin was introduced into clinical practice, it was added to cyclophosphamide, and this combination was the "standard of care" for over a decade until the introduction of paclitaxel in the 1980s. Paclitaxel soon replaced cyclophosphamide and paclitaxel plus cisplatin became the standard of care. Carboplatin was then substituted for cisplatin because of its improved toxicity profile, and paclitaxel plus carboplatin was adopted. During this same period, many researchers have conducted numerous clinical trials of intraperitoneal (IP) chemotherapy. In 2006, Armstrong and colleagues published the first IP therapy clinical trial to demonstrate a survival advantage over the standard IV regimen.[36] However, these advances in chemotherapy for the treatment of ovarian cancer have not translated into major changes in overall 5-year survival, which remains less then 20%.

Certain subgroups of patients have a better or worse response to chemotherapy. The histologic subtype of the tumor is a prognostic factor; clear cell histology is more likely to be poorly differentiated, faster growing, and have intrinsic drug resistance.[2,37] However, the extent of residual disease, size larger than 1 cm, and tumor grade are better predictors of response to chemotherapy and overall survival.[2]

In general, younger patients have a better performance status and tolerate chemotherapy better than elderly patients. For unknown reasons, white women tend to have a worse prognosis and response to therapy as compared with women of other ethnic backgrounds.[2,6,7]

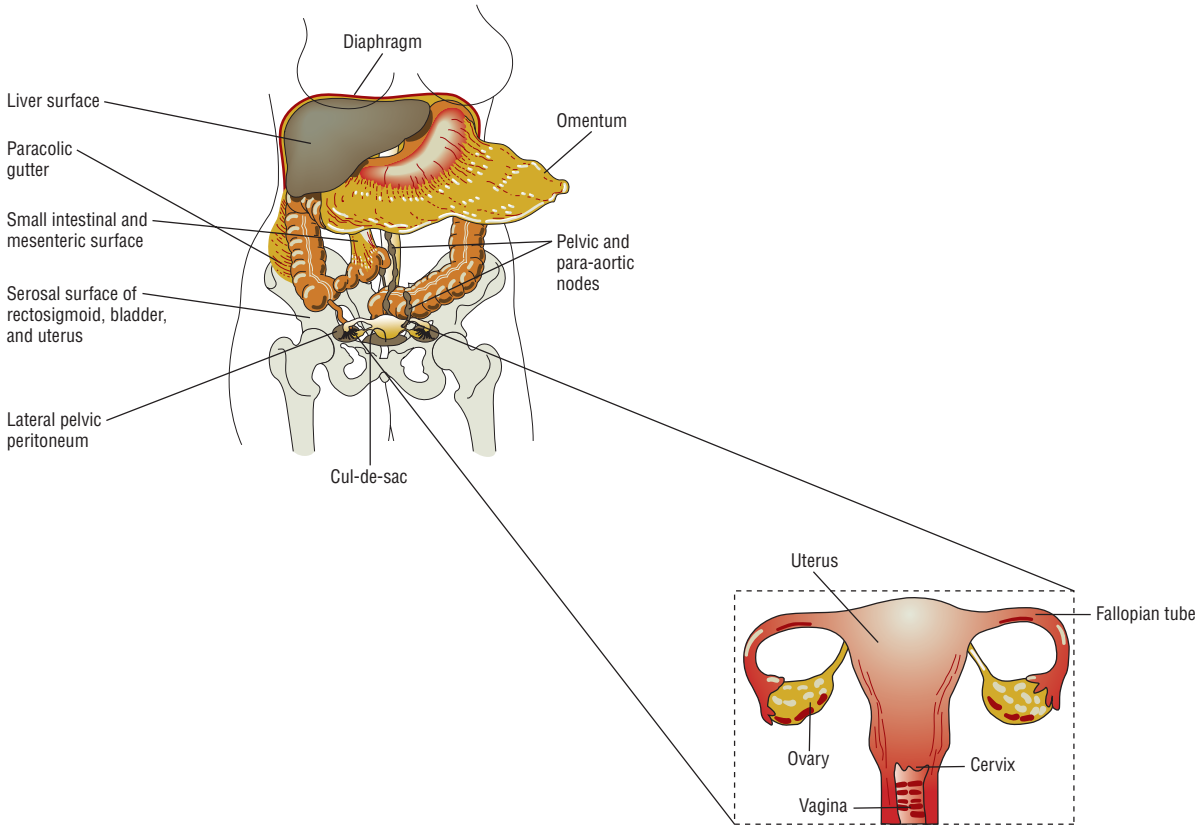

FIGURE 141-1. Staging laparotomy for ovarian cancer with diagram of female reproductive tract (uterus, fallopian tubes, ovaries, vagina). Dashed line box outlines what is removed during the total abdominal hysterectomy with bilateral salpingo-oophorectomy.

In patients with recurrent ovarian cancer, the goals of treatment are to relieve symptoms such as pain or discomfort from ascites, slow disease progression, and prevent serious complications such as small bowel obstructions.

SURGERY

Surgery is the primary treatment intervention for ovarian cancer.[37–41] Surgery may be curative for selected patients with limited stage IA disease.

Primary surgical treatment includes a total abdominal hysterectomy with bilateral salpingo-oophorectomy, omentectomy, and lymph node dissection (Fig. 141–1).[37–41] The primary objective of the surgery is to optimally debulk the tumor to less than 1 cm of residual disease.[42] Long-term follow-up studies confirm that residual disease smaller than 1 cm correlates with higher complete response rates to chemotherapy and longer overall survival as compared to patients with bulky residual disease (larger than 1 cm).[40,41]

A comprehensive exploratory laparotomy is vital for the accurate confirmation of diagnosis and staging of ovarian cancer.[37–39] 5 Unlike other cancers that are typically diagnosed by biopsy or laboratory results and clinically staged by results from imaging tests, gynecologic cancers, such as ovarian cancer, are surgically diagnosed and then staged according to the International Federation of Gynecology and Obstetrics (FIGO) staging algorithm (Fig. 141–2). The FIGO staging system requires a fairly extensive surgery by an experienced gynecologic oncologist. The skill of the surgeon has a significant impact on prognosis, with definitive benefit of a trained gynecologic oncologist performing surgery as compared with a gynecologist or general surgeon.[43] The reasons for this approach include (a) pelvic tumors cannot be readily biopsied without risk of "tumor seeding," which can increase the risk of recurrence, and (b) surgical staging takes into account the presence of microscopic disease in samples obtained by pelvic washing and lymph node dissection and read by a pathologist during the surgical procedure. It is recommended that the initial surgical staging and tumor-debulking surgery be completed by a trained gynecologic oncology surgeon when ovarian cancer is suspected to prevent understaging and to optimize overall outcome.[44]

Secondary cytoreduction or interval debulking is when surgery is performed after completion of some or all chemotherapy to remove residual disease. Some protocols include additional cycles of chemotherapy after the surgical procedure. The importance of cytoreduction before, during, or after chemotherapy is still controversial, but it has been recommended to facilitate response to chemotherapy and improve overall survival. Randomized trials of secondary surgical cytoreduction have reported conflicting results. In an older randomized trial, van der Burg et al. performed interval debulking surgery on 140 stage IIB to stage IV suboptimally debulked (less than 1 cm of residual disease) ovarian cancer patients after receiving three cycles of cisplatin plus cyclophosphamide.[45] Patients then received an additional three cycles of these same drugs after surgery. Patients randomized to the nonsurgical treatment arm received six cycles of chemotherapy. Interval debulking surgery significantly prolonged overall and progression-free survival and reduced the risk of death by 33%. However, in a recently published study of 550 women with stage III or IV disease treated with primary cytoreductive surgery and three cycles of paclitaxel and cisplatin, patients randomized to receive secondary cytoreductive surgery followed by three more cycles of chemotherapy had similar progression-free survival and overall survival as compared with those randomized to receive three more cycles of chemotherapy alone.[46]

The overall effect of interval debulking is influenced by several factors, including initial response to chemotherapy, the amount of residual disease before and after second-look surgery, and the presence of microscopic residual disease. The results of recent trials

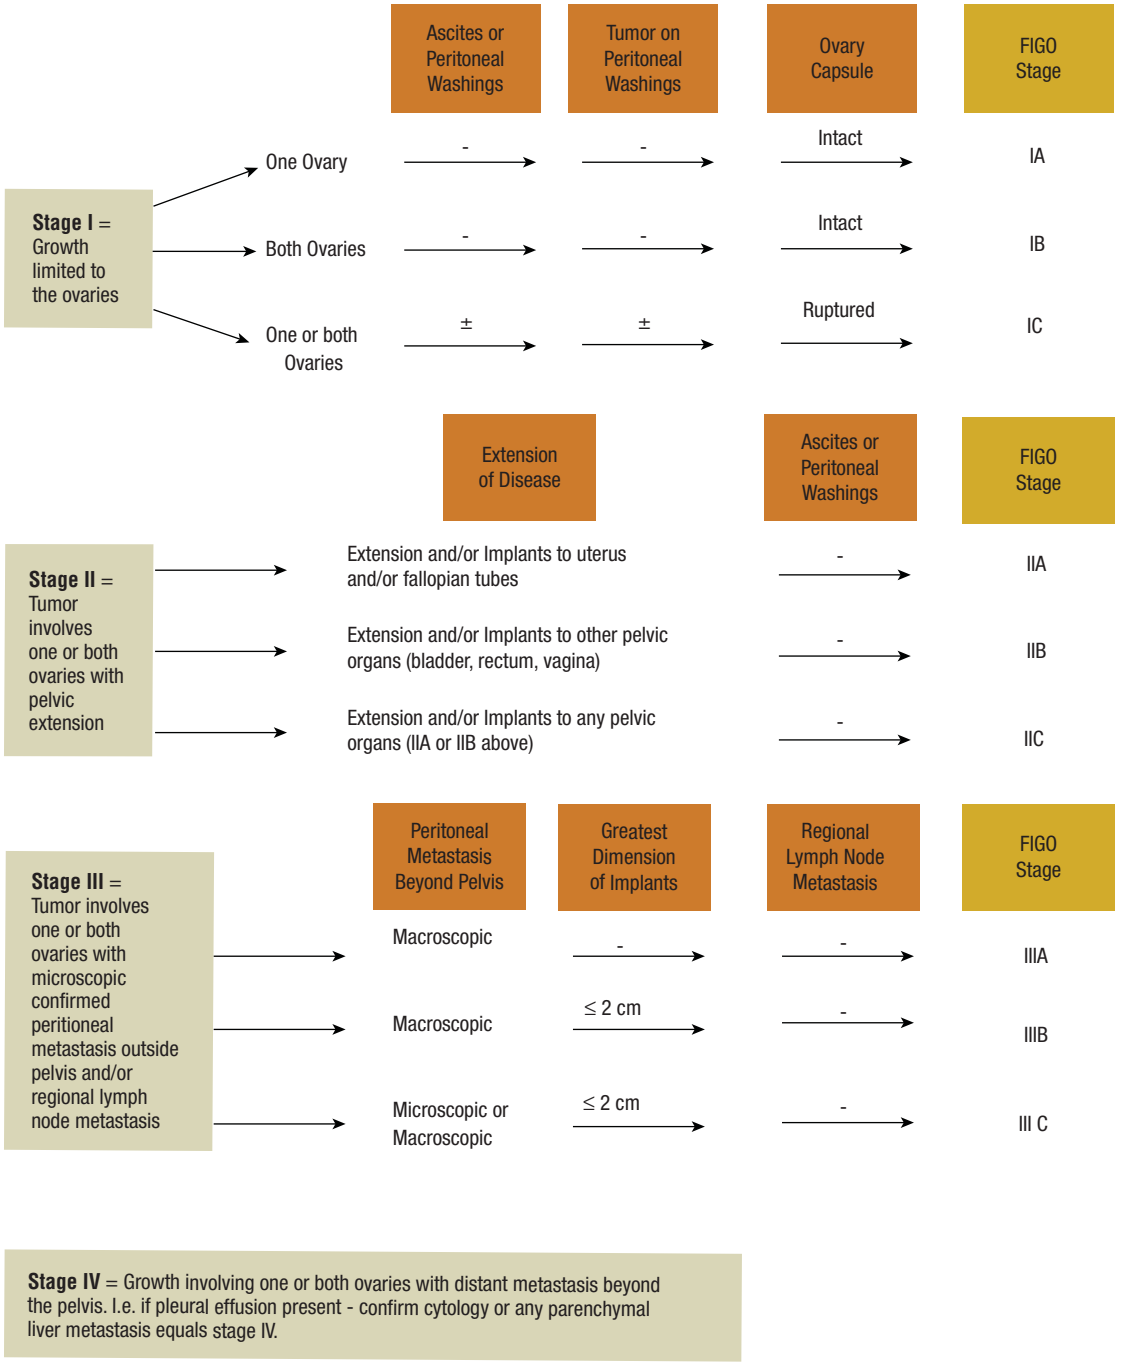

FIGURE 141-2. International Federation of Gynecology and Obstetrics (FIGO) staging algorithm.

suggest that secondary surgical cytoreduction does not prolong survival in patients who are treated with maximal primary cytoreductive surgery followed by appropriate postoperative chemotherapy.

"Second-look surgery" is an elective surgical procedure performed in patients who achieve a clinical complete response after primary chemotherapy to determine if any visible or microscopic disease is present in the peritoneal cavity. The benefit of "second-look laparotomy" to evaluate residual disease after completing chemotherapy remains controversial because it has been difficult to establish any impact on overall survival. It has questionable benefit because approximately 50% of those with a negative second look still relapsed.[3] If visible or microscopic disease is detected during second look, then the clinician may decide to give additional chemotherapy. But if no visible or microscopic disease is detected during second look, the clinician may decide to observe and monitor the patient. Use of laparoscopic surgical techniques is controversial for initial surgery but is sometimes considered in debulking of recurrent or advanced disease when the intent is palliative rather than curative.[40] In patients with recurrent disease, the goal of debulking surgery is to relieve symptoms associated with complications such as small bowel obstructions and to help improve the patient's quality of life.

RADIATION

Radiation has a limited role in the management of ovarian cancer. Use of radiation for treatment of early-stage disease has had no benefit or impact on overall survival.[47] Radiation therapy is most beneficial for palliation of symptoms in patients with recurrent pelvic disease, often associated with small bowel obstructions. The two

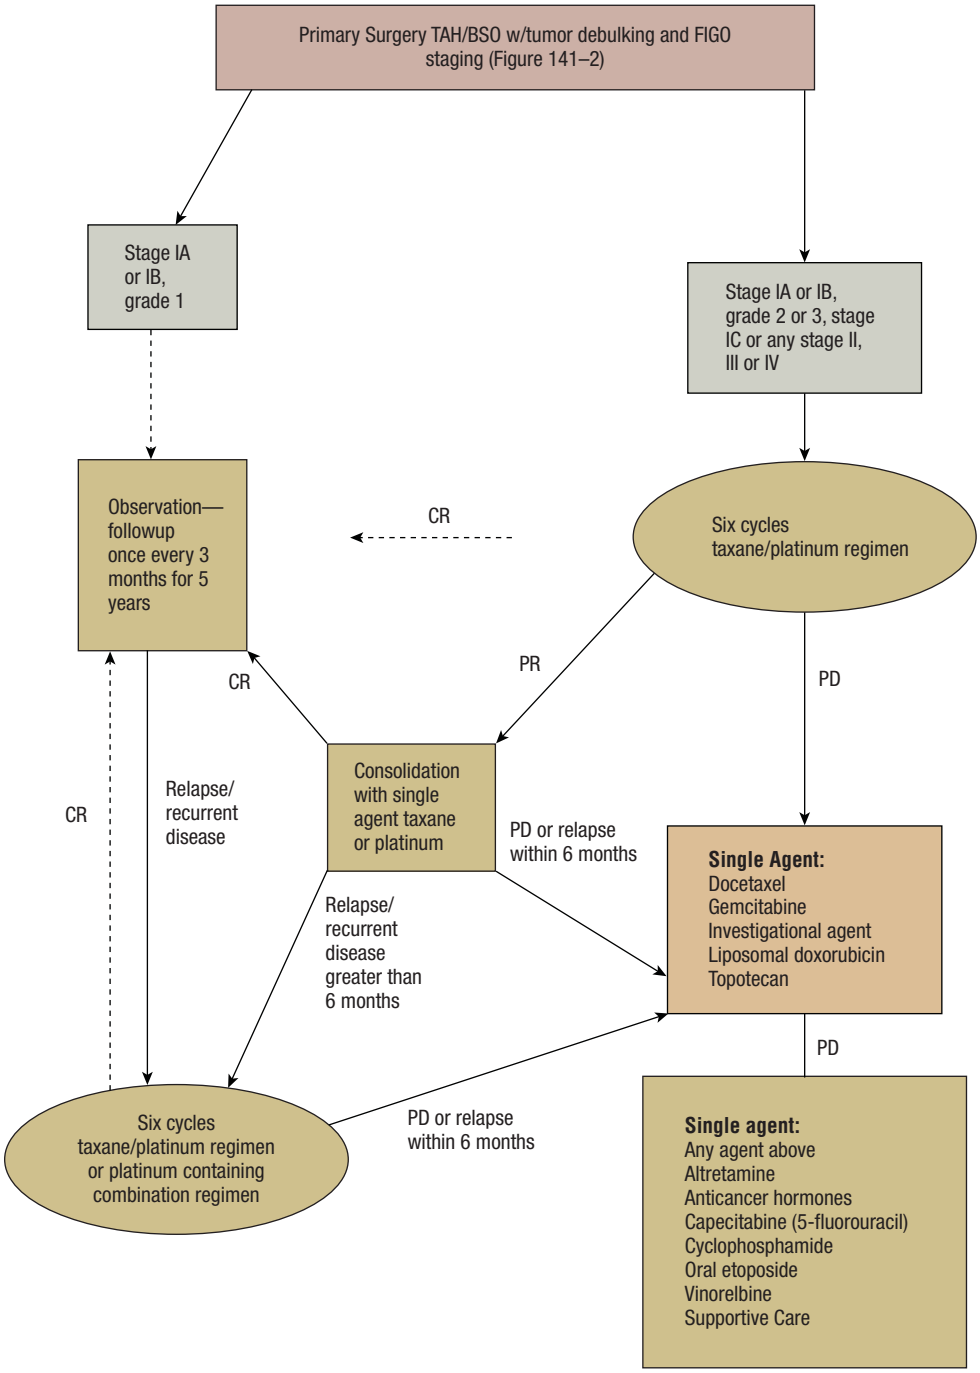

FIGURE 141-3. Management of newly diagnosed, refractory, and progressive epithelial ovarian cancer. All recommendations are category 2A unless otherwise indicated. (BSO, bilateral salpingo-oophorectomy; CR, complete response; PD, progression of disease; PR, partial response; TAH, total abdominal hysterectomy; USO, unilateral salpingo-oophorectomy.)

forms of radiation therapy used in ovarian cancer are external beam whole-abdominal irradiation and intraperitoneal isotopes such as ^{32}P. Alleviation of symptoms with external beam whole-abdominal irradiation is associated with a significant improvement in the patient's quality of life. The recommended dose ranges from 35 to 45 Gy (3500 to 4500 rad), depending on the treatment history and ability to tolerate radiation treatments.

CHEMOTHERAPY

The mainstay of ovarian cancer treatment is chemotherapy. It is used as a component of first-line treatment after completion of surgery and is the primary modality of treatment for recurrent ovarian cancer.

First-Line Treatment

Systemic chemotherapy with a taxane and platinum regimen following optimal surgical debulking is the standard of care for treatment of epithelial ovarian cancer (Fig. 141–3). Table 141–1 summarizes the chemotherapeutic regimens used as the initial treatment of newly diagnosed epithelial ovarian cancer. More than 60 randomized, controlled clinical trials have evaluated combination chemotherapy regimens for the treatment of advanced ovarian cancer, and a meta-analysis of these trials confirmed the efficacy of platinum and taxane regimens over other regimens.[48,49]

Historically, single-agent alkylating agents such as melphalan, and later cyclophosphamide, were used for the treatment of

TABLE 141-1 Initial Chemotherapeutic Regimens of Epithelial Ovarian Cancer

Drug(s)	Dose(s)	Cycle Frequency
Paclitaxel + carboplatin	175 mg/m² IV (3-h infusion) day 1 Dosed to AUC 5–7.5 IV day 1	Every 21 days
Paclitaxel + cisplatin (IV)	135 mg/m² IV (24-h infusion) day 1 75 mg/m² IV day 1	Every 21 days
Paclitaxel + cisplatin (IP)	Day 1: Paclitaxel 135 mg/m² IV infused over 24 hours + Day 2: Cisplatin 100 mg/m² IP infused over 1 hour + Day 8: Paclitaxel 60 mg/m² IP infused over 1 hour.	Every 21 days
Cisplatin + cyclophosphamide	50–100 mg/m² IV day 1 500–1,000 mg/m² IV day 1	Every 21–28 days
Docetaxel + carboplatin	75 mg/m² IV day 1 Dosed to AUC 5 IV day 1	Every 21 days

advanced ovarian cancer until the introduction of cisplatin in the 1970s. Combination chemotherapy regimens containing cisplatin and cyclophosphamide achieved higher response rates and overall survival than regimens without cisplatin in patients with advanced ovarian cancer.[50] Based on the results of these trials, the combination of cisplatin plus cyclophosphamide remained the standard of care for the treatment of ovarian cancer until the early 1990s.

The next major advance in the therapy of advanced ovarian cancer occurred with the introduction of paclitaxel into chemotherapy regimens. McGuire et al. reported the results of a Gynecologic Oncology Group (GOG)-111 study that found the combination of paclitaxel 135 mg/m² over 24 hours and cisplatin 75 mg/m² achieved higher response rates and longer survival than did cyclophosphamide 750 mg/m² and cisplatin 75 mg/m² in patients with newly diagnosed, suboptimally debulked, stages III and IV ovarian cancer.[51] Survival improved significantly in the paclitaxel arm, with an increase in median progression-free survival (18 months vs. 13 months) and overall survival (38 months vs. 24 months). Neutropenia, alopecia, and peripheral neuropathy were more severe in the paclitaxel plus cisplatin group. Similar results were reported in a large European-Canadian Intergroup Phase III randomized trial study (OV10) that also confirmed superior response rates with the paclitaxel 135 mg/m² over 24 hours with cisplatin 75 mg/m² regimen as compared with cyclophosphamide 750 mg/m² with cisplatin 75 mg/m² regimen.[52] Based on the results of these studies, paclitaxel plus cisplatin was widely adopted and became the accepted standard of care.

The availability of carboplatin led to clinical trials to evaluate whether carboplatin could be substituted for cisplatin, which would spare patients from the significant neurotoxicity and nephrotoxicity associated with cisplatin. Several prospective randomized comparisons of carboplatin plus paclitaxel versus cisplatin plus paclitaxel in patients with advanced ovarian cancer have been conducted.[53–56] The results of these trials show that carboplatin plus paclitaxel is equally efficacious and better tolerated than cisplatin and paclitaxel. In the GOG-158 study, 840 previously untreated patients with optimally resected stage III disease (no residual tumor nodule >1 cm) were randomized to carboplatin (area-under-the-curve = 7.5) plus paclitaxel 175 mg/m² over 3 hours, or cisplatin 75 mg/m² plus paclitaxel 135 mg/m² over 24 hours administered every 21 days for six cycles.[53,55] The results of that trial showed no difference in progression-free survival between the two treatment arms with a median time-to-progression of 19.4 months in the paclitaxel plus cisplatin arm versus 20.7 months in the paclitaxel plus carboplatin arm. As expected, the incidence of leukopenia, fever, gastrointestinal toxicity, and metabolic toxicity was higher in patients in the cisplatin arm, whereas patients in the carboplatin arm experienced more thrombocytopenia and pain. Although the incidence of neurotoxicity was similar in the two treatment arms, it was more severe in the paclitaxel plus cisplatin arm. The results of this study showed that the substitution of carboplatin for cisplatin in the regimen does not compromise efficacy and improves tolerability. These findings were confirmed in two other large randomized, controlled studies.[55,56] Based on these results, paclitaxel plus carboplatin became the accepted standard of care.

Other clinical trials have evaluated the use of docetaxel as a substitute for paclitaxel. In the Scottish Randomized Trial in Ovarian Cancer (SCOTROC), Vasey et al. compared carboplatin (area-under-the-curve = 5) combined with either docetaxel (75 mg/m² over 1 hour) or paclitaxel (175 mg/m² over 3 hours) administered every 21 days for six cycles as first-line chemotherapy for stages IC to IV epithelial ovarian cancer.[57] The results of this study showed that the substitution of docetaxel for paclitaxel does not compromise efficacy and improves tolerability, particularly neurotoxicity. These findings have not yet been confirmed in another randomized, controlled trial. Based on the results of this study, the combination of docetaxel plus carboplatin is considered a reasonable treatment option for patients with advanced ovarian cancer. Six cycles of paclitaxel plus carboplatin following tumor debulking surgery remain the current standard of care for treatment of advanced ovarian cancer.

Although the choice of taxane or platinum agent does not appear to have a major effect on antitumor activity, weekly paclitaxel administration ("dose density") may be superior to administration every 3 weeks.[58–60] In a phase III trial conducted in Japan, Katsumata et al. reported that patients randomized to six cycles of dose-dense weekly paclitaxel plus carboplatin every 3 weeks had longer progression-free survival as compared to the standard paclitaxel plus carboplatin every 3 weeks.[60] Overall survival at 3 years was also significantly longer in patients who received the dose-dense regimen (72% vs. 65%, P = 0.03). However, more patients who received the dose-dense regimen dropped out of the study because of treatment-related toxicities. A confirmatory Gynecologic Oncology Group (GOG) phase III trial is ongoing to confirm these results and address concerns regarding the feasibility of the dose-dense regimen in a larger group of patients.

CLINICAL CONTROVERSY

The use of IP chemotherapy as first-line treatment of advanced ovarian cancer has been recommended by the NCCN guidelines. Most clinical trials have used platinum agents given IP until the GOG172 trial that incorporated IP paclitaxel. Many clinicians are concerned about how to manage hypersensitivity reactions to either platinum or taxane agents when administered IP.

Intraperitoneal (IP) chemotherapy was initially employed as palliative care in the management of ascites and uncontrolled intraabdominal tumors. In the late 1970s, IP chemotherapy administration as a primary treatment intervention was initiated based on the rationale that exposure of the tumor to high drug concentrations would increase tumor drug uptake by passive diffusion and ultimately cancer cell death.[61] The increase in area-under-the-curve exposure in the peritoneal cavity was demonstrated, but the correlative increase in drug uptake in tumor tissue has yet to be validated in any preclinical or clinical study.

IP chemotherapy has demonstrated a benefit in the first-line treatment of patients with optimally debulked advanced-stage ovarian cancer.[49,62–64] In the most recent trial, Armstrong et al. reported the results of the GOG-172 study, which evaluated 415 patients randomized to receive either the combination regimen of paclitaxel 135 mg/m² over 24 hours and cisplatin 75 mg/m² or a new combination regimen that included paclitaxel 135 mg/m² IV infused over 24 hours

followed by cisplatin 100 mg/m^2 IP infused over 1 hour on day 2, and then paclitaxel 60 mg/m^2 IP infused over 1 hour on day 8.[36] Both treatment regimens were given once every 21 days for a total of six cycles. Patients randomized to the IP chemotherapy arm had a 5.5-month increase in the median progression-free survival and a 15.9-month increase in overall survival.[36]

Since the publication of this study, there has been a resurgence of interest in the use of IP chemotherapy despite the limitation that only 42% of the patients on the IP treatment arm were able to complete the planned six cycles as a result of significantly more toxicity, including pain, fatigue, myelosuppression, gastrointestinal, metabolic, and neurotoxicity.[36,63,65,66] Because only 42% of patients were able to complete the planned six courses of IP chemotherapy, some experts have questioned whether the route of administration was an important contributing factor in the observed differences in overall survival.[36] The significant increase in systemic toxicity, primarily neurotoxicity, has led to the question of whether IP carboplatin could be substituted for IP cisplatin. Although these platinum agents have demonstrated equal efficacy when administered intravenously to ovarian cancer patients, based on the concept that drug passively diffuses into the tumor, the difference in molecular size of cisplatin versus carboplatin makes it difficult to extrapolate IP activity of cisplatin to carboplatin.

The NCCN 2010 guidelines recommend that IP chemotherapy be considered and offered to patients as appropriate first-line treatment of optimally debulked, ≥1 cm residual disease, ovarian cancer.[67] The National Cancer Institute also released a position statement in January 2006 supporting the role of IP chemotherapy as first-line treatment for advanced ovarian cancer.[68] Because of the significant toxicities associated with IP therapy, only carefully selected patients should receive IP therapy. Ideal candidates for IP therapy are younger patients with good performance status, minimal comorbidities, adequate renal and liver function, and optimally debulked disease without significant bowel resection.[62,66]

In patients who are poor surgical candidates because of comorbidities or bulky tumors, neoadjuvant chemotherapy can be given prior to any surgical interventions.[69] In patients with bulky disease, the goal of neoadjuvant chemotherapy is to reduce tumor burden to make surgery more feasible and optimal tumor debulking more likely. The typical regimen used in neoadjuvant chemotherapy is three cycles of a taxane combined with a platinum agent followed by surgery. After surgery, patients usually receive another three to six cycles, depending on their response to chemotherapy. In patients who are poor candidates for surgery because of comorbidities, the, primary intent of neoadjuvant chemotherapy is to relieve symptoms and slow disease progression. In this setting, palliative chemotherapy alone has not been curative for patients with advanced ovarian cancer.[69] If tolerated, these patients will receive the standard taxane plus platinum chemotherapy regimen once every 3 to 4 weeks. Another option for palliative neoadjuvant chemotherapy, especially in elderly patients, is single-agent carboplatin once every 4 weeks.

Consolidation Therapy

If patients do not achieve a clinical complete response after completion of six cycles of taxane-platinum regimen, then consolidation chemotherapy should be considered in an attempt to achieve a complete response (Fig. 141–3). If the patient has a partial response to first-line chemotherapy, as measured by a greater than 50% decline in CA-125 (as compared with the presurgery level) or tumor regression, the cancer is still considered sensitive to the regimen. The typical regimens for consolidation chemotherapy are the taxane plus platinum regimen or single-agent therapy with either a taxane or platinum agent.[70] If the patient had a poor response to taxane and platinum, then alternative second-line agents can be considered.[67] Additional cycles of chemotherapy are given until complete response is achieved. Another alternative in the setting of no or minimal measurable disease after completion of primary chemotherapy is to just observe the patient and provide supportive care as indicated until disease progresses, then reinitiate chemotherapy at that time.[67]

Because the initial clinical complete response observed in first-line treatment has not been durable, optimization of first-line therapy is under investigation. Numerous options have been evaluated, including the use of additional cycles or maintenance chemotherapy and dose intensity.

Maintenance Chemotherapy Maintenance chemotherapy is similar to consolidation chemotherapy except maintenance chemotherapy is given to those patients who have achieved a clinically complete response. The primary differences between consolidation and maintenance chemotherapy are the types of agents used and duration of therapy. Consolidation therapy usually consists of more aggressive combination regimens, whereas maintenance chemotherapy usually consists of single agents given less frequently (i.e., once monthly) to minimize adverse effects. The goal of maintenance chemotherapy is to eradicate any residual microscopic disease that may be present to extend progression-free and overall survival.

Maintenance chemotherapy has gained popularity after the publication of the results of the collaborative Southwest Oncology Group and GOG 178 study that compared single-agent paclitaxel 175 mg/m^2 over 3 hours once every 21 days for three additional cycles versus an additional 12 cycles.[71,72] Eligible patients had to have been in complete clinical remission after at least five to six cycles of a taxane-platinum regimen. This study was closed after the interim analysis by the Southwest Oncology Group Safety Monitoring Committee because patients receiving the additional 12 cycles had longer progression-free survival than those receiving three cycles of single-agent paclitaxel (28 vs. 21 months). After the results were reported, many patients randomized to the three-cycle arm chose to receive nine additional cycles of paclitaxel, which reduced the ability of the trial to show a difference in overall survival.[73] Because this study was closed early and did not demonstrate an overall survival benefit, another randomized, controlled trial through the GOG was initiated to confirm the improvement in progression-free survival and to attempt to determine the impact on overall survival. Until these confirmatory trials are completed, the role of maintenance chemotherapy is controversial in the management of advanced ovarian cancer patients. Maintenance chemotherapy is listed as an option in the 2010 NCCN guidelines (2B recommendation).[67]

High-Dose Chemotherapy with Hematopoietic Stem Cell Rescue High-dose chemotherapy with autologous or allogeneic hematopoietic stem cell transplantation (HSCT) is an option for selected patients with chemosensitive disease, few comorbidities, and good performance status. Although high response rates have been reported in patients with recurrent ovarian cancer treated with autologous HSCT, the duration of response is usually short and few patients have experienced long-term progression-free survival.[74,75] Allogeneic HSCT has also been evaluated in recurrent ovarian cancer to induce an immune response against the tumor ("graft-versus-tumor" effect).

Based on the activity of autologous HSCT in recurrent ovarian cancer, Goncalves et al. evaluated the modality for first-line treatment of patients with optimally debulked ovarian cancer. In this multicenter phase II study, 34 patients received two cycles of high-dose cyclophosphamide-epirubicin once every 21 days followed by two cycles of high-dose carboplatin (days 42 and 98).[76] Each dose of high-dose carboplatin was followed by hematopoietic stem cell infusion. The results of this study failed to show an improvement in the rate of pathologic complete response with upfront autologous HSCT as compared with standard taxane plus platinum

TABLE 141-2 Single-Agent Chemotherapeutic Regimens for Recurrent or Refractory Ovarian Cancer

Drug(s)	Dose(s)	Cycle Frequency
Docetaxel	75 mg/m² IV day 1	Every 21 days
Pegylated-liposomal doxorubicin	40 mg/m² IV day 1	Every 28 days
Gemcitabine	800–1000 mg/m² IV days 1, 8, and 15	Every 28 days
Paclitaxel	60–80 mg/m² IV (1-h infusion) day 1	Every week
Paclitaxel	135–175 mg/m² IV day 1	Every 21 days
Carboplatin	AUC 5 IV day 1	Every 21–28 days
Cisplatin	75 mg/m² IV day 1	Every 21–28 days
Topotecan	1.3–1.5 mg/m² IV once daily for 5 days	Every 21 days
Topotecan	4 mg/m² IV once a week × 3 weeks, then 1 week off	Every 21 days
Etoposide	50 mg/m² orally once daily days 1–10 repeat every 21 days	Every 28 days
Capecitabine	1800–2000 mg/m² in divided dose twice a day for 2 weeks on, 1 week off	Every 21 days
Altretamine	260 mg/m² orally (total daily dose divided in four doses) for 14–21 days	Every 28 days
Tamoxifen	20 mg orally twice a day	Continuous
Letrozole	2.5 mg orally once daily	Continuous

chemotherapy. Additional studies are ongoing to determine the role of autologous or allogeneic HSCT in the treatment of advanced ovarian cancer.

Treatment of Recurrent Disease

4 Although most patients will achieve a complete response to initial treatment, most patients will eventually have recurrence of their disease. When a patient relapses, the prognostic factors are similar to the factors after initial surgery except that the disease-free interval—defined as the length of time that has lapsed since the completion of chemotherapy—should be considered to determine if the tumor is likely to be drug resistant. If recurrence occurs less than 6 months after completion of chemotherapy, or if the patient progresses during platinum-based chemotherapy, the tumor is defined as platinum-resistant. Patients with platinum-sensitive disease generally have a better prognosis than platinum-resistant patients.

Because the chemotherapy agents used for second-line treatment of recurrent or refractory platinum-resistant disease have similar response rates that average less than 30%, the selection of the agent depends on the toxicity profile of the agent, physician preference, patient performance status, residual toxicities, and patient convenience (Fig. 141–3). Participation in a clinical trial of an investigational agent is also a reasonable option for these patients. If the patient has a clinical complete response to first-line chemotherapy and the recurrence occurs more than 6 months after chemotherapy is completed, the tumor is considered platinum-sensitive. Table 141–2 summarizes some of the chemotherapeutic regimens used in the treatment of recurrent or refractory ovarian cancer.

CLINICAL CONTROVERSY

In patients with recurrent ovarian cancer that is platinum-sensitive, some clinicians will recommend re-treatment with a chemotherapy regimen including a platinum agent. Other clinicians suggest that the platinum-free interval for these patients should be extended and will recommend that recurrent disease first be treated with a nonplatinum regimen (i.e., liposomal doxorubicin) and reserving the platinum agent until the next relapse.

TABLE 141-3 Combination Chemotherapy Regimens for Platinum-Sensitive Recurrent Ovarian Cancer

Drug(s)	Dose(s)	Cycle Frequency
Gemcitabine + carboplatin	800 mg/m² IV day 1 & 8	Every 21 days
Gemcitabine + cisplatin	Dosed to AUC 5 IV day 1	Every 21 days
Liposomal doxorubicin + carboplatin	Day 1 & Day 8: Gemcitabine 800 mg/m² & Cisplatin 40 mg/m²	Every 28 days
Cyclophosphamide + bevacizumab	30 mg/m² IV over 1–3 hr & carboplatin AUC 5 50 mg PO once daily + bevacizumab 15 mg/kg q 3 weeks	Every 28 days

Platinum-Sensitive Disease Re-treatment with a platinum-containing regimen should be considered in patients with platinum-sensitive disease. The International Collaborative Ovarian Neoplasm 4 and Arbeitsgemeinschaft Gynaekologische randomized 802 patients with recurrent platinum-sensitive ovarian cancer to either single-agent platinum, a non–taxane-platinum combination, or a taxane plus platinum combination.[75] Patients treated with the paclitaxel plus platinum regimen had significantly longer progression-free (29 vs. 24 months) and overall survival (hazard ratio = 0.82 [95% CI 0.69 to 0.97]) as compared with the other two treatment arms.[77,78] Although the taxane–platinum combination was clearly superior in this European study, it is difficult to extrapolate these results to patients treated in the United States because of differences in first-line treatment. At the time that International Collaborative Ovarian Neoplasm (ICON) 4 was conducted, the standard of care in Europe for first-line treatment was single-agent carboplatin, so most patients enrolled in this study had no prior exposure to a taxane agent.[77] However, the standard of care in the United States has been a taxane-platinum combination since the early 1990s. Confirmatory data is needed to evaluate whether combination regimens would also be more beneficial in these patients for treatment of recurrent ovarian cancer.

The 2010 NCCN guidelines recommend the combination of carboplatin with gemcitabine, liposomal doxorubicin, or paclitaxel for treatment of platinum-sensitive recurrent ovarian cancer[67] (Table 141–3). In addition, the combination of gemcitabine plus cisplatin has demonstrated improvement in progression-free survival[78] (Table 141–3). Carboplatin alone or any of the second-line agents is recommended for patients with platinum-sensitive disease who are unable to tolerate additional combination chemotherapy regimens because of residual toxicity or poor performance status.[67,79]

Platinum-Resistant Disease Frequently patients present with recurrent drug-resistant disease after initial platinum-based therapy and cytoreductive surgery.[80,81] Patients who progress on a platinum agent or have no response are considered "platinum-refractory," whereas those patients who have recurrence within 6 months of completing a platinum-containing regimen are considered "platinum-resistant."[79] The 2010 NCCN guidelines list many possible treatment options for recurrent platinum-resistant or -refractory ovarian carcinoma.[67] The optimal chemotherapeutic agent or regimen in the treatment of platinum-resistant disease is currently unclear. Ideally, the agent should be active in ovarian cancer and non–cross-resistant with taxanes or platinum agents. Regrettably, the response rate is low for all of the agents in platinum-refractory or -resistant ovarian cancer.[82] Patients should typically be evaluated for response after treatment with at least three cycles of the chemotherapy agent or regimen. Because partial responses are rare, stable disease is considered a treatment success. If no response is observed, then an alternative chemotherapy regimen may be selected.

Topotecan, an analog of the plant alkaloid 20(S)-camptothecin, is active in patients with metastatic ovarian cancer and is

non–cross-resistant with platinum-based chemotherapy.[83] Preclinical studies suggest that protracted schedules of administration with low doses achieve the greatest antitumor response.[84] Topotecan has demonstrated activity in phase II trials as second-line and salvage therapy in patients who have relapsed after, or progressed during, platinum-based therapy.[83–85] A randomized phase III trial compared topotecan and paclitaxel in patients with advanced ovarian cancer who had failed one platinum-based regimen.[86] Patients were randomized to receive topotecan 1.5 mg/m^2 per day as a 30-minute infusion for 5 days repeated every 21 days or paclitaxel 175 mg/m^2 as a 3-hour infusion every 21 days. The overall response rate was 21% and 13% for the topotecan- and paclitaxel-treated groups, respectively. The median time-to-progression for topotecan-treated patients (32 weeks) was not significantly different from that for paclitaxel-treated patients (20 weeks). Median survival was 61 weeks in the topotecan-treated group and 43 weeks in the paclitaxel-treated group. Topotecan was well tolerated with minimal nonhematologic toxicities.[83,85,86]

Pegylated liposomal doxorubicin is one of the primary agents used for second-line therapy of recurrent ovarian cancer.[87–89] The drug tends to be better tolerated than topotecan, which is important for heavily pretreated patients with advanced disease. A large, randomized phase III study compared pegylated liposomal doxorubicin 50 mg/m^2 every 4 weeks to topotecan 1.5 mg/m^2 per day for 5 days repeated every 21 days in patients who failed first-line platinum therapy.[86] A total of 474 patients were randomized, 239 to pegylated liposomal doxorubicin and 235 to topotecan. The overall response rates for the pegylated liposomal doxorubicin and topotecan groups were 20% and 17%, respectively. Overall survival tended to favor pegylated liposomal doxorubicin, with a median of 108 weeks versus 71 weeks for topotecan. Differences in toxicity were observed between the arms, with more hematologic toxicity occurring in the topotecan arm and more palmar-plantar erythrodysesthesia (PPE) in the pegylated liposomal doxorubicin arm. However, the incidence of PPE has decreased in current clinical practice because the standard dose of pegylated liposomal doxorubicin used currently, 40 mg/m^2, is less than the dose that was used in the initial clinical trials and approved by the FDA.[90,91]

Gemcitabine, a novel pyrimidine antimetabolite, is also widely used in the treatment of recurrent platinum-resistant ovarian cancer. Although the overall response rate is only approximately 13% to 22% with single-agent gemcitabine in patients with platinum-refractory recurrent ovarian cancer, an additional 16% to 50% of patients have stable disease for a median of 7 months.[92,93] The main toxicities include myelosuppression, fatigue, myalgia, and skin rash. Because of its non–cross-resistant activity and in vivo synergy with platinum agents, gemcitabine is being evaluated in doublet regimens in patients with refractory disease and with carboplatin/taxane regimens in previously untreated patients.[93] The combination of gemcitabine with taxanes has demonstrated response rates from 36% to 90%, which if confirmed, are extremely encouraging.[93]

Other agents that have shown an overall response rate of 10% to 25% in patients with recurrent ovarian cancer include altretamine, etoposide, capecitabine, tamoxifen, letrozole, vinorelbine, and oxaliplatin.[94] Response rates tend to be higher in the platinum-sensitive subgroups. Most of these agents are available in oral formulations, which allows for outpatient administration in the palliative care setting.

Although there are no therapeutic guidelines for the selection of agents for the treatment of recurrent platinum-resistant ovarian cancer, the three most commonly used agents in clinical practice include pegylated liposomal doxorubicin, gemcitabine, and topotecan. These agents have demonstrated efficacy when used as a single agent and in combination with other agents. A phase II GOG study is ongoing to help define the optimal chemotherapy combination for treatment of recurrent or refractory platinum-resistant ovarian cancer.

Additional research continues to identify new agents and new targets for the treatment of ovarian cancer. Because platinum agents and taxanes have been identified as the most active classes of agents for treatment of ovarian cancer, drug development has focused on new platinum derivatives, taxanes and taxane analogs, and agents that exert cytotoxic activity by interacting with DNA directly. Specifically, new cytotoxic agents such as Yondelis, TLK-286, pemetrexed, and epothilones are currently being evaluated in clinical trials.

Biologic and Targeted Agents

Monoclonal antibodies such as bevacizumab and cetuximab and small-molecule tyrosine kinase inhibitors such as sunitinib, gefitinib, or sorafenib, are being incorporated into first-line and recurrent treatment regimens for ovarian cancer.[95–99] Although the biological agents as single agents have not demonstrated significant activity, the results of several clinical trials support the incorporation of agents such as bevacizumab into first-line and maintenance regimens to improve progression-free survival.

Bevacizumab Bevacizumab is a recombinant humanized monoclonal antibody that targets vascular endothelial growth factor (VEGF), a key mediator of angiogenesis. In the setting of recurrent disease, single-agent bevacizumab produces a response rate similar to other therapies of 16% to 21%.[100,101] Response rates with combinations of bevacizumab range from 15% to 80%.[98,100–110] However, these phase II trials have also reported a higher risk of bowel perforation in patients treated with bevacizumab-containing regimens.[100,101,111] Bevacizumab should therefore not be given to patients who have had recent bowel surgery or a history of significant bowel resections. Recent efforts have focused on the integration of bevacizumab into first-line treatment regimens. Phase II studies confirmed the safety and feasibility of six cycles of paclitaxel, carboplatin plus bevacizumab, given every 3 weeks, followed by maintenance bevacizumab once every 3 weeks for 1 year.[107,108] Based on these encouraging results, the GOG initiated a confirmatory phase III study comparing six cycles of standard paclitaxel plus carboplatin to six cycles of the same regimen with bevacizumab to determine whether bevacizumab improves the efficacy of paclitaxel plus carboplatin. The duration of maintenance bevacizumab remains controversial. The results of these trials should determine the role of bevacizumab in the treatment of ovarian cancer.

CLINICAL CONTROVERSY

Although bevacizumab has demonstrated some progression-free survival advantages when used in combination, its impact on overall survival is not clear. There are concerns regarding the high cost of bevacizumab with potential minimal or no benefit. As a result, health insurance companies do not consistently reimburse providers for bevacizumab when used for the treatment of ovarian cancer.

Targeted Agents Tyrosine kinase inhibitors such as sorafenib, sunitinib, pazopanib, and cediranib inhibit angiogenesis by specifically targeting the VEGF receptor (VEGFR). When given as single agents, tyrosine kinase inhibitors have demonstrated some antitumor activity in ovarian cancer.[112,113] Ongoing trials have focused on combination regimens with cytotoxic agents for first-line treatment and also treatment of recurrent ovarian cancer. Another interesting targeted agent is VEGF Trap (aflibercept), a fusion protein that targets VEGF-A. Aflibercept has been beneficial in the treatment

of malignant ascites and is currently being incorporated into first-line regimens. Epidermal growth factor receptor (EGFR) inhibitors such as erlotinib have not demonstrated activity either alone or combined with chemotherapy or bevacizumab for the treatment of ovarian cancer.[109] The newer classes of targeted therapies such as platelet-derived growth factor (PDGF) inhibitors and poly-ADP-ribose polymerase (PARP) inhibitors are being investigated in ongoing clinical trials.[114]

PHARMACOECONOMIC CONSIDERATIONS

Healthcare at the end of life is associated with higher costs than at any other time, and, unfortunately, most patients with ovarian cancer will eventually die from the disease.[115] In the past, cost-to-benefit analyses have demonstrated palliative care, despite the limited benefit, is cost-effective based on patients' expectations and "willingness to pay."[116,117] Economic analyses of new chemotherapy agents usually measure cost-effectiveness, where effectiveness is measured as changes in survival (i.e., overall survival, progression-free survival) or quality-adjusted life-years.[118]

The paclitaxel plus platinum regimen is the current accepted standard of care for first-line treatment of advanced ovarian cancer. When paclitaxel was initially evaluated as first-line treatment, several economic analyses showed that the cost-effectiveness ratio of paclitaxel and cisplatin was within the range of other accepted medical interventions and supported its adoption as first-line treatment of advanced ovarian cancer.[118,119] In another cost-benefit study, Dranitsaris et al. reported that patients were willing to pay a mean of $64, which was marginally lower than the incremental cost of $87 to receive docetaxel rather than paclitaxel to reduce their risk of toxicity, primarily neuropathy.[120]

In the setting of recurrent ovarian cancer, Smith et al. performed a retrospective cost minimization analysis of pegylated liposomal doxorubicin versus topotecan.[121] The results of that analysis showed that pegylated liposomal doxorubicin was the preferred second-line agent, based on lower costs because of reduced toxicities as compared with topotecan.[121]

Finally the other pharmacoeconomic struggle is the use of biologically targeted agents such as bevacizumab in the maintenance and recurrent ovarian treatment settings. Since neither the dose nor optimal regimen have been defined yet for treatment of ovarian cancer, this issue will remain unresolved until more long-term data are available.

EVALUATION OF THERAPEUTIC OUTCOMES

Patients receiving a taxane or platinum chemotherapy regimen should be monitored for signs of hypersensitivity or infusion-related reactions. Patients treated with paclitaxel often experience infusion-related reactions, which have been attributed to the cremophor diluent. Premedications including an H_1-blocker, H_2-blocker, and steroid should be administered prior to each chemotherapy administration to prevent hypersensitivity reactions. If a patient has a reaction, increasing the duration of the infusion from 3 to 6 hours may help with infusion-related reactions. For patients with a true taxane allergy, paclitaxel desensitization can be attempted with 24 hours of premedications (H_1-blocker, H_2-blocker, and steroids) followed by paclitaxel given as a titrated infusion (1:1000 → 1:100 →1:10 → full dose) over 8 hours. With repeated exposure (i.e., seven cycles or more) to carboplatin, patients can develop a delayed hypersensitivity reaction. A similar protocol can be used for carboplatin desensitization.

Ovarian cancer patients receive multiple courses of chemotherapy that can have varying effects on kidney and liver function. Appropriate laboratory tests should be ordered to assess organ function so that chemotherapy doses can be adjusted as indicated. Patients on platinum-containing regimens can often experience electrolyte wasting, so patients should be monitored for electrolyte replacement, intravenous or oral, as indicated. The use of myeloid growth factors should be considered to prevent treatment delays and/or dose reductions. Prevention of nausea and vomiting, both acute and delayed, is critical for patients receiving emetogenic chemotherapy regimens such as paclitaxel plus carboplatin.

During initial taxane plus platinum chemotherapy, a CA-125 level should be obtained with each cycle and monitored for at least a 50% reduction in CA-125 after completion of four cycles, which is related to an improved prognosis. Patients who achieve a complete response after completion of first-line treatment should have follow-up once every 3 months, including CA-125, physical examination, pelvic examination, and appropriate diagnostic scans (i.e., computed tomography, magnetic resonance imaging, or positron emission tomography), which should be evaluated for presence of disease. In addition to routine follow-up examinations, clinicians should monitor for resolution of any residual chemotherapy-related side effects, including neuropathies, nephrotoxicity, ototoxicity, myelosuppression, and nausea/vomiting.

In the progressive disease or recurrent setting, CA-125 levels can still be used to monitor for response and should be checked with each cycle, although no change in therapy is recommended until after completion of at least three cycles of the second-line chemotherapy. In addition to laboratory monitoring, appropriate diagnostic scans (i.e., computed tomography, magnetic resonance imaging, or positron emission tomography) should be done once every three cycles. Patients need to be monitored with each cycle of chemotherapy to evaluate for new or persistent toxicities such as neuropathies, fluid retention, PPE, myelosuppression, and nausea/vomiting. Another precaution to keep in mind for patients with significant ascites, the "dry weight" or an adjusted body weight should be used for dosing chemotherapy.

Eventually, most ovarian cancer patients will progress through all chemotherapy regimens and investigational treatment options, after which the best supportive care measures should be provided to maintain patient comfort and quality of life. A plan to treat common complications of progressive ovarian cancer, including thrombosis, ascites, uncontrollable pain, and small bowel obstruction should be developed. The primary goal at the end of life for patients with progressive ovarian cancer is to provide any measures necessary to maintain patient comfort and quality of life.

CONCLUSIONS

Despite gallant research efforts, ovarian cancer remains one of the major challenges in gynecologic oncology. One of the key issues for improving outcome is to educate patients as to the signs and symptoms of ovarian cancer. Earlier diagnosis is associated with a significant improvement in prognosis and overall survival. Although some milestones have been reached in extending progression-free and overall survival over the past few decades, there are still many unresolved issues. More data are needed to determine the role of biological agents to be used in first-line and recurrent treatment regimens and their impact on overall survival. Research needs to identify and develop new approaches to the treatment of advanced primary and recurrent or refractory ovarian cancer, such as agents to modulate or overcome drug resistance, new molecular targets, and optimized chemotherapy regimens.

ABBREVIATIONS

CHAPTER 142

Acute Leukemias

BETSY BICKERT POON AND DIANNE M. BRUNDAGE

KEY CONCEPTS

1. Acute leukemias are the most common malignancies in children and the leading cause of cancer-related death in patients younger than age 35 years.
2. To establish a definitive diagnosis of acute leukemia, the following diagnostic components are required: bone marrow biopsy and aspirate (with ≥20% blasts), cytogenetics, and immunophenotyping.
3. Several risk factors correlate with prognosis for acute lymphoblastic leukemia (ALL). Poor prognostic factors include high white blood cell count at presentation, very young or very old age at diagnosis, delayed remission induction and presence of certain cytogenetic abnormalities (e.g., Philadelphia [Ph^+] chromosome).
4. For children with ALL, remission induction therapy includes vincristine, a corticosteroid, and asparaginase, with or without an anthracycline. For adults with ALL, vincristine, prednisone, and an anthracycline are given, and asparaginase is sometimes added.
5. All patients with ALL require prophylactic therapy to prevent CNS disease because of the high risk of central nervous system relapse. The choice for therapy includes a combination of the following: cranial irradiation, intrathecal chemotherapy, or high-dose systemic chemotherapy with drugs that cross the blood–brain barrier.
6. Long-term maintenance therapy for 2 to 3 years is essential to eradicate residual leukemia cells and prolong the duration of remission in patients with ALL. Maintenance therapy consists of oral methotrexate and mercaptopurine, with or without monthly pulses of vincristine and a corticosteroid.
7. Disease-free survival is lower in adults with ALL and has been attributed to greater drug resistance, poor side-effect tolerance with subsequent nonadherence, and possibly less-effective therapy. This population is also more likely to have Ph^+ ALL, which is associated with a worse outcome.
8. Colony-stimulating factors can be safely and effectively used with myelosuppressive chemotherapy for acute leukemias. The benefits can include reduced incidence of serious infections, reduced hospital stays, and fewer treatment delays, but do not include prolonged disease-free survival or overall survival.
9. There are several poor prognostic factors for adult acute myeloid leukemia (AML): older age, organ impairment, certain FAB subtypes, presence of extramedullary disease, and presence of certain cytogenetic and molecular abnormalities.
10. Therapy of AML usually includes induction therapy with an anthracycline and cytarabine. Postremission therapy is required in all patients and can include either consolidation chemotherapy with or without maintenance therapy, or hematopoietic stem cell transplantation.
11. It is estimated that up to 10^8 to 10^9 malignant cells remain following attainment of a complete remission. Postremission therapy with either chemotherapy or hematopoietic stem cell transplantation is essential in AML.
12. Treatment of acute promyelocytic leukemia consists of induction therapy, followed by consolidation and maintenance therapy. Induction includes tretinoin and an anthracycline; consolidation therapy consists of two to three cycles of anthracycline-based therapy; maintenance consists of pulse doses of tretinoin, mercaptopurine, and methotrexate for 2 years.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

The leukemias are heterogeneous hematologic malignancies characterized by unregulated proliferation of the blood-forming cells in the bone marrow. These immature proliferating leukemia cells (blasts) physically "crowd out" or inhibit normal cellular maturation in bone marrow, resulting in anemia, neutropenia, and thrombocytopenia. Leukemic blasts may also infiltrate a variety of tissues such as lymph nodes, skin, liver, spleen, kidney, testes, and the central nervous system.

Historically, leukemia has been classified as acute or chronic based on differences in cell of origin and cell line maturation, clinical presentation, rapidity of progression of the untreated disease, and response to therapy. Four major leukemias are recognized: acute lymphoblastic (or lymphocytic) leukemia (ALL), acute myeloid leukemia (AML), chronic lymphocytic leukemia, and chronic myeloid leukemia. Undifferentiated immature cells that proliferate autonomously characterize acute leukemias. Chronic leukemias also proliferate autonomously, but the cells are more differentiated and mature. Untreated, acute leukemia is fatal within months.

EPIDEMIOLOGY

It is estimated that 17,660 new cases of acute leukemia—12,330 cases of AML and 5,330 cases of ALL—will be diagnosed in the United States in 2010, accounting for 1.2% of the total cancer

incidence.[1] The incidence has been relatively stable for two decades. An estimated 10,400 deaths per year, representing about 2% of all cancer deaths, are caused by acute leukemias.[1] 1 Leukemia is the leading cause of cancer-related deaths in persons younger than age 20 years, but an uncommon cause of cancer-related death after age 40 years.[1] Among adults, acute and chronic leukemias occur at equal rates. More than 90% of the cases of acute and chronic leukemia occur in adults. AML accounts for most cases of acute leukemia in adults, and occurs with increasing frequency in elderly patients. There are about 3.5 cases of AML and 1.6 cases of ALL per 100,000 individuals.[2] The median age at diagnosis of patients with AML is about 67 years, whereas the median age for ALL patients is about 13 years.[1,2] The incidence of AML rises with age from 1.7 per 100,000 in individuals younger than age 65 years to 16 per 100,000 in those 65 years or older.[2,3] Acute leukemia is slightly more common in males than in females. In the United States, acute leukemia is more common among whites than among African Americans, American Indians, and Hispanic ethnicities.[2]

Despite the low incidence rate, the acute leukemias are the most common malignancy in persons younger than 20 years of age, accounting for 27% of all childhood malignancies.[4] The lifetime risk of developing ALL is 1 in 810 Americans and 1 in 272 Americans for AML.[2] Approximately 77% of children with leukemia have ALL and 18% AML.[4] Childhood ALL is 30% more common in males than in females, peaks at 2 to 5 years of age, and is twice as likely to affect white children as African American children.[4,5] The incidence of childhood AML is highest in the Hispanic population and occurs throughout childhood without any peak age period. Acute leukemia during the first year of life (infant leukemia) slightly favors ALL over AML.[4,6]

Chemotherapy has dramatically improved the outlook of patients with acute leukemia. More than 85% of children and young adults with acute leukemia achieve an initial complete remission (CR) of their disease. Overall, 65% to 85% of adults achieve an initial CR.[3] For persons younger than 15 years of age, the 5-year survival rate is 88% for ALL and 55% for AML.[2] The prognosis of adult acute leukemia is generally worse than that of childhood leukemia, with only 30% to 40% of patients becoming long-term survivors. When all ages are included, the 5-year relative survival rate in 2004 for ALL was 65% and 23% for AML.[2]

ETIOLOGY

The exact cause of the acute leukemias is unknown. A multifactorial process involving genetics, environmental and socioeconomic factors, toxins, immunologic status, and viral exposures is likely. Table 142–1 summarizes the major factors that have been linked to acute leukemias. Infectious and genetic factors have the strongest associations to date.[5] In pediatric ALL, a number of environmental factors are inconsistently linked to the disease: exposure to ionizing radiation, toxic chemicals, herbicides and pesticides; maternal use of contraceptives, diethylstilbestrol, or cigarettes; parental exposure to drugs (amphetamines, diet pills, and mind-altering medications), diagnostic radiographs, alcohol consumption, or chemicals before and during pregnancy; and chemical contamination of groundwater.[7,8] A growing body of evidence indicates that high birthweight is a risk factor for ALL.[5,9] Ionizing radiation and benzene exposure are the only environmental risk factors strongly associated with ALL or AML.[8] A few studies have reported a possible link between electromagnetic fields of high-voltage power lines and the development of leukemia, but larger studies could not confirm this association. In most patients who develop leukemia, a cause cannot be identified.

Childhood AML is associated with Hispanic ethnicity, prior exposure to alkylating agents or epidopophyllotoxins, and in utero exposure to ionizing radiation.[6,8] Maternal alcohol consumption, parental and child organophosphate pesticide exposure, and parental benzene exposure are also associated with childhood AML.[6] AML has been associated with both low and high birth weight.[9]

TABLE 142-1 Risk Factors for Acute Leukemia

Drugs	**Chemical**
Alkylating agents	Benzene
Epidopophyllotoxins	**Pesticides**
Genetic conditions	**Pyrethroid-based shampoo**

Li Fraumeni syndrome	
Neurofibromatosis type 1	
Noonan syndrome	
Schwachman syndrome	
Severe combined immunodeficiency syndrome	
Wiskott-Aldrich syndrome	

PATHOPHYSIOLOGY

A basic understanding of normal hematopoiesis is needed before one can understand the pathogenesis of leukemia (see Chap. 95). Normal hematopoiesis consists of multiple well-orchestrated steps of cellular development. A pool of pluripotent stem cells undergoes differentiation, proliferation, and maturation, to form the mature blood cells seen in the peripheral circulation. These pluripotent stem cells initially differentiate to form two distinct stem cell pools. The myeloid stem cell gives rise to six types of blood cells (erythrocytes, platelets, monocytes, basophils, neutrophils, and eosinophils), while the lymphoid stem cell differentiates to form circulating B and T lymphocytes and natural killer cells. Leukemia may develop at any stage and within any cell line.

Two features are common to both AML and ALL: first, both arise from a single leukemic cell that expands and acquires additional mutations, culminating in a monoclonal population of leukemia cells. Second, the relative balance between proliferation and differentiation is not maintained, so that the cells do not differentiate past a particular stage of hematopoiesis. Cells (lymphoblasts or myeloblasts) then proliferate uncontrollably. Proliferation, differentiation, and apoptosis are under genetic control, and leukemia can occur when the balance between these processes is altered.

AML probably arises from a defect in the pluripotent stem cell or a more committed myeloid precursor, resulting in partial differentiation and proliferation of immature precursors of the myeloid blood-forming cells. In older patients, trilineage leukemic involvement occurs suggesting that the cell of origin is probably a stem or very early progenitor cell. In younger patients, a more differentiated progenitor becomes malignant, allowing maturation of some granulocytic and erythroid populations. These two forms of AML exhibit different patterns of resistance to chemotherapy, with resistance more evident in the older adults with AML. ALL is a disease characterized by proliferation of immature lymphoblasts. In

TABLE 142-2 Morphologic (FAB) Classification of Acute Myeloid Leukemia

		Frequency of FAB Subtype[a]		
	Subtype	***Adults (%)***	***Children <2 years (%)***	***Children >2 years (%)***
M0	Acute myeloblastic leukemia, without maturation	5	Low	Low
M1	Acute myeloblastic leukemia with minimal maturation	15	17	25
M2	Acute myeloblastic with maturation	25		27
M3	Acute promyelocytic leukemia	10		5
M4	Acute myelomonocytic leukemia	25	30	26
M5a	Acute monoblastic leukemia, poorly differentiated	5	52	16
M5b	Acute monoblastic leukemia, well differentiated	5		
M6	Acute erythroleukemia	5		2
M7	Acute megakaryoblastic leukemia	10		5–7

FAB, French-American-British.
[a]Percentages should be compared vertically, not horizontally.

this type of acute leukemia, the defect is probably at the level of the lymphopoietic stem cell or a very early lymphoid precursor.

Leukemic cells have growth and/or survival advantages over normal cells, leading to a "crowding out" phenomenon in the bone marrow. This growth advantage is not caused by more rapid proliferation as compared with normal cells. Some studies suggest that it is caused by factors produced by leukemic cells that either inhibit normal cellular proliferation and differentiation, or reduce apoptosis as compared with normal blood cells.

The types of genetic alterations that lead to leukemia have only recently become evident. The genetic defects may include (a) activation of a normally suppressed gene (protooncogene) to create an oncogene that produces a protein product that signals increased proliferation; (b) loss of signals for the blood cell to differentiate; (c) loss of tumor suppressor genes that control normal proliferation; and (d) loss of signals for apoptosis. Most normal cells are programmed to die eventually through apoptosis, but the appropriate programmed signal is often interrupted in cancer cells, leading to continued survival, replication, and drug resistance. Signal transduction, RNA transcription, cell-cycle control factors, cell differentiation, and programmed cell death may all be affected.

LEUKEMIA CLASSIFICATION

The French-American-British (FAB) classification system identifies eight different subtypes of AML based on granulocytic differentiation and maturation (Table 142–2), and this system is used to determine prognosis and choice of therapy. However, it does not consider clinical characteristics, clonal cytogenetic abnormalities, immunophenotyping, or response to therapy. In 2001, the World Health Organization (WHO), in collaboration with the Society for Hematopathology and the European Association of Haematopathology, proposed a new classification system for myeloid neoplasms. This new classification system incorporates not only morphologic findings, but also genetic, immunophenotypic, cytochemical, and clinical features. It has long been known that certain cytogenetic abnormalities have prognostic significance, but did not always correlate well with the FAB classification system. About 40% to 50% of adult patients with AML have no detectable chromosomal abnormality on standard cytogenetic analysis, but the percent increases with age.[10] The WHO classification attempts to formally incorporate the relationship between AML and myelodysplastic syndrome (MDS). In 2008, this classification was revised (Table 142–3) and is being used routinely in pediatric studies, but not in adults.[11]

A number of factors may affect the cytogenetics of acute myeloid leukemia in adults. First, in about 5% of adult AML patients, simultaneous blood and marrow samples demonstrate normal cytogenetics versus abnormal cytogenetics, respectively.[10] Second, central cytogenetic analysis is done in multi-center trials because of variability in specimen examination. A small number of patients may have a normal karyotype on standard review, but carry fusion genes, which are identical to those of translocations or inversions. These insertions of very small chromosome segments do not alter chromosome morphology but may affect outcome.

Lymphoblast analysis is used to classify ALL. Immunophenotype is determined by flow cytometry that analyzes specific antigens, known as clusters of differentiation (often abbreviated "CD"), present on the surface of hematopoietic cells. Although no leukemia-specific antigens have been identified, the pattern of cell-surface antigen expression reliably distinguishes between lymphoid and myeloid leukemia. The immunophenotype defines the cell of origin. The major phenotypes are mature B-cell, precursor B-cell, and T-cell disease. Eighty percent of childhood ALL derives from precursor B cells and about 15% from T cells. The remainder is either mixed lineage or from mature B cells.

TABLE 142-3 World Health Organization Classification of Acute Myeloid Leukemia

- Acute myeloid leukemia (AML) with recurrent genetic abnormalities
  - AML with t(8;21)(q22;q22), (AML1/ETO)
  - AML with abnormal bone marrow eosinophils and inv(16)(p13;q22) or t(16;16)(p13;q22), (CBFβ/MYH11)
  - Acute promyelocytic leukemia with t(15;17)(q22;q12), (PML/RAR-α) and variants
  - AML with 11q23 (MLL) abnormalities
- Acute myeloid leukemia with multilineage dysplasia
  - Following MDS or MDS/MPD disorder
  - Without antecedent MDS or MDS/MPD, but with dysplasia in at least 50% of cells or two or more lineages
- Acute myeloid leukemia and MDS, therapy-related
  - Alkylating agent/radiation-related type
  - Topoisomerase II inhibitor-related type (some may be lymphoid)
  - Others
- Acute myeloid leukemia, not otherwise categorized, classify as
  - Acute myeloid leukemia, minimally differentiated
  - Acute myeloid leukemia without maturation
  - Acute myeloid leukemia with maturation
  - Acute myelomonocytic leukemia
  - Acute monoblastic/acute monocytic leukemia
  - Acute erythroid leukemia (erythroid/myeloid and pure erythroleukemia)
  - Acute megakaryocytic leukemia
  - Acute basophilic leukemia
  - Acute panmyelosis with myelofibrosis
  - Myeloid sarcoma

MDS, myelodysplastic syndrome; MLL, mixed lineage leukemia; MPD, myeloproliferative disease; PML, promyelocytic leukemia; RAR, retinoic acid receptor-α.

ALL may also be described by cytogenetic abnormalities. Chromosome alterations include numerical (hyperdiploidy and hypodiploidy), and structural abnormalities due to exchanges of genetic information within (inversion) or between (translocation) chromosomes.[12]

ACUTE LYMPHOBLASTIC LEUKEMIA

CLINICAL PRESENTATION

Common signs and symptoms at presentation result from malignant cells that replace and suppress normal hematopoietic progenitor cells and infiltrate into extramedullary spaces. In addition to clinical presentation, laboratory and pathology evaluations are required for a definitive diagnosis of leukemia. An abnormal complete blood count is usually the diagnostic test that initiates a leukemia diagnostic workup. The most important test is a bone marrow biopsy and aspirate, which is submitted to hematopathology for numerous evaluations. A lumbar puncture is performed to determine if there are blasts in the central nervous system (CNS). A chest radiograph is performed to screen for a mediastinal mass (most common in T-cell disease).

2 Leukemia is suspected if the bone marrow contains greater than 5% blasts. Cytochemical stains are helpful to determine if the acute leukemia is of myeloid or lymphoid lineage. Cytogenetic analysis of the marrow to determine the presence of nonrandom numerical and structural chromosomal abnormalities in leukemic cells is also helpful for diagnosis, establishing prognosis, and evaluating response to therapy.[5,7] Chromosome translocations can result in abnormal expression and/or function of cellular oncogenes. Unique translocations can identify specific subtypes of acute leukemia. Twenty-five percent of children with precursor B-cell ALL have the *TEL-AML1* (translocation ETS leukemia-acute myeloid leukemia-1) fusion gene generated by the t(12;21)(p13;q22) chromosomal translocation.[5] This translocation gives the preleukemic cell altered self-renewal and survival properties. The most common translocation in adult ALL is the t(9;22) or Philadelphia chromosome which causes fusion of the BCR signaling protein to the ABL non-receptor tyrosine kinase, resulting in constitutive tyrosine kinase activity. More than 50% of childhood T-cell ALL have activating mutations of the *NOTCH1* gene that encodes for a transmembrane receptor implicated in regulation of T-cell development.[5]

CLINICAL PRESENTATION

General

- Recent history of vague symptoms such as tiredness, lack of exercise tolerance, and "feeling unwell," but in no obvious distress.

Symptoms

- Patient's commonly report fever, pallor, weight loss, malaise, fatigue, palpitations, and bone pain. Other possible symptoms include epistaxis, palpitations, dyspnea on exertion, seizures, headache, or diplopia.

Signs

- Temperature is often elevated and may be caused by disease or infection; ecchymoses or petechiae; painless testicular enlargement; splenomegaly, hepatomegaly, and/or lymphadenopathy; and, rarely, small, blue-green collections of leukemia cells under the skin (chloromas).

Laboratory Tests

- Complete blood count with differential. Anemia (43% <7 g/dL) is normochromic and normocytic (without a compensatory increase in reticulocytes). Thrombocytopenia (severe, <20,000 cells/mm^3) is present in 28% of cases. Leukopenia/leukocytosis: 17% of patients will present with a white blood cell (WBC) count ≥50,000 cells/mm^3 and 53% with a WBC <10,000 cells/mm^3.
- Uric acid may be elevated because of rapid cellular turnover and is more common in patients presenting with elevated WBC count.
- Electrolytes: potassium and phosphate may be elevated with a compensatory decrease in calcium.

Other Diagnostic Tests

- Bone marrow aspirate and biopsy: send for morphologic examination, cytochemical staining, immunophenotyping, and cytogenetic (chromosome) analysis. All patients should have a screening lumbar puncture performed to assess CNS involvement.

RISK CLASSIFICATION

Many clinical and biologic features at diagnosis are associated with response to treatment, as measured by the complete remission rate, duration of remission, and long-term survival. Identification of these risk factors allows the clinician to better understand the disease and to tailor treatment according to risk of disease recurrence (i.e., risk-adapted therapy). For example, if a patient has many clinical and laboratory features that are associated with a good response to chemotherapy ("standard-risk"), then the clinician may choose to give less intensive therapy to reduce the risk of long-term side effects. Conversely, if a patient is unlikely to respond well to standard therapy ("high-risk" or "very-high-risk" disease), then the clinician may choose to give more intensive chemotherapy.

3 The National Cancer Institute developed an ALL risk stratification to create a standard for comparison in children.[13] Induction therapy is initially selected based on this classification, which divides children into standard- or high-risk categories based on age and initial WBC count (Fig. 142–1). Karyotype is also considered if the results are available. Age remains an independent predictor of outcome with children aged 1 to 9 years having the best event-free survival (EFS). This is mostly explained by the more frequent occurrence of the *TEL-AML1* translocation and hyperdiploidy (>51 chromosomes) in addition to increased drug sensitivity in this age group.[14] Recently, more sophisticated biologic studies have allowed more refined risk stratification.[15] For example, the current algorithm incorporates treatment response through the measurement of subclinical minimal residual disease (MRD) by either flow cytometry or polymerase chain reaction.

The strongest prognostic factor for outcome for ALL is response to therapy, which traditionally was measured morphologically in bone marrow specimens. More recently molecular measurement of MRD has enabled detection of leukemic cells not visible on morphologic examination to assess treatment response and detect relapse in children and adults.[16] This technique allows detection of 1 leukemia cell in 10,000 normal cells, which is about 100-fold more sensitive than morphologic examination.[16] If MRD is detected at the end of induction therapy, the clinician may decide to give more intensive therapy to decrease the risk of relapse.

The Children's Oncology Group utilizes a risk- and response-based classification of childhood ALL (Fig. 142–1).[15] This classification system uses the National Cancer Institute risk assignment

	SR-low	SR-average	SR-high	Very-high risk
Biologic features	Triple trisomies or TEL-AML1 and No CNS2/3 or testicular disease AND	No triple trisomies or TEL-AML1 AND	ANY patient with MLL translocation with RER or CNS3 or testicular disease OR	BCR-ABL or MLL translocation with SER or Hypodiploid OR
Treatment response	Day 8 or 15 M1 BM and Day 29 M1 BM and Day 29 MRD <0.1%	Day 8 or 15 M1 BM and Day 29 M1 BM and Day 29 MRD <0.1%	Day 15 M2/M3 BM or Day 29 MRD ≥0.1–1%	Induction failure (Day 29 M3 BM) or Day 29 M2 BM or Day 29 MRD ≥1% with Day 43 M2/M3 BM or Day 43 MRD ≥1%

FIGURE 142-1. Risk- and response-based classification of childhood ALL. *Note:* Patients with T-cell ALL are automatically categorized as very-high-risk regardless of other factors. (BM, bone marrow; CNS2, lymphoblasts with <5 cells/microliter [<5 × 10^6/L]; CNS3, lymphoblasts with ≥5 cells/microliter [≥5 × 10^6/L] or clinical signs of CNS disease; M1, <5% blasts, M2, 5%–25% blasts, M3, >25% blasts; MLL, mixed lineage leukemia; MRD, minimal residual disease; RER, rapid early response; SER, slow early response; SR, standard risk; TEL-AML1, translocation ETS leukemia-acute myeloid leukemia-1; WBC, white blood cell.)

to initially categorize patients into standard- or high-risk groups. Patients categorized as high-risk usually receive more intensive remission induction therapy. Following remission induction therapy, risk is reclassified based on the biologic features (the presence or absence of molecular or cytogenetic abnormalities, and CNS or testicular involvement) and the rapidity and completeness of response to therapy (Fig. 142–1). Standard-risk patients are then classified as standard-risk-low, standard-risk-average, standard-risk-high, or very-high-risk. Patients who are initially high-risk remain in the high-risk category, unless they have biologic features or slow early response, as defined in the very-high-risk category.

Children who are initially classified as standard-risk and have three copies of chromosomes 4, 10, and 17 (triple trisomies) or the *TEL-AML1* fusion gene and less than 5% blasts in the bone marrow (M1) on days 15 and 29 of induction and MRD less than 0.1% on day 29 are reclassified as standard-risk-low and will have their therapy reduced. Children with the same rapid treatment response but without triple trisomies or the *TEL-AML1* fusion gene are reclassified as standard-risk-average. Children with certain biologic features (evidence of CNS or testicular disease, MLL translocation with a rapid early response to therapy), delayed treatment response (>5% blasts in the bone marrow (M2/M3) by day 15 or MRD ≥ 0.1% but <1% on day 29), or who received steroids prior to diagnosis are reclassified as standard-risk-high and have post-induction therapy intensified. Childhood precursor B-ALL with the Philadelphia chromosome [Ph^+ disease, t(9;22)], hypodiploidy (<44 chromosomes), induction failure, mixed lineage leukemia (MLL) gene rearrangement with a slow response to therapy are considered very-high-risk and have therapy intensified. Infant ALL and childhood

T-cell ALL have unique risk classification schemas. Children with T-cell ALL have an inferior response to standard-risk therapy and are automatically categorized as very-high-risk (Fig. 142–1). T-cell and mature B-cell disease are favorable phenotypes in adults.[5] Age is inversely associated with prognosis in patients with Ph^+ ALL.[5]

Other prognostic factors have been identified but are not the basis for therapy changes. Race is controversial, with older studies indicating worse outcomes for minorities. Male race and obesity have been associated with worse outcome in cooperative group studies, but not single-institution studies.[5] Hepatosplenomegaly and mediastinal mass are both associated with worse outcomes.

TREATMENT

Acute Lymphoblastic Leukemia

TREATMENT GOALS

The short-term goal for ALL treatment is to rapidly achieve a complete clinical and hematologic remission. A complete remission (CR) is defined as the disappearance of all physical and bone marrow evidence (normal cellularity with <5% blasts) of leukemia, with restoration of normal hematopoiesis. After a CR is achieved, the goal is to maintain the patient in continuous CR. In general, a child is considered to be "cured" after being in continuous CR for at least 5 years.

Successful treatment of ALL was first developed in children. Current regimens induce clinical remission in 96% to 99% of children with ALL.[5] MRD is a strong predictor of relapse in ALL. Children with MRD in the bone marrow at the end of induction have a 5-year EFS of 59% versus 88% in children without.[17] Children with low-risk disease have a 5-year EFS of 97%.[17] The 5-year EFS is 71% for high-risk childhood B-precursor and T-cell ALL including rapid and slow responders.[18] Children with very-high-risk disease have a 5-year EFS of less than 45%.[19] Response to treatment is determined by intrinsic drug sensitivity in concert with the patient's pharmacogenomics and pharmacodynamics, treatment received, and treatment adherence. Cure rates in children have risen from less than 5% with treatments used in the 1960s to about 90% by 2005.[12] The reason for this improvement lies largely in improved scheduling of existing drugs, as relatively few new drugs have come to the market since the 1960s.

Although treatment results with adult ALL are worse than those with childhood ALL, recent use of aggressive chemotherapy in adult ALL has increased the CR rate to 60% to 85%. Long-term EFS in this population, however, remains low (between 30% and 40%) because a higher proportion of adults present with poor-risk disease. CR rates and EFS vary according to a number of poor prognostic factors and certain types of ALL are associated with a very poor outcome.

CLINICAL CONTROVERSY

Which corticosteroid is superior for the treatment of ALL? Prednisone/prednisolone has been the steroid of choice for many years. Dexamethasone was recently shown to have better CNS penetration than prednisone with a consequent decrease in CNS relapse rate. However, the incidence of debilitating side effects such as osteonecrosis is higher with dexamethasone. Many investigators have difficulty weighing the quality-of-life decrease from the side effects against the small increase in survival.

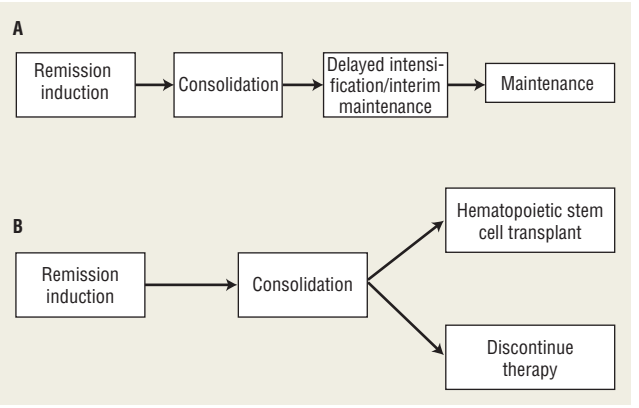

FIGURE 142-2. Treatment algorithm for *(A)* acute lymphoblastic leukemia and *(B)* acute myeloid leukemia.

TREATMENT PHASES

Therapy for childhood ALL is divided into five phases: (a) induction; (b) consolidation therapy; (c) interim maintenance; (d) delayed intensification; and (e) maintenance therapy (Fig. 142–2). CNS prophylaxis is a mandatory component of ALL treatment regimens and is administered longitudinally during all phases of treatment. The total duration of treatment is 2 to 3 years.

Induction

The goal of induction is to rapidly induce a complete clinical and hematologic remission. 4 The CR rate is 98% for standard-risk children treated with vincristine, a glucocorticoid (dexamethasone or prednisone), and asparaginase or pegaspargase.[12] Most treatment protocols add daunorubicin to induction (four-drug induction) for high-risk or very-high-risk ALL, while others add cyclophosphamide, methotrexate, or cytarabine. Most children achieve a CR in 4 weeks and are considered rapid early responders. Those who have a M2 (5%–25% blasts) or M3 (>25% blasts) marrow on day 15 of induction or have positive MRD at day 29 are considered slow early responders and receive intensified therapy. Half of the induction failures die from toxicity and half receive intensified therapy.[14]

Historically, prednisone has been the primary glucocorticoid used in pediatric ALL regimens. Dexamethasone is now being used in most standard-risk protocols because of its longer duration of action and higher cerebrospinal fluid penetration compared to prednisone.[5,12] Dexamethasone, when used in place of prednisone during induction, consolidation, and maintenance improves EFS 8% to 9% and decreases the risk of CNS relapse by about 3%.[14,20] However, dexamethasone increases the risk of side effects such as osteonecrosis, steroid myopathy, hyperglycemia, and infections.[20,21] Patients older than 10 years of age are particularly prone to osteonecrosis and receive prednisone instead of dexamethasone to minimize this side effect. Dexamethasone exposure is prolonged in children with ALL who have low serum albumin and may contribute to increased toxicity.[14] Patients with Down syndrome have increased infections and mortality with dexamethasone; therefore these patients receive prednisone.

The incidence of transient hyperglycemia during pediatric ALL induction therapy has increased. In a recent study where transient hyperglycemia was defined as at least two random serum glucose levels greater than or equal to 200 mg/dL (11.1 mmol/L), the overall incidence was 20%.[22] This increased to 42% for children over 10 years of age. The risk was higher for patients with a BMI greater than or equal to the 95th percentile and those receiving native l-asparaginase in comparison to pegaspargase.

Asparaginase is available in three forms. Asparaginase and pegaspargase are isolated from *Escherichia coli* while crisantaspase (investigational agent available if allergic to the other products) is isolated from *Erwinia chrysanthemi*. Pegaspargase is pegylated *E coli* asparaginase; pegylation prolongs its duration of activity and allows it to be given less frequently. Pegaspargase is used in the majority of protocols and is preferred over asparaginase because of fewer intramuscular injections, decreased antibody formation, and superior response rates. Pegaspargase is also approved for intravenous administration. Asparaginase products are the chemotherapeutic agents most likely to cause hypersensitivity reactions (10%–40%). The reaction is delayed with pegaspargase and usually occurs 6 to 12 hours following a dose. The hypersensitivity reaction to pegaspargase may also be prolonged and frequently requires hospitalization for 5 to 7 days.

Ph^+ ALL has historically been associated with a poor long-term outcome and is treated as very-high-risk disease. This includes a four-drug induction and a matched related-donor allogeneic hematopoietic stem cell transplant (HSCT) if available. The addition of continuous imatinib mesylate, a signal transduction inhibitor that inhibits BCR-ABL kinase, through all phases of treatment resulted in a 3-year EFS of 80% in comparison to 35% for historical controls.[19] The results for patients receiving chemotherapy with imatinib were equivalent to those receiving stem cell transplantation. Imatinib is currently incorporated into childhood treatment trials for Ph^+ ALL in Europe and the United States. Trials are ongoing with the more potent tyrosine kinase inhibitors, nilotinib and dasatinib.

Central Nervous System Prophylaxis

CNS prophylaxis is incorporated throughout all phases of therapy. The rationale for CNS prophylaxis is based on two observations. First, many chemotherapeutic agents do not readily cross the blood–brain barrier. Second, results from early clinical trials of ALL showed that 50% to 85% of patients with ALL and no CNS involvement at diagnosis experienced a CNS relapse.[7] These observations indicate that the CNS is a potential sanctuary for leukemic cells and that undetectable leukemic cells are present in the CNS in many patients at the time of diagnosis. Detectable CNS involvement at the time of diagnosis occurs in 3% of children with ALL.[14] Factors that are associated with an increased risk of CNS involvement at diagnosis in children include a high initial WBC count, T-cell phenotype, mature B-cell phenotype, age ≤1 year, African American race, thrombocytopenia, lymphadenopathy, and hepatomegaly or splenomegaly.[12]

The goal of CNS prophylaxis is to eradicate undetectable leukemic cells from the CNS while minimizing neurotoxicity and late effects. Leukemic meningitis is more easily prevented than treated. Once CNS relapse has occurred, patients are at increased risk of bone marrow relapse and death from refractory leukemia. Initial trials of childhood ALL in the 1960s established craniospinal irradiation as the standard for prevention of CNS relapse.[12] However, this approach was associated with long-term sequelae including neuropsychological deficits, precocious puberty, osteoporosis, decreased intellect, thyroid dysfunction, an increased risk of brain tumors, short stature, and obesity. Subsequent trials have demonstrated that irradiation may be replaced by frequent administration of intrathecal chemotherapy in most children with ALL.[12] Only patients with T-cell disease or very-high-risk disease receive prophylactic cranial radiation in the United States as a consequence of the long-term sequelae. Most children with CNS disease at diagnosis receive cranial radiation, but current research is aimed at eliminating this if possible.

5 The selection of a CNS prophylaxis regimen must consider efficacy, toxicity, and risk of CNS disease. Intrathecal chemotherapy, cranial irradiation, dexamethasone, and high-dose intravenous methotrexate or cytarabine can be used to treat or prevent CNS disease. Current treatment approaches have reduced isolated CNS relapses to less than 5% among children.[23] Risk factors for CNS relapse include male sex, hepatomegaly, T-cell phenotype, CNS2 disease (the presence of leukemic blasts in a cerebrospinal fluid sample that contains <5 WBC/mm^3 [<5 × 10^6/L]), age younger than 2 years or older than 6 years, and a bloody diagnostic lumbar puncture.[5,23] Intrathecal therapy consists of methotrexate and cytarabine, given either alone or in combination. When given together, hydrocortisone is commonly added (triple intrathecal therapy) to decrease the incidence of arachnoiditis. For standard-risk ALL, triple intrathecal therapy reduces CNS relapse rates by 2.5% in comparison to intrathecal methotrexate, but has no effect on overall survival.[23] The doses of intrathecal chemotherapy used for childhood ALL are age-based because of differences in the volume of cerebrospinal fluid at various ages. For example, intrathecal methotrexate is dosed as 8 mg if <2 years, 10 mg for 2 to 2.99 years, 12 mg for 3 to 8.99 years, and 15 mg for ≥9 years. Liposomal cytarabine induces CNS remission in 57% of relapsed patients, but is associated with a high incidence of arachnoiditis and other CNS-related side effects.[24] Currently its use is limited to refractory or relapsed CNS disease in children.

Patients with T-cell leukemia have an increased incidence of CNS disease and benefit from systemic therapy that penetrates the CNS such as high-dose methotrexate.[21] A WBC count greater than 100,000 cells/mm^3 (100 × 10^9/L)have an increased risk of CNS relapse.[5] Patients with T-cell disease have lower methotrexate polyglutamate accumulation and addition of high-dose methotrexate results in fewer CNS relapses and improves EFS.[14]

Consolidation Therapy

Consolidation therapy in ALL is started after a CR has been achieved, and refers to continued intensive chemotherapy in an attempt to eradicate clinically undetectable disease in order to secure (consolidate) the remission. Regimens usually incorporate either non–cross-resistant drugs that are different from the induction regimen, or more dose-intensive use of the same drugs.

Randomized trials show that consolidation therapy clearly improves patient outcome in children, but its benefit in adults is less clear.[12] The relative benefit of individual components of treatment regimens is difficult to demonstrate because of the overall complexity of therapy in ALL. Standard consolidation lasts 4 weeks and usually consists of vincristine, mercaptopurine, and intrathecal methotrexate. Children with testicular disease usually receive radiation during this phase of therapy if a complete clinical response in the testes is not achieved by the end of induction. In children, the intensity of consolidation therapy is based on the child's risk classification and rate of cytoreduction during induction. Patients who respond slowly to induction therapy are at higher risk of relapse if they are not treated on more aggressive regimens. Children who are slow early responders or have high-risk disease benefit from intensified consolidation that includes the addition of vincristine and pegaspargase to standard therapy (cyclophosphamide, low-dose cytarabine, mercaptopurine).[18]

Imatinib has been incorporated into consolidation for children with Ph^+ disease. Children with Ph^+ ALL, infants with mixed lineage leukemia (MLL), or children who only achieve a partial remission may receive an allogeneic HSCT in first remission if a suitable donor is available. Nelarabine is a prodrug of ara-G that preferentially accumulates in T-lymphoblasts as ara-GTP. Children and young adults in first bone marrow relapse had a 55% complete or partial response in the phase II trial.[25] Nelarabine is currently

incorporated into a high-risk backbone for initial therapy of childhood T-cell ALL.

Reinduction (Delayed Intensification/ Interim Maintenance)

One or two delayed intensification phases separated by low-intensity interim maintenance cycles have been added to maintain remission and to decrease cumulative toxicity. Delayed intensification usually consists of drugs used during induction and consolidation or agents that lack cross-resistance with those already received. This includes cyclophosphamide, methotrexate, and limited amounts of doxorubicin. The dose of methotrexate is variable. Standard-risk children generally receive 1 to 2 g/m^2 while those with T-cell disease generally receive 5 g/m^2. Interim maintenance usually consists of dexamethasone, vincristine, weekly methotrexate, mercaptopurine, and intrathecal methotrexate. Delayed intensification improves EFS for standard-risk children.[14,18] Intensified delayed intensification improved EFS and decreased late relapses for high-risk childhood ALL, but there was no additional benefit for two delayed intensification cycles.[18] Children on the intensified arms of the study received significantly more antifungals, antibacterials, blood products and parenteral nutrition but had no increase in mortality.[18] The antimetabolite-based regimens may have a reduced risk of late toxicities, but the more intensive regimens appear to result in better survival for some patients, especially those with higher-risk disease.

Maintenance Therapy

6 Maintenance therapy allows long-term drug exposure to slowly dividing cells, allows the immune system time to eradicate leukemia cells, and promotes apoptosis (programmed cell death). The goal of maintenance therapy is to further eradicate residual leukemic cells and prolong remission duration. Although maintenance therapy is clearly beneficial in childhood ALL, the possible benefit in adults has only recently been demonstrated.

Maintenance therapy usually consists of daily mercaptopurine and weekly methotrexate for 12-week courses, at doses that produce relatively little myelosuppression, with monthly "pulses" of vincristine and a steroid for 5 days per month. In an effort to determine the long-term outcome of the duration and intensity of maintenance therapy, the Childhood ALL Collaborative Group published findings from a large meta-analysis involving 12,000 randomized children from 42 trials initiated prior to 1987.[26] The analysis revealed that longer maintenance, pulses of vincristine and prednisone, and the inclusion of one or two delayed intensification courses significantly reduced the total number of deaths or relapse. However, only delayed intensification improved survival.

Based on the results of studies that show a trend toward an increase in late relapse (excluding isolated testicular relapse) among male children treated for 2 years versus 3 years, some centers treat female children for 2 years while males receive maintenance to complete a total of 3 years of therapy.

Interpatient variability in the pharmacokinetics of oral methotrexate and mercaptopurine may also be an important determinant of the effectiveness and toxicity of maintenance therapy. Patients who take oral methotrexate and mercaptopurine on an evening versus a morning schedule appear to have a superior outcome. Mercaptopurine cannot be given with milk or milk products because of the presence of xanthine oxidase. To account for the interpatient variability, most clinicians will titrate the dose of either agent to maintain an absolute neutrophil count of 500 to 1,500 cells/mm^3 (0.5 to 1.5 × 10^9/L).[5] Some protocols circumvent bio-availability and poor adherence issues by administering methotrexate intravenously or intramuscularly. The importance of these pharmacokinetic issues in adults is less well defined.

ACUTE LYMPHOBLASTIC LEUKEMIA IN INFANTS

ALL and AML in infants younger than 1 year of age accounts for less than 5% of the reported acute leukemias in childhood, but they are associated with poor outcomes. Overall survival (OS) in infant ALL is 30% to 50%.[27] Seventy percent to 80% of infants with acute leukemia have MLL gene rearrangements.[27] MLL gene rearrangements are associated with worse outcome, with only 18% to 34% 4- to 8-year EFS.[27] Infants with ALL are more likely to present with a high WBC count, hepatosplenomegaly, and CNS disease.[27] Age less than 6 months at diagnosis and poor response to a prednisone prophase are poor prognostic indicators.[27] Infants with MLL gene rearrangements are more likely to overexpress FLT3, a tyrosine kinase implicated in leukemogenesis. Current research is testing the efficacy of lestaurtinib, a FLT3 inhibitor, following chemotherapy against infant ALL.[14]

Patients with infant ALL may have greater drug resistance to asparaginase, vincristine, and corticosteroids, but increased sensitivity to cytarabine and cladribine.[27] Although intensive regimens such as high-dose methotrexate and high-dose cytarabine have improved survival rates, unacceptably high mortality rates have also been observed with some regimens. Lack of pharmacokinetic data for chemotherapy in infants has contributed to toxicity from inappropriate dosing of doxorubicin and vincristine. To reduce neuropsychological complications, most protocols avoid cranial irradiation. The use of allogeneic HSCT for infants with ALL remains controversial due to a lack of donors, concerns over the long-term toxicity of total body irradiation, and excessive mortality in some series.

ACUTE LYMPHOBLASTIC LEUKEMIA IN ADULTS

Complete remission is achieved in 70% to 90% of adults with a four-drug regimen containing daunorubicin or doxorubicin, vincristine, asparaginase, and prednisone.[7] EFS is considerably lower and is achieved in 30% to 40% of patients. Recent comparison of 5-year EFS for adolescents and young adults found approximately 30% improvement when treated on pediatric versus adult protocols in the United States and Europe.[14]

The value of adding more drugs to the basic three- or four-drug induction regimen is unclear. Equally unclear is the value of higher doses of standard combinations of drugs for remission induction. Some studies suggest that high-dose methotrexate and cytarabine alternating with fractionated cyclophosphamide plus vincristine, doxorubicin, and dexamethasone (HyperCVAD) may improve response and survival in adults with ALL.[28] Intrathecal chemotherapy during the first cycle of HyperCVAD is held until blasts disappear from the peripheral differential in order to prevent seeding of the central nervous system. 7 Poorer outcomes in adults have been attributed to greater drug resistance, poor side-effect tolerance with subsequent nonadherence, and possibly less-effective therapy.

A considerable number of ALL cases occur in patients older than age 60 years, and treatment of this group of patients is an even greater challenge. The response to therapy and durability of response seem less than in younger adults or children. Treatment-related mortality rates during remission induction therapy are also higher in this population. Older patients are more likely to be Ph$^+$ positive, with the Ph$^+$ present in most patients age 55 years and older. Older patients are less likely to have T-cell ALL.[7] Based on data demonstrating improved and sustained responses in Ph$^+$ chronic myeloid leukemia with the tyrosine kinase inhibitor imatinib, several groups have evaluated the addition of imatinib to conventional chemotherapy in Ph$^+$ ALL patients.[29–32] Although no randomized trials have compared imatinib and conventional chemotherapy versus conventional chemotherapy alone, several single-center uncontrolled

trials have reported improved OS with the addition of imatinib.[29,30] This approach also appears to be tolerated in the elderly.[31] Two other tyrosine kinase inhibitors, dasatinib and nilotinib, have also been evaluated in imatinib-resistant Ph+ leukemias. Responses are achieved, although are short lived, with relapses occurring within 6 months.[33,34] A primary concern with the tyrosine kinase inhibitors is the emergence of resistance, specifically T315I mutations. A prospective study of adult patients with Ph+ ALL demonstrated a modest benefit of allogeneic transplantation over chemotherapy, but the study was conducted before the availability of imatinib.[35] The CR was 82%, with an OS of 22% at 5 years. Age and presenting WBC were the factors predicting achievement of CR. Currently a study adding imatinib into the intensification and induction phases is underway.

TREATMENT OF RELAPSED ACUTE LYMPHOBLASTIC LEUKEMIA

Approximately 20% of children with ALL will relapse.[36] The most common site for relapse is the bone marrow (53%), although isolated relapses can occur in the CNS (19%) or testicles (5%), in addition to multiple sites of disease.[36] Because marrow relapse usually follows isolated CNS or testicular relapses, patients with isolated extramedullary relapses are treated with localized radiation (cranial or testicular) and aggressive systemic chemotherapy similar to that given to patients with a marrow relapse.[37]

Children who fail to achieve a CR by day 29 of induction therapy at initial diagnosis receive an additional 2 weeks of four-drug induction therapy. If the child does not achieve a CR with the additional therapy, they are usually treated for bone marrow relapse. This includes an intensive induction therapy consisting of at least three cycles of chemotherapy. Such cycles may include vincristine, pegaspargase, corticosteroid, and doxorubicin; etoposide, cyclophosphamide, and high-dose methotrexate; and high-dose cytarabine and asparaginase.[38]

Patients who have completed treatment and who have stayed in remission for longer periods are more likely to be reinduced into remission again. Patients with more favorable risk factors initially, and those who received less intensive initial treatments, are more likely to respond well to reinduction/salvage regimens. A second remission with anthracycline, corticosteroid, vincristine, and asparaginase/pegaspargase occurs in 38% of children whose initial remission lasts less than 18 months, 80% if 18 to 36 months, and 95% if more than 36 months.[36] The 3-year OS following bone marrow (28%), CNS (60%), and testicular relapse (60%) is not optimal.[37] With the three cycle reinduction protocol described above, 68% of patients achieved CR if relapsed within 36 months and 96% if greater than 36 months.[38] For extramedullary relapse, overall survival is improved if relapse is at least 18 months after initial remission.[36] Survival is only 8% for children achieving a third remission after a second bone marrow relapse.[37] Clofarabine, a purine antimetabolite, achieves a 12.5% complete response rate, but the duration of response is less than 6 months. Current research is assessing clofarabine in combination with cytarabine.

Allogeneic HSCT (alloHSCT) is the treatment of choice for early bone marrow relapse (first CR less than 36 months).[37] Children who relapse more than 36 months after completion of initial therapy have reasonable outcomes with chemotherapy alone.[12,39] For patients with initial remissions less than 36 months, alloHSCT performed while in second CR is associated with a 8-year EFS of 41%, versus 23% with chemotherapy.[40] Patients who undergo alloHSCT are less likely to relapse, but are more likely to experience treatment-related morbidity and mortality if total-body irradiation is included in the conditioning regimen.[41]

Historically high-risk adult patients with a human leukocyte antigen (HLA)-matched sibling have been offered alloHSCT, but recent data suggest that there is no benefit to alloHSCT in this population (with the exception of Ph+ ALL). High treatment-related mortality in this group may offset any benefit from a lower relapse rate.[42] Most elderly patients are not candidates for standard alloHSCT but are candidates for nonmyeloablative alloHSCT. Whether this approach will reduce treatment-related mortality and result in more favorable outcomes is currently unknown. The National Marrow Donor Program and the American Society for Blood and Marrow Transplantation have developed guidelines for transplant consultation based on current clinical practice and evidence-based medicine. The following groups of ALL patients are at risk for progression and should be referred for transplant evaluation: high-risk ALL, including patients with high-risk cytogenetics (i.e., Ph+), high WBC count (>30,000–50,000 cells/mm^3 [>30 × 10^9 to 50 × 10^9/L]) at diagnosis, CNS or testicular leukemia, no CR within 4 weeks of initial treatment, remission induction failures, and those patients in second CR and beyond.[43,44]

PHARMACOGENOMICS

Genetic polymorphisms may affect drug metabolism, receptor expression, drug transportation, drug disposition, and pharmacologic response. These alterations may contribute to acute and chronic toxicity from ALL therapy as well as differences in treatment outcome. The most studied polymorphism involves thiopurine metabolism. Cellular thiopurine S-methyltransferase (TPMT) catalyzes S-methylation of thiopurines such as mercaptopurine and thioguanine resulting in inactivation. Approximately 10% of the population has intermediate TPMT activity as a result of heterozygous polymorphisms in the gene encoding for TPMT, and 1 in 300 has extremely low activity as a result of homozygous presence of this TPMT polymorphism.[5] Deficiency of TPMT activity results in excessive myelosuppression from thiopurines. Patients with low activity (homozygous mutant TPMT genotype) require 85% to 90% dose reductions.[45] Approximately half of the heterozygous patients will require dose reductions.[5] TPMT deficiency also confers an increased risk of developing secondary AML and radiation-induced brain tumors.[5] Prospective evaluation of TPMT status was complicated in the past, as many ALL patients receive transfusions prior to definitive diagnosis. TPMT status can now be determined directly by DNA-based testing, which may become a standard of care in the near future.

LATE EFFECTS OF ACUTE LYMPHOBLASTIC LEUKEMIA

Certain late effects associated with cranial or craniospinal irradiation and/or corticosteroids were discussed earlier. The Childhood Cancer Survivor Study tracks the health status of adults treated for childhood cancer between 1970 and 1986 and has yielded invaluable information on how to monitor adult survivors.[46] Leukemia survivors are 3.7 times more likely to develop a severe or life-threatening chronic health condition as compared with healthy siblings, and 2.8 times more likely to report multiple chronic conditions.[46] Former ALL regimens that incorporated intensive use of topoisomerase II inhibitors (etoposide and teniposide) are associated with unacceptably high risks of development of secondary leukemia.[12] High cumulative doses of anthracyclines used in high-risk or relapsed patients can cause cardiomyopathy. Cranial irradiation has also been found to cause learning deficits, especially in patients younger than 5 years of age at the time of treatment. Patients who received cranial radiation as children also have higher unemployment rates and lower marital rates among females 2 decades after diagnosis.[46] The Children's Oncology Group has developed long-term, follow-up guidelines for survivors of childhood, adolescent, and young adult cancers (*www.survivorshipguidelines.org*).

ACUTE MYELOID LEUKEMIA

CLINICAL PRESENTATION

Common signs and symptoms at presentation are described below. In addition to clinical presentation, laboratory and pathology evaluations are required for a definitive diagnosis of leukemia. The most important test is a bone marrow aspirate and biopsy, which is submitted to hematopathology for testing and evaluation. The WHO classification defines acute leukemias as >19% blasts in the marrow or blood; previous and ongoing trials may use the criteria of >29% blasts until study completion. Cytochemical stains are helpful to determine if the acute leukemia is of myeloid or lymphoid lineage. Immunophenotyping is necessary and was described in the ALL clinical presentation above. Cytogenetic analysis of the marrow to determine the presence of nonrandom numerical and structural chromosomal abnormalities in leukemic cells is also helpful for diagnosis, establishing prognosis, and evaluating response to therapy.[47] Chromosome translocations can result in abnormal expression and/or function of cellular oncogenes. Unique translocations can identify specific subtypes of acute leukemia. For example, acute promyelocytic leukemia (APL) is characterized by a specific translocation between chromosomes 15 and 17: t(15;17). Recently, technically difficult cytogenetic analysis has been supplemented with fluorescent in situ hybridization that allows for quick, sensitive analysis of samples that might be inadequate for karyotyping. Molecular tests may be used to identify products of specific translocations, such as promyelocytic leukemia (PML) retinoic acid receptor-α (RARα) in APL and AML1-ETO and CBF-β/MYH 11 in other subtypes of AML. The results of some of these molecular tests correlate with prognosis and are discussed in Risk Classification below. Testing for FLT3-ITD, c-KIT and NPM1 are not commonly available in the community so samples may be frozen for testing at a later point if it becomes relevant.[48]

CLINICAL PRESENTATION

General

- Recent history of vague symptoms such as tiredness, lack of exercise tolerance, chest pain, and "feeling unwell" but in no obvious distress.

Symptoms

- The patient may report weight loss, malaise, fatigue, and palpitations and dyspnea on exertion. They may also present with fever, chills, and rigors suggestive of infection; bruising (excessive vaginal bleeding, epistaxis, ecchymoses, and petechiae); gum hypertrophy (AML M4 and AML M5 subtypes); bone pain; seizures; headache; and diplopia.

Signs

- Temperature may be elevated because of low neutrophil count; petechiae.

Laboratory Tests

- Complete blood cell count (with differential). Anemia is usually present and is normochromic and normocytic (without a compensatory increase in reticulocytes). Thrombocytopenia (severe, <50,000 cells/mm^3) is present in approximately 50% of cases. Leukopenia/leukocytosis: approximately 20% of patients will present with an elevated WBC count, 20% with a low WBC count, and the rest with normal counts. Even patients with elevated counts can be considered functionally neutropenic.
- Uric acid may be elevated as a result of rapid cellular turnover (more common in patients presenting with elevated WBC counts).
- Electrolytes: potassium and phosphate are usually elevated.
- Coagulation: elevated prothrombin time, partial thromboplastin time, D-dimers; hypofibrinogenemia.

Other Diagnostic Tests

- Bone marrow biopsy and aspirate: send for morphologic examination, cytochemical staining, immunophenotyping, and cytogenetic (chromosome) analysis. At diagnosis the marrow is typically hypercellular, with normal erythropoiesis being replaced by leukemic blasts. To be diagnosed with AML, there needs to be more than 20% blasts. Molecular testing for FMS-like tyrosine kinase 3 (FLT3) mutations is warranted.
- For patients presenting with CNS signs, a diagnostic lumbar puncture should be performed. This is typically performed once there is clearance of blasts from the peripheral blood. CNS involvement is common with AML M4 and M5 subtypes.

RISK CLASSIFICATION

Many clinical and laboratory features at diagnosis are associated with response to treatment, as measured by the CR rate, duration of remission, and long-term survival. Identification of these risk factors may allow the clinician to better understand the disease and to tailor treatment according to risk of disease recurrence. For example, if a patient has many clinical and laboratory features that are associated with a good response to chemotherapy ("good-risk"), then the clinician may choose to give less-intensive therapy to reduce the risk of long-term toxic effects. Conversely, if a patient is unlikely to respond well to therapy ("high-risk"), then the clinician may choose to give more intensive chemotherapy that might include HSCT.

Several prognostic factors have been identified for adults with AML. 9 The most important patient factor is age, with younger patients more likely to achieve a CR than patients older than age 60 years.[3,49] The lower CR rate in older patients results from an increased frequency of fatal infection and bleeding complications and resistance to conventional chemotherapy. The duration of remission is also shorter in older patients as compared to younger patients. Other patient-specific prognostic factors include concurrent infection and any major organ impairment.[3] FAB morphologic subtype may be important, with some subtypes associated with a worse outcome. Patients with extramedullary disease, CNS involvement, or underlying MDS have a worse prognosis. Other unfavorable prognostic factors in adult AML include: age >60 years, multidrug resistance gene expression, WBC >100,000 cells/mm^3 (>100 $\times$ 10^9/L), and therapy-related AML.[50] Age must be evaluated as a continuous variable when looking at prognostic factors. The clinical difference between a patient 61 years old and one 71 years old, is much greater than a 59 year old and a 61 year old. Certain cytogenetic abnormalities are also known to worsen the response rate and survival of patients with AML (Table 142–4).[3,47] Chromosome 16 or translocations between chromosome 8 and 21 alter core binding factor. Core binding factor is associated with sensitivity to cytarabine, gemtuzumab, and ozogamicin[51] In addition, patients who develop a "secondary" leukemia after treatment of another malignancy usually have a very poor response to antileukemic chemotherapy (i.e. therapy-related AML). Another factor that needs consideration for any cancer treatment is performance status. A bedridden patient with a new diagnosis of AML would not be a good candidate for treatment because of high

TABLE 142-4 Risk Category According to Cytogenetic Abnormalities Present

Disease	Risk Category		
	Good-Risk	***Intermediate-Risk***	***High-Risk***
AML	t(8;21); inv(16)/t(16;16); t(15;17);	Normal karyotype; trisomy 6, 8; –Y, del(12p)	Complex abn(3q), (9q), (11q),(21q) –5/del(5q), –7, t(6;9), t(9:22), add(5q), add (7q), –17, and abn(17p)
4-Year survival	≥70%	40%–50%	≤20%
ALL	Hyperdiploidy; t(10;14); or 6q		t(9;22); t(8;14); t(4;11); t(1;9)

ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; abn, abnormal.
Data from Jemel et al.[1] and Grimwade and Hills.[52]

treatment-related morbidity and mortality. Patients with poor performance status are excluded from protocols or treatment.

Cytogenetics may be the most important prognostic factor for a newly diagnosed patient with AML.[52] Patients with core binding factor with t(8;21)(q22;q22) or inv(16)(p13q22)/t(16;16)(p13;q22) treated with a cytarabine based regimen have a relatively favorable prognosis. Adults with 3q(abn(3q)], deletions of 5q [del(5q)], monosomies of chromosome 5 and/or 7(–5/–7) have a poor prognosis with standard chemotherapy for AML, and may benefit from experimental treatments. The limitations to karyotype as a risk stratification tool include: failed cytogenetic analysis, presence of cryptic chromosomal rearrangements, and about 40% of cases have a normal karyotype. Genomic mutations, such as FLT3, nucleophosmin, and CCAAT/enhancer–binding protein alpha, have helped distinguish subsets of patients with differing outcome who have normal karyotypes. FLT3 is a receptor tyrosine kinase which is mutated in about 33% of AML, including those with normal karyotype, and is associated with higher presenting WBC and a poorer prognosis. Nucleophosmin is present in about 30% of AML, even in patients with normal karyotype, and commonly coexists with FLT3, and is associated with a higher CR and reduced relapse risk compared to patients without the mutation. CCAAT/enhancer binding protein alpha is present in about 10% of AML, and is associated with a favorable outcome. The area of cytogenetics is complex and still evolving.

Prognostic factors associated with pediatric AML have been reported but few have been shown to consistently predict treatment outcome. Poor prognostic factors include an FAB subtype M0 and M7, monosomy 7, age older than 10 years, black race, internal tandem duplications of FLT3, and having AML secondary to prior chemotherapy or radiation therapy.[6] Inversion of chromosome 16, trisomy 21, and t(8;21) are associated with a favorable outcome.[6]

More recently, several genetic molecular abnormalities have been identified in adults with AML that have prognostic significance. Abnormalities that are associated with a poor outcome include FLT3 abnormalities; MLL; brain and acute leukemia gene, cytoplasmic (*BAALC*) and Wilms tumor gene (*WT-1*).[10] Nucleophosmin mutations, member 1 (*NPM1*) (in the absence of FLT3 abnormalities) are associated with an improved relapse-free survival and OS.[10] The future of AML treatment may lie in targeted therapy based on molecular classification. Treatment algorithms based on the presence or absence of these abnormalities have been proposed but they are not currently incorporated into standard practice.[10]

TREATMENT

Acute Myeloid Leukemia

TREATMENT GOALS

The short-term goal of treatment for AML is to rapidly achieve a complete clinical and hematologic remission. In the absence of a CR, a rapid and fatal outcome is inevitable. CR is defined as the disappearance of all clinical and bone marrow evidence (normal cellularity >20% with <5% blasts) of leukemia, with restoration of normal hematopoiesis (neutrophils ≥1,000 cells/mm^3 [≥1 × 10^9/L] and platelets >100,000/mm^3 [>100 × 10^9/L]).[53] Partial remission is a significant response to treatment (a decrease of at least 50% of blasts), but evidence of residual disease in the bone marrow remains (5%–25% blasts) and is considered a treatment failure requiring additional therapy. The definition of response for adult AML was reevaluated in 2003, and changes in the definition of response were proposed to include not only CR (morphologic CR with restoration of normal hematopoiesis), but also CR with incomplete blood count recovery (CRi), cytogenetic CR ([CRc] patient with normal cytogenetics in which cytogenetics were previously abnormal), and molecular CR ([CRm] molecular studies negative).[53] If there is a question of residual leukemia on bone marrow biopsy in adults, a bone marrow aspirate/biopsy should be repeated in 1 week.

After a CR is achieved, the goal is to maintain the patient in continuous CR. As discussed later, the occurrence of leukemic relapse in the bone marrow significantly reduces the likelihood of cure. Most patients who will die from acute leukemia die within the first 6 years; the survival curve (percentage alive versus time) beyond the 6th year after therapy does not continue to decline as rapidly ("survival plateau"), and at this time patients can be considered "cured."

With recent advances in chemotherapy and supportive care, 65% to 85% of all patients with AML achieve a CR, and 20% to 40% become long-term survivors.[3] Overall, the median duration of remission is 1 to 2 years. In patients older than 60 years of age, the percentage of patients achieving a CR is lower (39%–64%), and the median duration of remission is shorter than 1 year.[54] In contrast to ALL, effective therapies used in AML cause severe and often prolonged myelosuppression, with the exception of tretinoin. As a result, patients with AML, particularly patients older than 60 years of age, are at greater risk for treatment-related fatal infectious and bleeding complications.

The 5-year survival in children with AML has increased from 17% in 1976 to 50% in 2005.[6,21] Children with Down syndrome and AML receive less-intense therapy and have a 83% EFS.[6,21] Treatment of childhood AML, unlike that of ALL, usually only consists of induction and intensive postremission therapy (Fig. 142–2). CNS prophylaxis is not routinely given to patients with AML.

TREATMENT PHASES

Remission Induction

As with ALL, the goal of remission induction for AML is to rapidly induce a CR with associated restoration of normal hematopoiesis. Compared to ALL, however, fewer patients with AML achieve CR. Because the CR rate in AML is related to the intensity of the remission induction regimen, the drugs used in AML are given at doses that uniformly cause severe myelosuppression (except tretinoin).

One reason for the lower CR rate in AML as compared to ALL is the inability to give optimal doses of chemotherapy because of marrow toxicity. With continued improvement of supportive care for patients undergoing chemotherapy, more intensive treatment regimens are being given in an effort to reduce the high rate of leukemic relapse and increase the proportion of long-term survivors. Most patients achieve a CR after one or two courses of chemotherapy. Patients who require additional chemotherapy to achieve a CR have been reported to have a poor prognosis, even if remission is ultimately achieved.

10 The most active single agents in AML are the anthracycline antibiotics (daunorubicin, doxorubicin, and idarubicin), anthracenediones (mitoxantrone), and the antimetabolite cytarabine. The most common regimen ("7+3") combines daunorubicin administered as a short infusion of 45 to 60 mg/m^2/day on days 1 to 3, along with cytarabine administered as a continuous 24-hour infusion of 100 to 200 mg/m^2/day on days 1 to 7.[3,55,56] The CR rate with the 7+3 regimen is 65% to 75% in patients 18 to 60 years old. Several trials have attempted to improve upon conventional 7+3 therapy, but have shown no improvement by (a) increasing cytarabine to 10 days, (b) shortening cytarabine to 5 days, (c) substituting doxorubicin for daunorubicin, (d) adding thioguanine, or (e) increasing cytarabine dosage to 200 mg/m^2/day (given by continuous infusion).[3] Results of a recently published study showed that increasing the daunorubicin dose may improve treatment outcome. In that study, adults ≤60 years old with AML who were randomized to receive higher daunorubicin dosages (90 mg/m^2 given over 3 days) in combination with 7 days of standard-dose cytarabine (100 mg/m^2/day) had a significantly higher CR rate (71% vs 57%) and increased overall median survival (23.7 vs 15.7 months) as compared with those who received the standard 7+3 regimen of daunorubicin (45 mg/m^2 given over 3 days) and cytarabine.[57]

Idarubicin or mitoxantrone has been evaluated as alternatives to daunorubicin in combination with standard-dose continuous infusion cytarabine. Trials in younger patients reported improved CR rates with these newer anthracyclines/anthracenediones and one trial demonstrated prolonged survival. Among older adults, the CR rate and OS does not appear to be different among the different anthracyclines/anthracenediones.[55,56] Thus the anthracycline of choice for the standard 7+3 regimen remains controversial, with many centers adopting idarubicin into the induction regimen in younger AML patients, and the choice in the elderly is based on individual clinician preference and institutional acquisition costs. The anthracycline of choice is now more controversial given the results of the recent studies of treatment of newly diagnosed AML.[57,58]

CLINICAL CONTROVERSY

Is there a superior anthracycline to use as part of the induction regimen for AML? Some clinicians believe that idarubicin is superior in attaining a complete remission following one cycle of induction compared to alternative anthracyclines or anthracenediones. Randomized trials in the elderly show similar remission rates with all anthracyclines and anthracenediones. Whether there is a difference in younger patient's remains to be seen.

Other strategies that have been evaluated include adding another agent such as etoposide to the induction regimen.[3,55,56] A comparison of the standard 7+3 regimen with or without etoposide on days 1 to 7 ("7+3+7") in newly diagnosed AML patients ages 15 to 70 years demonstrated no difference in CR rates or OS. A subset analysis of patients younger than 55 years of age demonstrated a doubling of the duration of remission and OS in the etoposide-containing arm. The 7+3+7 regimen was more toxic in patients older than 55 years of age. These results have been confirmed in other studies, but as yet are to be adopted in the United States as part of standard therapy.

Based on experimental tumor models that showed a steep dose–response curve for cytarabine, higher doses of cytarabine have also been evaluated as a means to enhance the outcome of remission induction therapy. Several groups, including the Southwest Oncology Group and the Australian Leukemia Study Group, have evaluated the impact of adding high-dose cytarabine to induction therapy. This strategy does not improve the CR rate or OS, but does improve EFS. A retrospective study conducted by the European Group for Blood and Marrow Transplantation demonstrated that the cytarabine dose administered during induction and/or consolidation did not influence the outcome in patients who ultimately went on to receive allogeneic or autologous HSCT.[59] These data suggest that high doses of cytarabine during induction may not be needed in patients who receive HSCT as postremission therapy. In summary, the role of high-dose cytarabine during induction remains controversial. If used during induction, high-dose cytarabine is more appropriate in younger patients than in elderly patients because of poor tolerance by elderly patients.

The National Comprehensive Cancer Network (NCCN) has published guidelines for the treatment of AML.[44] The classic 7+3 regimen may be inadequate in adults younger than 60 years of age because the duration of remission is less than that reported in some studies that employed high-dose cytarabine during induction.[44] The NCCN guideline recommends that adults younger than 60 years of age without an antecedent hematologic disorder (i.e., no preexisting hematologic malignancy such as MDS) be treated with either the 7+3 regimen or more aggressive chemotherapy including high-dose cytarabine with an anthracycline or anthracenedione. In patients ≥60 years of age with good performance status, the conventional 7+3 regimen should be used or the patient should be enrolled in available clinical trials. The approach in patients with an antecedent hematologic disorder differs, and younger patients (<60 years) should be offered available clinical trials or proceed to alloHSCT (provided a suitable donor is available). Older patients (≥60 years) with an antecedent hematologic disorder or those with significant comorbidities unrelated to leukemia should be offered a clinical trial or best supportive care because of the dismal outcomes associated with conventional chemotherapy. All adult patients who present with CNS symptoms, and all AML M4 and AML M5 patients who are not symptomatic, should have a diagnostic lumbar puncture, and if it is positive, should be treated for disease. Methotrexate 12 to 15 mg, with or without cytarabine, should be administered intrathecally twice a week until clearance of leukemic blasts from the cerebrospinal fluid, and then monthly for about 6 months.

Intensive Postremission Therapy

Although most adults with AML achieve a CR, the duration of remission is short (4–8 months) if no further treatment is given. Relapse is presumably a consequence of the presence of residual, but clinically undetectable, leukemic cells after remission induction therapy. The goal of intensive postremission therapy is to eradicate these residual leukemic cells and to prevent the emergence of drug-resistant disease. 11 The need for postremission therapy is based on postmortem analysis and cell kinetic data suggesting that nearly 10^9 residual leukemic cells remain after effective remission induction therapy. Strategies evaluated as postremission therapy

include (a) low-dose, prolonged maintenance therapy, (b) short-course intensive chemotherapy-alone regimens and (c) high-dose chemotherapy with or without radiation therapy followed by alloHSCT or autologous HSCT.

Chemotherapy In the treatment of AML, intensive postremission therapy is often referred to as consolidation therapy. Results of randomized trials in adults clearly show that intensive postremission therapy following remission induction therapy prolongs survival versus no therapy, although the exact duration of postremission therapy is controversial.[3,55,56]

The intensity of postremission therapy is important. In a large Cancer and Leukemia Group B (CALGB) trial, all patients who achieve a CR after standard 7+3 induction, were randomized to receive one of three cytarabine-based consolidation regimens: 100 mg/m^2/day or 400 mg/m^2/day as a continuous 24-hour infusion, or 3,000 mg/m^2 every 12 hours on days 1, 3, and 5.[60] For adults younger than age 60 years, the probability of remaining in CR after 4 years was significantly higher in patients who received high-dose cytarabine (25% vs 29% vs 44%, respectively).[60] Elderly patients had lower response rates in all arms and did not benefit from the administration of higher doses of cytarabine, probably because they were unable to tolerate the high-dose regimen. Dose-limiting neurotoxicity in the high-dose arm was greater in elderly patients and those patients with impaired kidney function.[60]

It is not clear whether the same agents (cytarabine and an anthracycline) given for remission induction should be used for postremission therapy in higher doses, or whether different agents should be given. If leukemic relapse is caused by a resistant cell line, then the use of different agents that are non–cross-resistant with drugs used in induction might be beneficial.

High-dose cytarabine appears to be a key part of postremission therapy, particularly if not used in induction therapy. However, many questions remain, such as the optimal dose (g/m^2), number of doses per cycle, and number of cycles of high-dose cytarabine. Among patients with core-binding factor AML, defined as the presence of either t(8;21) or inv(16), it is clear that multiple cycles are beneficial, generally three to four cycles.[61] The NCCN guideline recommends four cycles of high-dose cytarabine for adults younger than 60 years of age and with good cytogenetics or, alternatively, one cycle of high-dose cytarabine followed by autologous HSCT.[48] Patients with intermediate-risk cytogenetics should receive four cycles of high-dose cytarabine or undergo either an autoHSCT or an allogeneic (sibling) HSCT.[48] If a patient is 60 years of age or older, standard-dose cytarabine with or without anthracycline for one to two cycles, a reduced-dose high-dose cytarabine regimen (1–1.5 g/m^2/day for four to six doses) for one to two cycles, or enrollment in a clinical trial is recommended. Patients with high-risk cytogenetics, underlying MDS, or secondary AML should either be enrolled in a clinical trial or be referred for either a matched sibling or alternative donor alloHSCT.[48]

CLINICAL CONTROVERSY

Intensive postremission therapy is clearly necessary to prevent relapse and those regimens containing high-dose cytarabine appear to be a key part of postremission therapy. However, the optimal dose of high-dose cytarabine, the number of doses per cycle, and the number of cycles to give remain unknown.

Allogeneic Hematopoietic Stem Cell Transplantation AlloHSCT represents the most aggressive approach to postremission therapy in the management of AML. Much controversy surrounds this treatment approach, specifically the appropriateness, timing, treatment design, and donor selection.

The antileukemic activity of alloHSCT is based on the administration of pretransplant high-dose chemotherapy (or chemoradiotherapy) and the development of a posttransplant immune-based antileukemic response. The immune-based response, referred to as a graft-versus-leukemia (GVL) effect, often accompanies the graft-versus-host disease (GVHD) reaction. The immune-based benefit of alloHSCT has been demonstrated through the observation of consistently lower relapse rates with alloHSCT as compared to autologous or syngeneic HSCT. This potential benefit of alloHSCT can be offset by the risk of posttransplant complications such as GVHD, sinusoidal obstruction syndrome, graft failure, and infections.

AlloHSCT was first evaluated as a treatment modality for AML in refractory patients, but because of initial success in small numbers of patients, it has also been evaluated as intensive postremission therapy in AML patients in first or subsequent remission. Nonrandomized trials of HLA-identical sibling alloHSCT performed in AML patients in first CR (CR1) reported 5-year survival rates of 45% to 60% with relapse rates of 10% to 20%.[3,55,56] Transplant-related mortality following HLA-matched sibling alloHSCT is 15% to 25% in most series. As clinicians have gained more experience in this intensive form of therapy and been provided with more effective immunosuppressive and antibiotic regimens, transplant-related mortality rates have decreased and survival rates have increased. Bone marrow registry data indicate that long-term survival rates in AML patients who receive a matched sibling alloHSCT while in first remission have increased from about 45% in the early 1980s to about 60% in the mid-1990s.

AlloHSCT from an HLA-matched sibling donor for AML patients in CR1 results in long-term EFS in 43% to 55% of patients. Although the results vary, some of the studies show longer EFS and lower relapse rates with alloHSCT in AML in CR1 as compared to chemotherapy-alone postremission regimens.

AlloHSCT is generally restricted to patients younger than 60 years of age, which limits the number of patients eligible for treatment of a disease that primarily affects older adults. One new approach, termed nonmyeloablative stem cell transplant (NST), uses reduced intensity preparative regimens and is now being evaluated in AML patients, particularly in older patients and those with comorbid illnesses that would limit their eligibility for conventional alloHSCT. NST is designed to provide enough immunosuppression in the preparative regimen to allow for engraftment of donor cells, and depends heavily on the development of a GVL effect as a means to treat and prevent relapse of AML. Initial results of NST in AML indicate that the procedure is well tolerated in a wide age range of patients, and that it is associated with low rates of regimen-related toxicity.[62,63] Evaluations in larger numbers of patients are necessary to determine the comparative impact of NST on GVHD, EFS, and OS. Because only 30% of patients have an HLA-matched sibling donor, alloHSCT is further restricted as a treatment alternative for AML patients.[64] Matched unrelated donor transplantation with a phenotypically HLA-matched donor identified from bone marrow registries is also a treatment option in young adults and pediatric AML patients. This approach is associated with long-term EFS rates of 30% to 40%, which are slightly lower than in AML patients undergoing HLA-matched sibling alloHSCT because of a higher risk of treatment-related mortality with the procedure.[3,56]

The decision to transplant a patient depends a great deal on which biological risk group the patient belongs. Among patients with favorable risk AML, alloHSCT does not result in better outcomes as compared to high-dose cytarabine-based therapy. All patients with high-risk AML, including those with an antecedent

hematologic disorder, treatment-related MDS, or induction failure, should undergo evaluation for HSCT. Similarly patients in CR1 with high-risk cytogenetics and patients in second CR (CR2) and beyond should undergo evaluation for alloHSCT.[44]

Autologous Hematopoietic Stem Cell Transplantation Compared to alloHSCT, autologous HSCT (autoHSCT) has the advantage of a lower risk of posttransplant complications because of lack of immunosuppression and GVHD, and more broad applicability because of a lack of donor limitations and fewer age restrictions. Although the preparative regimen still provides antileukemic activity, autoHSCT is associated with a higher risk of relapse because of a lack of a GVL effect and potential tumor contamination with autologous stem cells. EFS following autoHSCT for AML in CR1 ranges from 40% to 60%, with treatment-related mortality of 5% to 15% and relapse rates of 30% to 50%.[65] Long-term response rates decrease proportionally as autoHSCT is employed in second or subsequent CR. Controversies in autoHSCT include the optimal timing of therapy, the amount of consolidation therapy needed prior to HSCT, the dose of stem cells needed, and the impact of posttransplant therapy.[65]

Comparisons of Postremission Therapy Options Several randomized trials in AML patients in CR1 have compared outcomes following alloHSCT, autoHSCT, and/or intensive consolidation chemotherapy (Table 142–5).[56] In most trials, eligible patients based on age and donor availability received an alloHSCT and the remaining patients were randomized between autoHSCT and chemotherapy alone. The European Organization for Research and Treatment of Cancer-GIMEMA (Gruppo Italiano Malattie Ematologiche Maligne dell'Adulto) trial observed a EFS advantage and reduced relapse risk for alloHSCT or autoHSCT as compared to chemotherapy alone, but no differences in OS.[3,56] Survival rates were comparable because of a higher relapse rate in the chemotherapy group as compared to a higher treatment-related mortality rate in the alloHSCT group. This is the only trial that has demonstrated superior 4-year EFS with transplantation versus chemotherapy. Interestingly, the response rates in the conventional chemotherapy arm in this trial were lower than those reported in other studies, which may account for the survival benefit in the transplant group. Several other trials have shown no difference in EFS or OS between autoHSCT, alloHSCT, and conventional chemotherapy. In aggregate, these trials show that either autoHSCT or alloHSCT can reduce the risk of relapse, although this has not translated into a survival benefit. One trial design issue that might explain this lack of survival benefit was the low percentage of patients who progressed to transplantation when randomized, thus diluting the effect of transplantation. The effect of stem cell source on EFS and OS is controversial. Several comparative trials of bone marrow versus peripheral blood have been completed in patients with hematologic malignancies, and a meta-analysis of nine randomized trials demonstrated a lower relapse rate for those patients receiving peripheral blood stem cells.[66]

Most transplant centers base their decision to transplant on cytogenetic risk category.[3] Patients with high-risk cytogenetics do poorly with conventional chemotherapy or autoHSCT (EFS <15%), making alloHSCT the treatment of choice in this population. Patients with good-risk cytogenetics should not proceed to transplant in CR1, as neither auto- nor alloHSCT is superior to conventional chemotherapy. The optimal treatment of choice in patients with intermediate-risk cytogenetics is not clear and is based on clinician preference. Many centers consider a relapse probability of 40% to 50% sufficiently high so as to warrant the risk of transplantation-related mortality. The decision to proceed with HSCT in this group may rest on the results of molecular testing. As discussed in Risk Classification above, several genetic molecular abnormalities have been identified in adults with AML that have prognostic significance. Abnormalities that are associated with a poor outcome include FLT3 abnormalities, myeloid/lymphoid or MLL abnormalities, BAALC, and WT-1.

According to the NCCN guidelines, the decision to proceed to HSCT depends on cytogenetics.[48] If the patient has a good-risk cytogenetic profile and is younger than age 60 years, then high-dose cytarabine for four cycles or one cycle of high-dose cytarabine-based therapy followed by autoHSCT is preferred over alloHSCT. If the patient has a high-risk cytogenetic profile and is younger than 60 years of age, then alloHSCT should be considered early after remission induction. Patients with intermediate-risk cytogenetics should be entered into a clinical trial, but if a clinical trial is not available, either a matched sibling alloHSCT or an autoHSCT should be considered. AutoHSCT can be used if a hematologic and cytogenetic remission is achieved. For patients 60 years and older, the NCCN guidelines do not favor HSCT and recommend either enrollment into a clinical trial, or consideration of conventional dose cytarabine with or without an anthracycline or intermediate-dose cytarabine. Clinicians increasingly consider autoHSCT as a treatment option, and for selected patients older than 60 years of age, NST is being used more frequently.[62,63] For the AML patient who relapses early after induction therapy, if a sibling or matched related donor is available, then alloHSCT is the primary reinduction therapy because conventional chemotherapy offers little benefit. If the relapse occurs late, then HSCT can be used as postremission consolidation after conventional induction therapy.[48]

CHILDHOOD ACUTE MYELOID LEUKEMIA

The most effective induction regimens for children include an anthracycline, cytarabine, and etoposide, yielding a CR rate of

80% to 90%.[6] Five-year OS is 36% to 66%.[6] The use of risk-adapted therapy is not as prevalent with AML as with ALL. Intensified therapy regimens, which include more antileukemic agents, higher doses of agents, or compression of the time in which the agents are delivered, improve survival rates. The Children's Cancer Group used a compressed regimen, whereby the second course of therapy was given 6 to 10 days after the first instead of 14 days, without waiting for marrow recovery to occur. Although intensive therapy is associated with an increased mortality rate as compared with standard chemotherapy in children with AML, the long-term EFS is significantly better in the intensive-therapy group (49% vs 35%).[67] The use of intrathecal CNS prophylaxis varies by cooperative group, due to the low CNS relapse rate (2%).[6] Cranial radiation is only rarely used in the United States for patients with refractory CNS disease.

Gemtuzumab ozogamicin is an immunoconjugate that consists of a monoclonal antibody to CD33 which is expressed on >80% of AML blasts linked to calicheamicin, a potent antineoplastic agent. Following the binding of the antibody to the myeloblasts, the antibody-antigen complex is internalized causing the release of the calicheamicin inside the cell. The Children's Oncology Group has established a dose for gemtuzumab when given in combination with chemotherapy and is assessing the benefit of adding gemtuzumab to frontline therapy in a current phase III clinical trial.[68] As of October 1, 2010, gemtuzumab ozogamicin is no longer commercially available. Future access may be available only through clinical trials.

Following induction therapy, patients should be evaluated for a response. Those not achieving a CR will require additional chemotherapy called *reinduction*. A bone marrow biopsy is usually performed 7 to 10 days after the completion of chemotherapy to document disease eradication. If there is persistent disease, a second course of therapy is administered. The second course may be identical to the initial induction regimen, or include high-dose cytarabine and asparaginase, or mitoxantrone and cytarabine. If the marrow is aplastic, a repeat marrow biopsy should be performed upon hematologic recovery to document a CR.

Following induction, children proceed onto consolidation therapy. An evidence-based review of the role of HSCT in the treatment of pediatric AML concluded that HSCT was indicated in the following settings: (a) initial CR: matched sibling alloHSCT is superior to autoHSCT and chemotherapy, but are only available in 25% of children; (b) second CR: alloHSCT is preferable to chemotherapy and autoHSCT.[6,69] Children with no suitable donor should receive consolidation chemotherapy including high-dose cytarabine, which yields results similar to those seen with autoHSCT.[6] Maintenance chemotherapy is not used in children in the United States.

Infant AML is usually myelomonoblastic or monoblastic in morphology. Poor prognostic factors include t(1;22), high WBC count, and CNS disease. Neonates with Down syndrome may develop transient myeloproliferative disease that usually spontaneously resolves without treatment within a few months. Infants with AML receive the same therapy as children of other ages, with the dosing per kilogram and not per body surface area.

ACUTE MYELOID LEUKEMIA IN THE ELDERLY

As the median age at diagnosis is in the range of 65 to 70 years, AML is a disease of the elderly. Unfortunately, long-term EFS is lower in older patients, ranging from 5% to 15%, as compared with 40% in younger patients.[54] In patients older than age 55 years, a review of ECOG studies reported the median duration of survival to be 6 to 9 months, as compared with 11 months in patients younger than age 55 years. The actual response and survival rates may be even lower, as many elderly patients with AML are not included in clinical trials because of a lack of eligibility and poor performance status.[3,54]

Elderly patients with AML have a poor outcome as a result of the frequent presence of unfavorable prognostic factors, including high-risk cytogenetic features, preceding myelodysplasia, and a higher incidence of inherent drug resistance.[3] More than 70% of de novo AML patients older than age 55 years will express the multidrug resistance phenotype associated with chemotherapy resistance, including resistance to the leukemia-active anthracyclines and etoposide.[54] Older patients with AML may also have poor outcome because of the inability to withstand aggressive therapy as a result of poor organ function, poor performance status, or existing comorbidities. Although older patients with AML may be able to tolerate aggressive remission induction therapy, they often cannot tolerate intensive postremission therapy, which increases their likelihood of leukemic relapse. Despite newer therapies, the prognosis of AML in the elderly has not changed significantly over the last several decades.

The potential therapeutic strategies in elderly AML patients include (a) no chemotherapy (i.e., best supportive care or palliative care therapy), (b) attenuated chemotherapy, (c) investigational therapy, or (d) standard-dose chemotherapy.[3] The palliative approach is most appropriate in patients with slowly progressive leukemia ("smoldering leukemia"). The difficulty lies in the ability to reliably identify these patients at diagnosis. Although initially accepted in older patients, palliative care approaches in older patients with AML with moderate-to-good performance status and organ function are now considered inappropriate. An ECOG-CALGB study randomized patients to either conventional chemotherapy or to observation in which patients could receive modest doses of chemotherapy for symptom palliation. Survival was twice as long in the chemotherapy group. The quality-of-life of each group was similar, with patients in each group spending approximately 50% of the study time in the hospital.[70]

These results show that chemotherapy prolongs survival without significantly decreasing the quality-of-life for elderly patients. Thus chemotherapy is a viable treatment option for elderly patients, although the best chemotherapy regimen and overall treatment approach are controversial. One approach is to attenuate the dose of chemotherapy, preferably with oral agents where possible, or lower doses of intravenous agents. Agents used in this strategy include oral etoposide, low-dose subcutaneous cytarabine, and other oral agents such as thioguanine and idarubicin (oral idarubicin is not currently commercially available in the United States). The United Kingdom AML Study Group recently published a comparative trial of low-dose subcutaneous cytarabine twice daily versus hydroxyurea. Low-dose cytarabine produced a greater number of complete remissions compared to placebo, and prolonged 1-year survival.[71]

Another approach is to use the same remission induction regimens that would be used in younger adults. With this approach, the complete remission rate in older AML patients ranges from 41% to 62%, as compared with 65% to 73% in adults younger than 60 years of age, and are very short-lived (5–10 months). Treatment-related mortality ranges from 15% to 20%. More elderly patients than younger patients will require two courses of remission induction therapy to achieve a complete remission. In an effort to improve response rates, some trials have attempted to determine the optimal anthracycline and the appropriate dose. Unlike younger patients, results of clinical trials in elderly patients do not suggest any efficacy or toxicity advantages of idarubicin or mitoxantrone over daunorubicin for AML induction therapy.[72] Older patients with AML also do not experience added benefit when etoposide is incorporated into an anthracycline and

cytarabine-containing regimen, or when etoposide is substituted for cytarabine in induction.[73,74] The combination of clofarabine 30 mg/m^2/day for 5 days and cytarabine was found to be an effective first-line regimen for patients over 59 years with AML and high-risk MDS by achieving a CR rate of 56%.[75] Recently, a randomized trial of daunorubicin 30 mg/m^2/day on days 1 through 3 with cytarabine 200 mg/m^2/day as a continuous 7-day infusion in patients older than 60 years demonstrated a more rapid response with a higher response rate (64% vs 54%) as compared with the conventional dose of daunorubicin (45 mg/m^2 over 3 days) with cytarabine. While there was no difference in toxicity, 30-day mortality or life-threatening events, overall survival was only improved in the subgroup of patients aged 60 to 65 years (38% vs 23%).[58]

Postremission strategies in elderly AML patients are less-well defined.[3] Although high-dose cytarabine is a standard component of postremission therapy in younger patients, it has not been shown to be beneficial in elderly AML patients. In the elderly, attenuated-dose cytarabine during remission induction decreases remission and survival rates while decreasing treatment-related mortality rates, which raises the concern that attenuated-dose cytarabine during postremission therapy may cause similar outcomes. In the CALGB trial that compared postremission cytarabine doses, higher doses of cytarabine (3,000 mg/m^2) was not as effective in patients older than age 60 years as it was in younger patients.[60] Serious toxicities, particularly neurotoxicity, were more frequent in elderly patients, and these toxicities limited the ability to deliver the planned four courses of therapy. An ECOG review concluded that lower doses of cytarabine (1,500 mg/m^2 for 6 to 12 doses) in older AML patients are well tolerated, with a treatment-related mortality rate of only 2% and median survival at 2 years of 30%.[76] Based on these data, some clinicians suggest that attenuated high-dose regimens (such as 1,500 mg/m^2) may be sufficient for elderly AML patients. The appropriate number of cycles of postremission consolidation therapy is unknown and currently under investigation in a randomized ECOG trial. An alternative approach to intensive postremission therapy is the administration of multiple courses of chemotherapy in the ambulatory setting. The Acute Leukemia French Association recently demonstrated improved overall survival among patients receiving 6 monthly courses of outpatient chemotherapy (daunorubicin or idarubicin day 1; low-dose subcutaneous cytarabine for 5 days) compared to intensive consolidation (daunorubicin or idarubicin days 1 to 4; cytarabine continuous infusion).[77]

Although maintenance therapy is considered inferior to intensive consolidation chemotherapy in younger patients, its role in older patients with AML is still undefined. Some studies suggest that maintenance therapy following consolidation prolongs EFS but not OS as compared to no maintenance therapy.[78] Because older patients may not be able to tolerate more aggressive postremission strategies such as HSCT, maintenance therapy may play an important role in improving outcomes.

Several FLT3 inhibitors are in clinical development, including ABT-869, lestaurtinib (CEP-701), and midostaurin (PKC 412). Inhibition of farnesyl transferase is another treatment target. Tipifarnib has been the most extensively evaluated, demonstrating CR rates of 14%.[79] Other approaches include antiangiogenic therapies (e.g., lenalidomide, semaxanib [SU5416], axitinib [AG013736], bevacizumab, arsenic trioxide), proteasome inhibition and antiapoptotic therapies (e.g., bortezomib, oblimersen), epigenetic therapies (e.g., azacitidine, decitabine), and novel alkylating agents such as cloretazine. Response rates with these new approaches in the elderly range from 0% to 59%. Whether they can modify the course of disease resulting in prolonged survival is unclear.

NST is another therapeutic option in elderly patients with AML and MDS. Two small studies suggest this is a feasible option, with actuarial OS and EFS rates of 44% to 69% and 37% to 56%, respectively.[62,63] The advantage of this approach is less toxicity as a result of less-intensive chemotherapy, with the immune system providing the major antileukemic effect via GVHD/GVL mechanisms (see Chap. 148).

TREATMENT OF RELAPSED OR REFRACTORY ACUTE MYELOID LEUKEMIA

The most common cause of treatment failure in AML patients receiving chemotherapy alone or undergoing HSCT is relapse. In addition, many patients, particularly elderly patients, have refractory disease as defined by the inability to achieve a CR after two courses of induction therapy. In most cases, the preferred method of treatment for relapsed or refractory disease is HSCT. Prolonged EFS is observed in 30% to 40% of patients receiving allo- or autoHSCT in first relapse or CR2. Unfortunately, only a small percentage of relapsed or refractory adult patients will be eligible for HSCT, particularly alloHSCT, because of age and donor restrictions. The role of NST is also being evaluated in this setting.

The timing of HSCT to treat relapse is controversial. Some studies suggest that outcomes of HLA-matched, related alloHSCT are similar regardless of whether the transplant is performed at the time of early first relapse or in CR2. The difficulty with this approach is identifying a patient in "early relapse," as often the patient will present in a florid relapse. While performing the alloHSCT in first relapse eliminates the need for and toxicity of salvage chemotherapy, the feasibility of this approach is limited by the lead time required to activate a donor search. An International Bone Marrow Transplant Registry study demonstrated that alloHSCT was superior to chemotherapy for treatment of relapse occurring 1 to 2 years following induction.[80] Prolonged leukemia-free survival occurred in at least twofold more alloHSCT recipients as compared to patients receiving chemotherapy. In the treatment of refractory disease, alloHSCT is superior to autoHSCT in adults younger than age 55 years.

Patients who relapse following alloHSCT have a poor outcome, with a median survival of about 3 to 4 months.[81] In this setting, treatment options depend on performance status, clinical condition, and the time since alloHSCT. Patients relapsing less than 100 days following alloHSCT are unlikely to respond to current therapies, and salvage attempts are often associated with a high treatment-related mortality. For selected patients relapsing more than 1 year after alloHSCT, a second alloHSCT may be an alternative, but the likelihood of prolonged survival is generally less than 10% with a second transplant. Other strategies being investigated for the treatment of relapse after alloHSCT include immune manipulation to stimulate a GVL effect through donor lymphocyte infusions, and premature discontinuation of calcineurin inhibitors and other immunosuppressants.

AutoHSCT is an option at the time of first relapse if cells have been previously collected and stored during first remission. If such cells were not collected, then it is necessary to achieve a second CR in order to proceed to autoHSCT. Prolonged EFS of 30% and 20% are reported when autoHSCT is performed in CR2 and CR3, respectively. The advantages of autoHSCT are the lack of donor limitations and fewer age-based restrictions; the disadvantage is the need to achieve a CR, which requires exposure to more cytotoxic chemotherapy. If patients relapse following autoHSCT, alloHSCT from a related or unrelated donor is preferred in selected younger patients. NST or other investigational therapies can be considered for older patients who relapse after autoHSCT.

If patients with relapsed or refractory disease are not candidates for HSCT, until recently the primary mode of treatment was salvage chemotherapy. The ability to achieve a second CR with salvage chemotherapy is related to the duration of the first remission. About 50% to 60% of patients who relapse longer than 2 years after induction therapy will achieve a second CR, often with the same induction regimen.[3,56] If the patient relapses 1 to 2 years after induction therapy, the second CR rate decreases to 40%, and only 10% to 20% of patients who relapse within 6 to 12 months following induction are able to achieve a second CR with alternate salvage chemotherapy regimens. Long-term survival at 3 years ranges from zero in patients who relapse early to 20% to 25% in those who experience a prolonged duration of initial remission. Based on these data, a risk-adapted approach should be taken when considering treatment options.

The most commonly used salvage regimens include high-dose cytarabine given at doses of 2,000 to 3,000 mg/m^2 every 12 hours for 8 to 12 doses. High-dose cytarabine schedules that use once-daily doses or alternate-day doses have also been used in an attempt to minimize toxicity.[56] Cytarabine has been administered alone or in combination with various agents, including etoposide, fludarabine, topotecan, clofarabine, and an anthracycline, as treatment of relapsed or refractory AML. Response rates to such salvage regimens range from 30% to 50%, but are often short-lived. Patients who received high-dose cytarabine during remission induction may be less likely to benefit from such a regimen for treatment of relapse, and thus require alternate salvage strategies. Patients with remission duration of longer than 1 year appear to benefit most from high-dose cytarabine regimens.[3,56]

About 70% of relapsed or refractory AML express the multidrug resistance phenotype, which confers a high degree of chemotherapy resistance because of its encoding and overexpression of P-glycoprotein. P-glycoprotein is a membrane protein capable of removing certain antineoplastics from the intracellular to extracellular space. Monoclonal antibodies have the potential to deliver targeted therapy to the malignant cell. Patients with AML in first untreated relapse treated with gemtuzumab (9 mg/m^2 for two doses separated by 14 days) attained a CR in 16% of patients, with an additional 13% of patients having normalization of blood counts with the exception of persistent platelet counts <100,000/mm^3 (<100 × 10^9/L).[82] Toxicity can be problematic with gemtuzumab. Common adverse effects include infusion-related reactions (fever and chills), prolonged neutropenia and thrombocytopenia, and transient elevations in hepatic enzymes. A more serious adverse event associated with gemtuzumab therapy is sinusoidal obstruction syndrome. It was initially thought that this only occurred in patients receiving gemtuzumab following HSCT, but has now been described in several patients who never underwent HSCT. Patients treated with gemtuzumab should have their weight and liver function tests, particularly bilirubin, monitored. Because gemtuzumab lacks specific dose-limiting organ toxicities, it has also been investigated in combination with other chemotherapy agents. In a salvage regimen consisting of gemtuzumab 9 mg/m^2 on day 4, cytarabine 1,000 mg/m^2 every 12 hours on days 1 through 5, and mitoxantrone 12 mg/m^2 on days 1 through 3, the 2-year EFS was 33% making gemtuzumab an attractive addition to salvage therapy.[83] The future role of gemtuzumab ozogamicin will need to be determined by clinical trials since its withdrawal from the commercial market in fall 2010.

Several classes of new agents are being investigated as alternate treatment approaches for relapsed or refractory AML, including the ubiquitin-proteasome pathway inhibitors (bortezomib), new novel nucleoside analogs (troxacitabine), hypomethylating agents (decitabine and 5-azacitidine), histone deacetylase inhibitors (phenylbutyrate, vorinostat), and angiogenesis modulators (bevacizumab and thalidomide).[84] Arsenic trioxide, which is effective in the treatment of APL, is being investigated for the treatment of AML via its modulation of apoptotic and chromatin remodeling pathways.

In children with AML, the duration of first CR predicts response to salvage chemotherapy. The BFM (Berlin-Frankfurt-Munster) group reported that patients who relapse within 1.5 years of initial diagnosis have a 5-year survival of 10%, versus 40% for those who relapse later than 1.5 years after initial diagnosis.[85] In children with relapsed or refractory AML, a regimen of mitoxantrone 12 mg/m^2/day for 4 days starting on the third day of treatment and cytarabine 1,000 mg/m^2 per dose every 12 hours for eight doses can achieve a second CR rate of 76% with only a 3% mortality rate.[86] However, the 2-year OS rate was only 24%. Patients were eligible to receive intensification with high-dose cytarabine and etoposide at the investigator's discretion, and this arm was closed as a consequence of a toxic death rate of 10%. Currently, most pediatric patients in CR2 receive alloHSCT if a suitable donor is available with 30% OS.[6]

LATE EFFECTS OF THERAPY FOR ACUTE MYELOID LEUKEMIA

Because of the intense therapy received by children with AML, they are at risk for a variety of long-term sequelae. A recent study reported that more than 50% of survivors have growth abnormalities.[87] Other findings include neurocognitive deficits, transfusion-associated hepatitis, endocrine disorders, cataracts, and cardiomyopathy (median cumulative anthracycline dose: 335 mg/m^2). The 20-year cumulative risk for a second malignancy is estimated to be 1.8%.

TREATMENT

Acute Promyelocytic Leukemia

APL is a subclass of AML (FAB M3) that accounts for about 10% of all cases, and is the most curable of the AML subtypes. Most patients are diagnosed between the ages of 15 and 60 years. Five-year EFS rates of 70% to 80% are reported with APL.[88] APL is clinically unique from the other subclasses because of the common occurrence of severe coagulopathy (characterized by disseminated intravascular coagulation) at diagnosis and during induction therapy, which frequently resulted in intracerebral hemorrhage. In APL, differentiation and maturation arrest are caused by alterations in the RAR because of the translocation of chromosomes 15 and 17. The discovery of t(15;17) now provides a cytogenetic marker of the disease and is predictive of response to differentiation therapy with tretinoin (commonly referred to as all-*trans* retinoic acid or ATRA). This translocation leads to a fusion protein of the PML gene on chromosome 15 and the RAR-α on chromosome 17.

Prior to the availability of tretinoin in the late 1980s, treatment of APL consisted of the same combination chemotherapy regimens used in the treatment of other subclasses of AML. Such standard regimens produced CR rates of 50% to 60%, but were associated with a high treatment-related mortality rate caused by hemorrhagic complications. The introduction of molecularly targeted therapy with tretinoin allows for high CR rates with a significant reduction in life-threatening bleeding complications. Arsenic trioxide targets the PML moiety, resulting in apoptosis, and appears to be synergistic with tretinoin.

The WBC count at initial presentation is the most important prognostic factor in patients with APL. Abnormal creatinine,

increased peripheral blast count and presence of coagulopathy are prognostic factors that predict for early death due to hemorrhage.[89]

TREATMENT PHASES

Induction

Tretinoin, an oral vitamin A analog, is given orally in a dose of 45 mg/m^2/day, as a single dose or divided into two doses, given after a meal. Tretinoin-based regimens achieve CR rates as high as 95% in APL patients within 1 to 3 months. Because tretinoin does not cross the blood–brain barrier, leukemic meningitis should be treated with conventional intrathecal chemotherapy.

Although devoid of myelosuppressive effects, tretinoin therapy is associated with headache, skin and mucous membrane reactions, bone pain, nausea, and the retinoic acid syndrome. When tretinoin is started, rapid onset of differentiation of promyelocytes occurs, which can lead to leukocytosis and retinoic acid syndrome. The retinoic acid syndrome (fever, respiratory distress, interstitial pulmonary infiltrates, pleural effusions, and weight gain) is now referred to as the APL differentiation syndrome or APL hyperleukocytosis syndrome, because it is associated with other treatment modalities in the management of APL. Among tretinoin-treated patients, this syndrome is fatal in 5% to 29% of cases. A combination of chemotherapy with tretinoin induction decreases the risk of APL differentiation syndrome, and rapid initiation of dexamethasone 10 mg (0.2 mg/kg per dose in children) twice daily for 3 days upon development of symptoms decreases associated mortality.[88]

A number of clinical trials have evaluated treatment regimens for APL since the discovery of tretinoin.[88] These trials demonstrated that tretinoin induction therapy, followed by consolidation chemotherapy, produced similar CR rates but decreased relapse and increased EFS and OS as compared to chemotherapy alone for remission induction and consolidation. However, a significant proportion of patients receiving tretinoin in that study relapsed by 4 years, and 25% of patients experienced the APL differentiation syndrome. In an effort to extend the duration of remission and decrease tretinoin-associated toxicity, other trials have evaluated the sequential and concurrent administration of tretinoin with chemotherapy during remission induction therapy. The United Kingdom Medical Research Council trial compared concurrent administration of tretinoin with chemotherapy to sequential tretinoin during induction (given 5 days before anthracycline-based remission induction chemotherapy) with the hope of reducing coagulopathy-related complications. Concurrent administration was superior in terms of CR rates, early death, and EFS and OS at 3 years. The French study demonstrated similar CR rates with concurrent or sequential tretinoin and standard induction chemotherapy, but noted a better EFS and EFS at 2 years in the concurrent administration group (suggesting a synergistic or additive effect for the combination).[88] 12 Based on these data, the current NCCN guideline for induction therapy for newly diagnosed APL patients include tretinoin 45 mg/m^2/day until a CR is achieved, in combination with an anthracycline (either daunorubicin 50–60 mg/m^2 per dose for 3 days, or idarubicin 12 mg/m^2 per dose every other day for four doses) or tretinoin plus arsenic trioxide for patients unable to tolerate anthracycline therapy.[48] Similar CR rates are observed with daunorubicin or idarubicin. APL cells appear to be more sensitive to anthracyclines, perhaps as a consequence of decreased P-glycoprotein expression.

It is important to note that chemotherapy regimens used in combination with tretinoin differ from standard AML regimens, primarily as a result of the lack of cytarabine. Several studies have evaluated the role of cytarabine in remission induction regimens for APL. In earlier trials, the addition of cytarabine did not improve the CR rate.[88] Children should also be treated with tretinoin and an anthracycline, with results similar to those achieved in adults.

Another difference in the treatment of APL is the timing of bone marrow biopsy. Assessment of response to treatment of APL is done at the time of count recovery after induction therapy. A day 10 to 14 day bone marrow biopsy, which is usually done for monitoring the effect of induction chemotherapy for other types of AML, is not long enough because leukemic promyelocytes need more time for differentiation. Assessment of molecular remission should be made after consolidation.

Arsenic trioxide is a compound with demonstrated efficacy in relapsed APL. It has been evaluated as part of remission induction therapy in several small studies. The concept of a "chemotherapy-free" regimen in this disease is attractive. Administration of arsenic trioxide with or without tretinoin (± chemotherapy) results in high initial CR rates and molecular response rates.[90] Larger studies are needed before this can be adopted as a standard of care.

Consolidation Therapy

Consolidation chemotherapy should be administered to patients with APL because of the high relapse rate. Consolidation therapy usually consists of an idarubicin or daunorubicin-based regimen in combination with tretinoin. Arsenic trioxide has also been evaluated in consolidation therapy. The CALGB recently released the results of a randomized trial that compared standard chemotherapy plus tretinoin followed by arsenic trioxide to standard chemotherapy plus tretinoin followed by standard postremission therapy. The addition of arsenic trioxide resulted in longer EFS and OS.[91]

Post-Consolidation Therapy

Unlike other subtypes of AML, maintenance therapy is an important component of therapy for APL. Before the advent of tretinoin, nonrandomized trials suggested a benefit of continuous low-dose methotrexate and mercaptopurine in prevention of relapse of APL. Larger prospective randomized trials have demonstrated decreased relapse rates in patients who received maintenance therapy (either tretinoin or combination chemotherapy), and some trials have demonstrated increased EFS and OS.[88] In a study that compared maintenance with tretinoin, chemotherapy, or tretinoin plus chemotherapy versus observation, observation was associated with the highest relapse rate and tretinoin plus chemotherapy with the lowest relapse rate.[88] Current recommendations for maintenance therapy in adult APL patients include tretinoin 45 mg/m^2/day for 15 days every 3 months, in addition to mercaptopurine 100 mg/m^2 orally daily and methotrexate 10 mg/m^2/week, for 2 years in all patients.[88] The NCCN guidelines also recommend tretinoin maintenance therapy with or without mercaptopurine and methotrexate.[48]

TREATMENT OF RELAPSED ACUTE PROMYELOCYTIC LEUKEMIA

Relapsed APL can also be effectively treated with tretinoin therapy. Patients relapsing after tretinoin-based therapy can achieve a second CR with tretinoin-based reinduction. For patients resistant to induction or reinduction with tretinoin-based regimens, alternative strategies include arsenic trioxide, and allo- or autoHSCT. Outcomes with autoHSCT depend on the disease status of the patient at the time of transplant. AutoHSCT in CR2 (versus CR1) is associated with a lower OS, leukemia-free survival, and increased treatment-related mortality. Based on the sensitive nature of

patients to chemotherapy, autoHSCT in CR1 is currently not warranted, but offers an excellent option for polymerase chain reaction PML/RAR-α–negative patients in CR2. AlloHSCT should not be offered to patients in CR1, as the mortality associated with alloHSCT outweighs the risks of conventional chemotherapy. However, it is an appropriate choice in CR2 as consolidation after reinduction with either arsenic trioxide or tretinoin.[92]

Arsenic trioxide has induced clinical remissions in relapsed APL through its induction of apoptosis and differentiation.[93,94] The recommended dose is 0.15 mg/kg/day intravenously until bone marrow remission, not to exceed 60 doses, followed by consolidation beginning 3 to 6 weeks after completion of induction at the same dose for a total of 25 doses over a period up to 5 weeks. Arsenic trioxide therapy is associated with two specific toxicities. First, it can cause the APL hyperleukocytosis syndrome, similar to that seen with tretinoin. Management is similar: corticosteroids at first signs of pulmonary distress or a rapidly rising WBC count. The second toxicity is a prolongation of the QT_c interval. Consequently, it is important to obtain a baseline 12-lead electrocardiogram prior to starting therapy with arsenic trioxide, and correct any electrolyte abnormalities, including potassium, calcium, and magnesium. Other medications known to prolong the QT_c interval should be avoided, if possible, during arsenic trioxide therapy. The QT_c interval should not exceed 500 milliseconds at baseline, and if it increases to >500 milliseconds during therapy, the patient should be reevaluated. Do not reintroduce the arsenic trioxide until the QT_c is <460 milliseconds. Following induction of a second CR with arsenic trioxide in relapsed patients, postremission therapy with combination arsenic trioxide and chemotherapy can result in molecular remissions and improved EFS, as compared to chemotherapy or arsenic trioxide alone following remission.[94] Additional investigations are underway to evaluate the role of arsenic trioxide in multidrug postremission regimens.

Gemtuzumab ozogamicin was recommended by the NCCN panel for patients who have relapsed within 6 months of arsenic trioxide therapy as second-line therapy after tretinoin and arsenic trioxide therapy, until gemtuzumab ozogamicin was withdrawn from the market. Caution should be exercised if the patient is a potential candidate for either auto- or alloHSCT because of the apparent increased risk for sinusoidal obstruction syndrome.[48]

PATIENT MONITORING

In comparison to non-APL AML, molecular and cytogenetic testing at the end of remission induction therapy in APL has no prognostic value. Clinicians should not make decisions based on the presence or absence of any genetic abnormalities at this time. Because terminal differentiation of blasts in APL requires more than 40 days, results of a bone marrow biopsy obtained at the end of remission induction can be misleading because insufficient time has elapsed to determine response. Molecular and cytogenetic response assessment should occur after the completion of consolidation treatment.

Detection of residual PML/RAR-α transcripts in the bone marrow at the end of consolidation therapy is strongly associated with subsequent hematologic relapse. Achievement of PML/RAR-α–negative status is associated with a higher probability of cure. The use of this molecular technique allows the clinician to assess response to therapy and also detect relapse earlier, which might prevent the development of overt disease recurrence and is associated with improved outcome compared with delaying treatment until overt morphologic relapse.[88] Most experts recommend that APL patients should be routinely evaluated for continuous remission status. Suggested followup includes polymerase chain reaction for PML/RAR-α every 3 to 6 months for 2 years, and then every 6 months for 2 years.[88]

ROLE OF COLONY-STIMULATING FACTORS IN ACUTE MYELOID LEUKEMIA

8 Colony-stimulating factors have been evaluated in AML patients to enhance chemotherapy cytotoxicity, shorten the duration of neutropenia, and reduce the incidence and severity of infection following induction and consolidation chemotherapy. Most studies show limited benefit with the use of colony-stimulating factors as "priming" agents administered during remission induction therapy in an effort to recruit leukemia cells into the cycle to enhance susceptibility to cell-cycle–specific chemotherapy agents, leading to increased cell kill. A recent trial demonstrated similar response rates, but those patients in CR following remission induction chemotherapy had a higher EFS if they received filgastrim.[95] No effect on OS was observed. Subgroup analysis demonstrated improved OS and EFS for patients with standard-risk AML receiving filgrastim. Results from the French Association (ALFA)-9000 trial were recently published. In that trial, the addition of sargramostim to induction and consolidation courses resulted in higher CR rates and EFS, but no effect on OS was observed.[96] Use of colony-stimulating factors concurrently during chemotherapy administration is discouraged outside the setting of a clinical trial and is not recommended for this use in the American Society of Clinical Oncology guidelines.[97]

Both filgrastim and sargramostim are FDA approved to prevent neutropenic complications in adult AML patients receiving intensive chemotherapy. The original package inserts listed myeloid malignancies as a contraindication to the use of filgrastim or sargramostim. Myeloid blast cells have receptors for granulocyte colony-stimulating factor and granulocyte-macrophage colony-stimulating factor, and there was initial concern that the use of these factors would stimulate regrowth of the myeloid leukemia. Although subsequent studies have addressed these concerns, many pediatric clinicians do not initiate filgrastim until an initial remission is achieved.

A number of randomized trials, primarily in elderly patients, consistently demonstrate that filgrastim or sargramostim reduces the duration of neutropenia following AML induction chemotherapy.[97] While neutropenia can be reduced from 2 to 12 days depending on the trial, results vary in terms of improvements in infectious morbidity and mortality, resource use, and disease response rates. The American Society of Clinical Oncology Guidelines for the Use of White Blood Cell Growth Factors considers the use of colony-stimulating factors after initial induction therapy reasonable, with the understanding that the effects on length of hospitalization and incidence of severe infection are modest.[97] Patients older than age 55 years appear to derive the greatest benefit, and use is appropriate in this population where more rapid marrow recovery might decrease the duration of hospitalization.[97] Following consolidation therapy, patients receiving colony-stimulating factors have a more profound shortening of the duration of severe neutropenia resulting in a reduction in infection rates and an associated reduction in the use of antibiotic therapy.[97] Growth factor use after consolidation does not affect CR duration or OS. Further pharmacoeconomic data are required in this setting, but the body of evidence supports their use following consolidation therapy in adults. Other controversial issues surrounding colony-stimulating factor use in AML include which colony-stimulating factor to use, what dose, which day to start after chemotherapy, how long to continue, and should the marrow be examined for leukemia prior to starting a colony-stimulating factor. All growth factors have been evaluated in patients with AML, including sargramostim, filgrastim, and pegfilgrastim. Although pegfilgrastim is not FDA approved for this indication, research supports its use in this setting.[98] The use of colony-stimulating factors can also interfere with the interpretation of the day 14 bone marrow examination. Growth factors should be discontinued at least 7 days

prior to a bone marrow aspirate and biopsy to avoid interfering with the interpretation of the results (i.e., may see immature myeloid forms that would suggest residual disease).

SUPPORTIVE CARE

The most common and significant toxic effect of antileukemic agents is marrow suppression. With the exception of corticosteroids, tretinoin, asparaginase/pegaspargase, and vincristine, antineoplastic agents used to treat acute leukemia cause myelosuppression. During AML remission and postremission therapy, daily monitoring of the complete blood count and the absolute neutrophil count is necessary to determine when red cell and platelet transfusions are needed and when neutropenia is achieved. Less-frequent monitoring may be sufficient during ALL induction. Marrow hypoplasia from the myelosuppressive regimens usually reaches its lowest point (nadir) after 1 to 2 weeks of therapy and lasts for another 1 to 2 weeks. During this period of hypoplasia, infectious and bleeding complications are major causes of death in leukemic patients. As typical signs and symptoms of infection may be absent in the neutropenic host, frequent monitoring of vital signs (especially fever) and daily physical examination are important.[99] Infection control strategies often include routine hand washing; dietary restrictions; reverse isolation and laminar-air flow rooms; fungal, *Pneumocystis*, and bacterial prophylaxis; and the empiric use of broad-spectrum antibiotics when fever occurs (see Chap. 131).[99] In contrast to the practice at many institutions, the NCCN guidelines do not recommend prophylactic antimicrobials or gut decontamination during induction or consolidation, and leave the choice to the discretion of the treating facility based on local infection patterns and concerns.[48] Several groups have analyzed the literature surrounding the use of prophylactic antibacterials. In general, prophylactic antibacterials should be reserved for patients who are expected to have prolonged (more than 7 days) and profound (absolute neutrophil count <100 cells/mm^3 [<0.1 × 10^9/L]) neutropenia. Based on these criteria, prophylaxis following induction chemotherapy is warranted and postconsolidation therapy is warranted on a case-by-case basis.

In children, prophylactic antibiotics have not proven useful and have resulted in increased resistance. Pediatric ALL patients on standard induction regimens, which generally are minimally myelosuppressive, often have recovered blood counts earlier and do not require very aggressive measures. However, they do require close monitoring of vital signs and blood counts until their counts recover. Pediatric AML patients are usually admitted for at least 1 month during induction and again for consolidation. Infectious complications, especially fungal, are a major cause of morbidity and mortality. The incidence of viridans streptococci has increased with the intensity of therapy and is most associated with high-dose cytarabine. These infections can lead to meningitis or delayed acute respiratory distress syndrome.

Pneumocystis jiroveci prophylaxis (usually trimethoprim-sulfamethoxazole) is begun in all adults and children with ALL by the end of induction and continues until 6 months after therapy is discontinued. Infants are at high-risk for developing *Pneumocystis jiroveci* pneumonia early in therapy, so should start prophylaxis immediately.[27] These infants can receive trimethoprim-sulfamethoxazole despite the risk of kernicterus with careful monitoring.

Acute leukemia patients, particularly those patients with an initial elevated WBC count, are at risk for tumor lysis syndrome. Preventive measures include allopurinol or rasburicase, and adequate hydration (with or without sodium bicarbonate) prior to and during chemotherapy to prevent the development of urate nephropathy from rapid destruction of WBCs. Rasburicase, a recombinant urate-oxidase enzyme produced by genetic modification of *Saccharomyces cerevisiae*, catalyzes the enzymatic oxidation of uric acid into the inactive soluble metabolite, allantoin. In children, rasburicase more rapidly reduces uric acid levels in patients with aggressive malignancies compared to allopurinol, and reduces the need for dialysis.[100] Rasburicase has been evaluated in adults, and some studies in adults show that fixed dosing produces equivalent outcomes to a mg/kg dosing strategy.[101] Because of its cost, this product is usually limited to patients with ALL who have a high WBC count or bulky extramedullary disease, aggressive non-Hodgkin lymphoma, or patients with AML with a high presenting WBC. Most institutions also include an elevated uric acid as part of the criteria for use. Rasburicase has a rapid onset of action and long duration of action, so many institutions also limit its use to a single dose and allow repeat doses when the criteria for use are met again. Rasburicase is contraindicated in patients with glucose-6-phosphate dehydrogenase deficiency. Tumor lysis syndrome may lead not only to hyperuricemia, but also to hyperkalemia, hyperphosphatemia, and hypocalcemia.[100]

Hematologic support consists primarily of platelet and packed red blood cell transfusions. Platelet transfusions are often given for peripheral counts below 10,000 cells/mm^3 (10 × 10^9/L) or clinical signs of bleeding. Transfusions of packed red cells may also be indicated for a hemoglobin less than 8 gm/dL (80 g/L; 4.97 mmol/L), profound fatigue, shortness of breath, tachycardia, or chest pain. APL can release procoagulants that can cause disseminated intravascular coagulation, necessitating close monitoring and replacement of coagulation factors with cryoprecipitate. Because of the gastrointestinal toxic effects of chemotherapy, parenteral nutrition may be required. Patients are frequently receiving infusions of antibiotics, fluids, hyperalimentation, and blood products simultaneously. To provide the total support needed for these patients, a multiple-lumen central venous access device should be considered at the start of therapy.

EVALUATION OF THERAPEUTIC OUTCOMES

Appropriate development of a pharmaceutical care plan for the acute leukemia patient begins with establishing the diagnosis and prognosis for the patient. Long-term therapeutic goals for the patient may include long-term EFS, although palliative care is a possibility in some patients. The desired short-term outcome is the establishment of remission. The return of hematologic values to normal and a repeat bone marrow biopsy that demonstrates no evidence of disease serve as documentation that remission has been achieved. Monitoring guidelines for induction or consolidation are similar (Table 142–6). After the appropriate post-remission therapy has been completed, the patient may return monthly for 1 year, and then every 3 months, to check hematologic values. If no evidence of disease exists after 5 years from the diagnosis and the patient has been in continuous CR, the patient is considered cured.

Intense monitoring of fevers, hematologic and chemistry laboratory values, microbiology reports, and the patient's physical condition are necessary to identify infection, risk of bleeding, and tumor lysis syndrome early. A coagulation screening panel will identify patients with ongoing disseminated intravascular coagulation, a particular risk with APL.

During therapy, the pharmacist can be an important provider of patient education. Patients should receive information regarding acute and chronic toxicities of the chemotherapy being administered, as well as possible treatments for those toxicities. Pharmacists should follow patients during consolidation therapy for dosing adjustments and toxicities due to chemotherapy. For

TABLE 142-6 Acute Myeloid Leukemia Assessment and Monitoring

Baseline Workup	Monitoring during Therapy	Postremission Monitoring
History and physical examination	Daily physical examination	Routine physical examination at clinic visit
CBC with differential, platelets	CBC with differential, platelets	CBC with differential, platelets
Serum chemistries (creatinine, bilirubin, AST, ALT to assess organ function)	Serum chemistries (including uric acid, K^+, Ca^{+2}, PO_4, S_{cr} during tumor lysis syndrome risk period[a])	Bone marrow biopsy and aspirate at set intervals to evaluate ongoing remission and if peripheral blood counts are abnormal or if they fail to recover within 5 weeks of treatment
Coagulation (PT, PTT, D-dimers, fibrinogen)	Coagulation (PT, PTT, D-dimers, fibrinogen [if APL])	PML/RARα monitoring [if APL]
Bone marrow biopsy and aspirate with cytogenetics	Bone marrow biopsy and aspirate 7–10 days after end of chemotherapy. Repeat bone marrow biopsy and aspirate upon hematologic recovery to document complete response (with cytogenetics if initially abnormal)	
Immunophenotyping and cytochemistry	Temperature curve (initiate antibiotics when febrile)	
Human leukocyte antigen (HLA) typing	Lumbar puncture (with intrathecal chemotherapy) if initial lumbar puncture was positive for leukemia)	
Cardiac workup (MUGA or echocardiogram; ECG)		
Intravascular access		
Lumbar puncture (if symptomatic or AML M4 or M5)		
Chest radiography		
Height and weight		
Molecular testing for genetic aberrations (FLT3, NPM1)		

ALT, alanine aminotransferase; APL, acute promyelocytic leukemia; AST, aspartate aminotransferase; CBC, complete blood cell count; ECG, electrocardiogram; FLT3, FMS-related tyrosine kinase 3; MUGA, multiple-gated acquisition (blood pool scan); NMP1, nucleophosmin; PML/RARα, promyelocytic-leukemia retinoic acid receptor-α; PT, prothrombin time; PTT, partial thromboplastin time; S_{cr}, serum creatinine.

[a]Risk for tumor lysis syndrome during induction therapy only.

example, the pharmacist should make sure the patient is receiving corticosteroid and saline eye drops 4 times daily while the patient is receiving high-dose cytarabine to prevent the ocular toxicity of cytarabine. The pharmacist can also be an important resource for information regarding antibiotics, antiemetics, nutritional support, colony-stimulating factors, and other supportive care issues.

Pharmacists should be involved in checking drug doses and any dose modifications for organ dysfunction or prior toxicity. Pharmacists are often in the best position to recognize the potential for medication errors and drug interaction and to help avoid them. Similarly, pharmacists are often able to identify the possibility that patient problems are secondary to drug treatments.

Numerous late sequelae from leukemia therapy have been recognized and should be included in the monitoring plan after therapy is completed. Chapter 148 discusses the long-term consequences of HSCT.

ABBREVIATIONS

ALL: acute lymphoblastic leukemia

AML: acute myeloid leukemia

APML: acute promyelocytic leukemia

alloHSCT: allogeneic hematopoietic stem cell transplantation

autoHSCT: autologous hematopoietic stem cell transplantation

CALGB: Cancer and Leukemia Group B

CNS: central nervous system

CR: complete remission

ECOG: Eastern Cooperative Oncology Group

EFS: event-free survival

FAB: French-American-British classification system

HSCT: hematopoietic stem cell transplantation

MDS: myelodysplastic syndrome

MLL: mixed lineage leukemia

MRD: minimal residual disease

NCCN: National Comprehensive Cancer Network

OS: overall survival

Ph^+: Philadelphia chromosome

TPMT: thiopurine methyltransferase

WBC: white blood cell

CHAPTER 143

Chronic Leukemias

CHRISTOPHER A. FAUSEL AND PATRICK J. KIEL

KEY CONCEPTS

1. Chronic myelogenous leukemia (CML) is defined by the presence of the Philadelphia chromosome (Ph), a translocation between chromosomes 9 and 22. The resulting abnormal fusion protein, p210 *BCR-ABL*, phosphorylates tyrosine kinase residues and is constitutively active, resulting in uncontrolled hematopoietic cell proliferation.
2. The disease course of CML is characterized by a progressive increase in white blood cells over a period of years that ultimately transforms to an acute leukemia.
3. Imatinib is a tyrosine kinase inhibitor and is the most commonly used therapy in the treatment of chronic phase CML. Second-generation tyrosine kinase inhibitors, dasatinib and nilotinib, are active in most patients that have resistance or intolerance to imatinib.
4. Interferon alfa (IFN-α) plays a minor role in the current treatment of CML and is reserved for patients who fail tyrosine kinase inhibitors and are ineligible for allogeneic hematopoietic stem cell transplant (HSCT).
5. Allogeneic HSCT is the only known curative treatment option for CML and is reserved for patients with a suitable donor and progression after treatment with tyrosine kinase-based therapy.
6. The management of CLL is highly individualized and includes observation in patients with early stage disease and treatment with chemotherapy, biologic therapy or both in patients with more advanced disease.
7. Alemtuzumab is a monoclonal antibody against CD52, which is expressed on B and T cells. It has proven activity in first-line treatment and relapsed disease. Routine use must be balanced against the known risks of opportunistic infections.
8. Regimens such as fludarabine, cyclophosphamide, and rituximab are considered as first-line therapy for patients with CLL who are younger or have more aggressive disease, such as the presence of chromosome 17 deletion.
9. Allogeneic HSCT in patients with CLL appears to achieve long-term disease-free survival in some patients, but the older patient population diagnosed with the disease and donor availability preclude widespread use.

The chronic leukemias include chronic myeloid leukemia (CML), chronic lymphocytic leukemia (CLL), hairy cell leukemia, and prolymphocytic leukemia. The typical clinical presentation of the chronic leukemias is an indolent course in contrast to patients with acute leukemia who will die of their disease within weeks to months if not treated. The introduction of tyrosine kinase inhibitor therapy has dramatically changed the clinical course of CML where patients can now expect to maintain disease control for many years. This chapter focuses on the two most common types of chronic leukemia, CML and CLL.

CHRONIC MYELOID LEUKEMIA

Chronic myeloid leukemia is a myeloproliferative disease that results from malignant transformation of a subpopulation of pluripotent hematopoietic stem cells. Bone marrow hyperplasia and accumulation of differentiated myeloid cells in the peripheral blood are the initial presenting features of the disease. The terminal stage of CML develops over a period of years and is characterized by rapid accumulation of blast cells in the bone marrow and suppression of normal hematopoiesis that will ultimately become fatal. Chronic myeloid leukemia was the first malignant disease to be identified with a consistent cytogenetic abnormality, namely the Philadelphia chromosome (Ph) that codes for the *BCR-ABL* oncogene. This dominant cytogenetic abnormality has allowed CML to become the template for development of molecular targeted drug therapies.

EPIDEMIOLOGY AND ETIOLOGY

It is estimated that 4,870 new cases of CML will be diagnosed in the United States in 2010, representing 11% of all leukemias.[1] Median age at diagnosis is 65 years and incidence increases with age.[2] There are no currently known associations between the development of CML and hereditary, familial, geographic, ethnic, or economic status. An increased risk of CML has been noted with ionizing radiation exposure and in atomic bomb survivors from Hiroshima and Nagasaki.[3,4]

PATHOPHYSIOLOGY

Chronic myeloid leukemia was first described in 1845, but extensive research into the genetic and molecular characteristics of the disease began with the discovery of the Philadelphia chromosome (Ph) in 1960 by Nowell and Hungerford.[5] Research in the 1980s

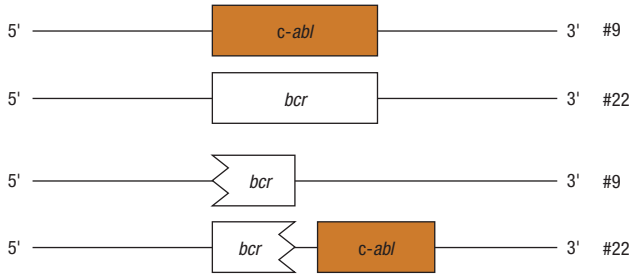

FIGURE 143-1. Diagram of the chromosomal translocation that results in the Philadelphia chromosome. *(Reprinted with permission from Fishleder AJ. Oncogenes and cancer: Clinical applications. Cleve Clin J Med 1990; 57:721–726. Copyright © 1990 Cleveland Clinic. All rights reserved.)*

identified the molecular changes that occur as a result of the Ph when an oncogenic protein was identified and implicated in the pathophysiology of CML.[5,6]

Ph is the first karyotypic abnormality specifically implicated in the pathogenesis of cancer, and its discovery has resulted in extensive research into the molecular biology of CML.[7] This chromosomal abnormality is characteristic of CML and is present in approximately 95% of patients with the disease.[8,9]

1 Ph, identified as a shortened long arm of chromosome 22, is found in granulocyte and erythrocyte progenitors, macrophages, megakaryocytes, and lymphocytes. The Ph is the consequence of breaks in chromosomes 9 and 22 resulting in a transposition that relocates the 3' end of *ABL* (Abelson proto-oncogene) from its normal site on chromosome 9 at band 34 to the 5' end of *BCR* (breakpoint cluster region) on chromosome 22 at band 11 [symbolized as t(9;22)(q34;q11)].[9,10] This results in the formation of the hybrid *BCR-ABL* fusion gene (Fig. 143–1). Through this chromosomal translocation, the *ABL* protooncogene is able to escape the normal genetic controls on its senescence and is activated into a functional oncogene, directing the transcription of an 8.5-kilobase messenger ribonucleic acid (mRNA) molecule. The mRNA is translated into a 210-kDa protein—$p210^{BCR\text{-}ABL}$—that is constitutively (constantly) activated compared to the 145-kDa protein translated by the normal *ABL* gene.[8,9] Although $p210^{BCR\text{-}ABL}$ is the most common tyrosine kinase found in CML, variations in the breakpoints in the *ABL* gene encode different size proteins. For example, a smaller protein, p190 *BCR-ABL*, is involved in two thirds of adults with Ph-positive acute lymphoblastic leukemia, although rarely found in patients with CML.[9]

Since CML begins with the malignant transformation of a single cell, it is considered a clonal disease. The progeny from this transformed primitive hematopoietic stem cell results in a proliferative advantage over normal hematopoietic cells that displaces normal hematopoiesis. The Ph can be found in both myeloid and lymphoid cells, which suggests that the transformed cell of CML is a pluripotent stem cell.[10] This alteration gives the transformed progenitor cell an inheritable growth advantage, leading to the proliferation of a neoplastic, monoclonal population of cells.[9] Disrupted maturation leads to additional divisions by CML progenitor cells before reaching a nonproliferative stage; the resulting number of circulating granulocytes may be many times higher than normal. In the advanced stages of CML, cytopenias may occur in association with fibrotic changes in the bone marrow.[9]

The *BCR-ABL* fusion gene encodes for a constitutively active tyrosine kinase that is involved in both the increased proliferation of the CML clone and the reduction in FAS-mediated apoptosis. Characterization of the adenosine triphosphate binding site on the *BCR-ABL* tyrosine kinase has provided a target for inhibition of tyrosine kinase activity. The first FDA-approved tyrosine kinase inhibitor, imatinib mesylate (Gleevec®), was indicated for patients in chronic phase who had failed interferon alfa (IFN-α) or for those with advanced disease. Imatinib received additional FDA approval in 2002 for first-line treatment in newly diagnosed CML. Second-generation tyrosine kinase inhibitors with a higher binding affinity and selectivity for *ABL* kinase have been developed and approved for use in patients who are intolerant or resistant to imatinib.

CLINICAL PRESENTATION

CLINICAL PRESENTATION OF CML[1]

General

- 90% of patients are diagnosed in chronic phase
- 50% are asymptomatic in chronic phase and often diagnosed following abnormal complete blood count

Signs and Symptoms

- Fatigue
- Left upper quadrant pain
- Abdominal pain or distension
- Weight loss
- Night sweats

Physical Examination

- Splenomegaly
- Hepatomegaly

Laboratory Tests

- Peripheral blood
  - Leukocytosis
  - Thrombocytosis
  - Basophilia
  - Low or undetectable leukocyte alkaline phosphatase
  - Elevated uric acid and lactate dehydrogenase
- Molecular testing
  - Presence of *bcr-abl* by reverse-transcription polymerase chain reaction
- Bone marrow
  - Hypercellular
  - Fully mature myeloid cells
  - Increased megakaryocytes
  - <10% blasts in chronic phase
- Cytogenetics
  - Presence of the Ph chromosome
  - Additional abnormalities

CLINICAL COURSE

2 Three clinical phases of CML are recognized: chronic phase (CP), accelerated phase (AP), and blast crisis (BC). Nearly 90% of patients present with chronic phase at the time of diagnosis. Often the diagnosis of CML is found incidentally during routine examination or if a complete blood count is obtained for unrelated reasons because patients are often asymptomatic upon presentation. Signs and symptoms include fatigue, sweating, bone pain, weight loss, abdominal discomfort, and early satiety secondary to splenomegaly. Leukocytosis is the hallmark of CP, which can be as high as 1,000,000 cells/mm^3 (1,000 × 10^9/L) placing patients at risk for

complications of leukostasis. Symptoms secondary to leukostasis include acute abdominal pain resulting from splenic infarctions, priapism, retinal hemorrhage, cerebrovascular accidents, confusion, hyperuricemia, and gouty arthritis.[9] CP has an approximately three to 5-year survival without treatment.

Initial laboratory workup includes complete blood count with differential, complete metabolic panel, and serum uric acid. A bone marrow aspiration and biopsy is required to confirm the diagnosis of CML. The differential diagnosis of CML includes infection, myeloproliferative disorders (i.e., polycythemia vera, essential thrombocythemia, myelofibrosis), and chronic myelomonocytic leukemia. Bone marrow is markedly hypercellular (75%–90%) with increased granulocyte/erythroid ratio increased (10–30:1), erythropoiesis increased megakaryocytes normal. Karyotyping (cytogenetic analysis) is required for a diagnosis. The bone marrow aspiration is analyzed with Fluorescent in situ hybridization (FISH) to determine the presence of the Ph chromosome. Quantitative real time polymerase chain reaction (RT-PCR) is also performed to assess the baseline *BCR-ABL* transcript levels.

Accelerated phase is characterized by progressive myeloid maturation arrest and loss of efficacy of drug therapy directed to attenuate the increase in white blood cells. Clinical findings of AP include anemia, increasing peripheral blood and bone marrow blasts and basophils, clonal cytogenetic evolution, extramedullary disease sites (bone, breast, CNS, mucosal tissue, lymph nodes, and skin), exacerbation of splenomegaly, and either thrombocytosis or thrombocytopenia. Nonspecific findings such as bone pain, fever, night sweats, and weight loss may occur. The most commonly observed cytogenetic changes with disease progression are an additional Ph chromosome, trisomy 8, and isochrome I(17q). Survival typically will not exceed several months. The World Health Organization (WHO) classification defines AP CML as one or more of the following changes: 10% to 19% of blasts in the peripheral blood or bone marrow, persistent thrombocytopenia less than 100,000 cells/mm^3 (100×10^9/L) (not related to drug therapy), thrombocytosis greater than 1,000,000 cells/mm^3 ($1,000 \times 10^9$/L) despite drug therapy, peripheral basophilia >20%, increasing spleen size and white blood cell count despite drug therapy, bone marrow evidence of progression of the leukemic clone or new cytogenetic abnormalities (Table 143–1).[11]

Blast crisis is the terminal stage of disease and clinically resembles acute leukemia where the leukemic clone overwhelmingly dominates the bone marrow at the expense of normal hematopoiesis. The WHO classification defines BC CML as the presence of one or more of the following: >20% blasts in the peripheral blood or bone marrow, extramedullary disease, or large clusters of blasts in the bone marrow (Table 143–1).[11] A minority of patients present with BC without an apparent AP. One third of patients present with BC of lymphoid lineage, whereas two thirds present with BC of myeloid lineage or undifferentiated like phenotype. The increased proliferative rate in BC CML is the consequence of a number of factors in addition to *BCR-ABL*, such as the activation of the RAC- and RAS-signaling pathways and loss of tumor suppressors such as p53. Duration of BC is typically days to weeks before death.

TABLE 143-1 Criteria for Defining Phases of Chronic Myelogenous Leukemia

Chronic Phase	Accelerated Phase	Blast Crisis
• <10% blasts in peripheral blood or bone marrow	• 10%–29% blasts in peripheral blood or bone marrow • Platelets <100,000 cells/mm^3 or >1,000,000 cells/mm^3 Additional findings • Cytogenetic evolution • Progressive splenomegaly	• >30% blasts in peripheral blood or bone marrow • Large clusters of blasts on bone marrow biopsy • Presence of extramedullary infiltrates Additional findings • Fever • Malaise • Splenomegaly

Data from Cortes JE, Talpaz M, O'Brien S, et al. Staging of chronic myeloid leukemia in the imatinib era. Cancer 2006;106:1306–1315.

PROGNOSIS

Several models have been proposed for estimating prognosis in patients with CML, but the one proposed by Sokal et al. has become the most widely used.[13] The Sokal algorithm uses spleen size, percentage of circulating blasts, platelet count, and age as prognostic factors for patients in CP. However, this scoring system was developed prior to the advent of tyrosine kinase inhibitor therapy and may have limited predictive value in the era of imatinib. The median overall survival for patient diagnosed with CP, AP, and BC CML was reported to be 47 months, 12 to 24 months, and 3 to 6 months respectively in the era prior to the introduction of tyrosine kinase inhibitors.[13,14]

TREATMENT

GOALS OF TREATMENT

Without effective treatment, CML disease progression leads inexorably to a fatal outcome within five years. The overriding treatment goals for CML include the eradication of the leukemic clone from the bone marrow and maintenance of CP with minimal toxicity from treatment. The only proven therapy to eradicate the malignant clone from the bone marrow is a hematopoietic stem cell transplant (HSCT). Both immunotherapy with IFN-α and tyrosine kinase inhibitor based therapies have demonstrated the ability to extend CP beyond the expected period of several years, but data to confirm the curative ability of these agents are lacking. The current standard of practice is to institute imatinib therapy for newly diagnosed CML patients. Long-term follow-up from phase III trials have documented a response in excess of 85% of patients that receive imatinib as primary treatment.[15,16] Table 143–2 shows the effect of various treatment modalities on survival in CP CML.

Clinical response in CML is measured by hematologic, cytogenetic, and molecular indices all of which have standardized criteria.[17] *Hematologic response* is defined as the normalization of peripheral blood counts and is the earliest type of response observed in CML patients. *Cytogenetic responses* are based on the percentage of cells positive for Ph in a bone marrow biopsy.

TABLE 143-2 Effect of Therapy on Survival in Patients with Early Chronic-Phase Chronic Myelogenous Leukemia

Therapy	5-Year Survival (%)	Median Survival (Months)
Busulfan[25]	30–40	40–50
Hydroxyurea[25]	40–50	50–60
IFN-α[1]	50–70	60–80
IFN-α + ara-C[1]	60–80	NR
Allogeneic transplantation		
Matched sibling[1,55]	60–80	NR
Matched unrelated[1,7]	40–70	NR
Imatinib[21]	89	NR

NR, not yet reached.

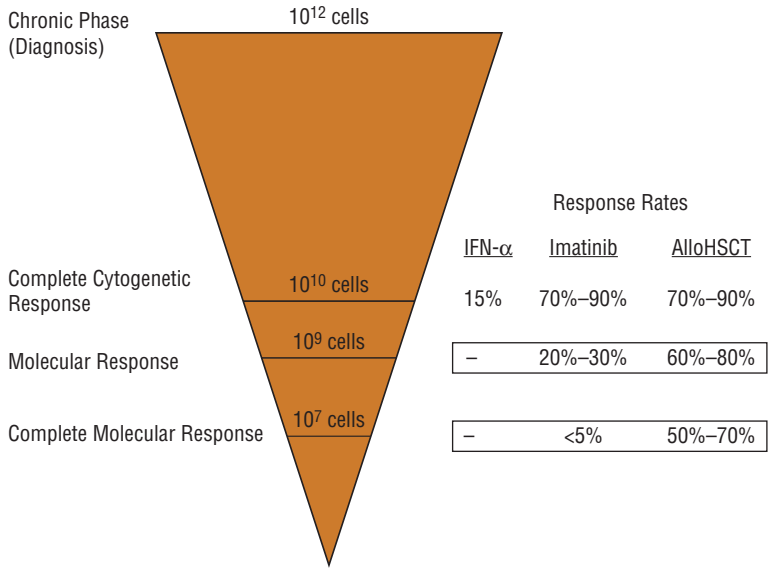

FIGURE 143-2. Type and frequency of response associated with common CML therapies. (AlloHSCT, allogeneic hematopoietic stem cell transplantation; IFN, interferon.) *(Adapted from Lowenberg B. Minimal residual disease in chronic myeloid leukemia. N Engl J Med 2003;349(15): 1399–1401. Copyright © 2003 Massachusetts Medical Society. All rights reserved.)*

Complete cytogenetic response is defined as the elimination of Ph from all cells in the marrow sample whereas *major cytogenetic response* is defined as fewer than 35% Ph-positive cells. Patients who have a major or complete cytogenetic response have an improved survival compared to those who fail to achieve a cytogenetic response.[18]

Because most patients on imatinib achieve a complete cytogenetic response, more sensitive tests to monitor disease status have become more prominently used. *Molecular responses* are determined by quantitative reverse-transcriptase polymerase chain reactions (RT-PCR), which are several logs more sensitive than methods used to measure cytogenetic responses. A *complete molecular response* is the absence of *BCR-ABL* transcripts by RT-PCR. RT-PCR assays should be interpreted carefully because they have varying sensitivities and may show a complete molecular remission even when low levels of *BCR-ABL* transcripts are present.[18] Quantitative RT-PCR should be performed on every patient prior to initiating therapy and throughout therapy to monitor residual disease. Because bone marrow and peripheral blood *BCR-ABL* mRNA levels are correlated, peripheral blood can often be used for this analysis.[17,18] Figure 143–2 illustrates the residual disease that remains after various types of responses and the response rates obtained with the common therapies for CML.

CONVENTIONAL CHEMOTHERAPY

Conventional cytotoxic chemotherapy is used in CP CML to reduce and temporarily control high peripheral white blood cell (WBC) counts. Historically, the two agents used for leukoreduction are busulfan (Myleran®) and hydroxyurea (Hydrea®). Busulfan is no longer used because randomized trials have shown that hydroxyurea treatment provides a modest survival advantage and busulfan has a risk of potentially life-threatening pulmonary fibrosis.[19]

Hydroxyurea rapidly lowers high circulating WBCs in CP CML by inhibiting ribonucleotide reductase, which inhibits DNA synthesis, eliminating cells in the S phase of the cell cycle, and synchronizing cells in the G_1 or pre-DNA synthesis phase. Hydroxyurea is initiated at 40 to 50 mg/kg/day in divided doses until the WBC count falls to approximately 10,000 cells/mm^3 (10×10^9/L). Hydroxyurea may be discontinued once adequate control of the WBC count is achieved and imatinib has been initiated. Hydroxyurea is not specifically active against Ph and will not alter the natural progression of the disease to BC.

IMATINIB MESYLATE (GLEEVEC®)

A transformative discovery in cancer therapeutics was the characterization of the adenosine triphosphate binding site on the *BCR-ABL* tyrosine kinase. This specific receptor established a novel drug discovery platform for molecular targeted therapy in CML. Numerous tyrosine kinase inhibitors were in development in the 1990s and STI571 (STI stands for signal transduction inhibitor), subsequently named imatinib (Gleevec®), emerged as the drug with the best oral bioavailability and high binding affinity for the *BCR-ABL* tyrosine kinase.[20,21] In 2001, imatinib mesylate received FDA approval for patients in CP who had failed IFN-α treatment and in patients with AP or BC based on phase II studies. In 2002, it received FDA approval for first-line treatment in newly diagnosed CML on the basis of the 2-year follow-up in the International Randomized Interferon vs STI571 (IRIS) phase III trial.[22]

Imatinib inhibits several other tyrosine kinases including *BCR-ABL*, c-KIT, and platelet-derived growth factor receptor. Imatinib competitively binds to the adenosine triphosphate (ATP)-binding site on *BCR-ABL*, which inhibits the phosphorylation of proteins involved with CML clone proliferation.[23] Table 143–3 summarizes the clinical results of imatinib in CML patients in CP, AP, and BC. Early phase I and phase II studies of imatinib, designed to determine maximum tolerated dose and safety, showed higher than expected response rates in all stages of CML.[24]

TABLE 143-3 Cytogenetic Response Associated with Tyrosine Kinase Inhibitor Therapy in Chronic Myelogenous Leukemia

Drug (Disease Status)	Daily Dose	MCyR	CCyR	Median Follow-up
Imatinib (CP)[21]	400 mg	92%	87%	60 months
	800 mg	96%	90%	30 months
Imatinib (AP)[38]	600 mg	49%	43%	12 months
	400 mg	16%	11%	
Imatinib (BC)[20,39]	400–800 mg	16%	7.4%	–
Dasatinib (CP)	100 mg	59%	41%	6 months
Dasatinib (AP)	140 mg	39%	32%	15 months
Nilotinib (AP)	800 mg	29%	16%	12 months

CCyR, complete cytogenetic response; CML, chronic myelogenous leukemia; AP, accelerated phase; BC, blast crisis; CP, chronic phase; MCyR, major cytogenetic response.

Chronic Phase

The IRIS study (N = 1,106) compared imatinib 400 mg orally daily to IFN-α plus low-dose subcutaneous cytarabine.[22] After a median follow-up of 19 months, patients who received imatinib achieved a complete hematologic response of 96%, major cytogenetic response of 85%, and complete cytogenetic response of 69%. Six percent of patients had progressed to AP or BC and only 4% discontinued imatinib due to an adverse event. The study was designed to allow crossover to the opposite treatment arm for lack of response or intolerance. After 60 months of follow-up, only 3% of patients who were originally randomized to receive IFN-α remained on their initial regimen compared with 69% of patients in the imatinib arm. The 5-year follow-up data from the IRIS trial was published in December 2006 and 6-year follow-up data in March 2009.[15,25] The estimated 5-year and 6-year overall survival of the 553 patients who were originally randomized to receive imatinib is 89% and 88%, respectively. At 60 months, the best observed rate of a major cytogenetic response and complete cytogenetic response while on imatinib was 89% and 82%, respectively. When the Sokal prognostic scoring system was used the complete cytogenetic response rates were 89%, 82%, and 69% in low-risk, intermediate-risk, and high-risk patients, respectively.

Cytogenetic and molecular responses secondary to imatinib are associated with event-free survival and risk of progression to AP or BC. Patients that do not achieve a hematologic response by 3 months, cytogenetic response by 6 months, or a major cytogenetic response by 12 months fare significantly worse compared to responders. Additionally, patients with a complete cytogenetic response and at least a 3-log reduction in *BCR-ABL* levels via RT-PCR correlated with a 100% survival without disease progression at 18 months. The risk of disease progression according to the Sokal scoring system estimated the rates of disease progression to be 3%, 8%, and 17% in low-risk, intermediate-risk, and high-risk patients, respectively. However, the Sokal score was not associated with disease progression in patients who achieved a complete cytogenetic response.[15]

3 Although most patients attain a complete cytogenetic response on imatinib, very few patients achieve a complete molecular remission. In a study of patients enrolled in the IRIS study, Hughes et al. reported that less than 5% of patients on imatinib have undetectable levels of *BCR-ABL* when analyzed by RT-PCR.[26] Recent data suggest that the level of residual disease is predictive of progression-free survival. A decline in *BCL-ABL* mRNA by 3-log within 3 months after achieving a complete cytogenetic response is reported to be a predictor of longer progression-free survival.[27] Careful monitoring of *BCR-ABL* levels by RT-PCR is necessary to guide clinician decision making for therapy modification.

The 2011 National Comprehensive Cancer Network (NCCN) guidelines recommend imatinib 400 mg orally daily as one of several options for patients in CP.[16] Most newly diagnosed patients in CP will be started on imatinib 400 mg daily and nearly 90% of these patients will achieve a complete cytogenetic response (see Table 143–3).

Higher imatinib doses are being evaluated in clinical trials. The European LeukemiaNet conducted a randomized phase II trial in high-risk patients defined by the Sokol scoring system to imatinib 400 mg daily (n = 108) vs 800 mg daily (n = 108) and evaluated the proportion of patients achieving a complete cytogenetic response at 12 months.[28] Patients receiving the higher dose of imatinib achieved a 64% complete cytogenetic response compared to 58% of patients receiving standard dose with a median follow-up period of 12 months (P = 0.435). These study results do not justify the routine use of imatinib 800 mg daily as front-line therapy in high-risk patients with CP CML. A phase II trial evaluated imatinib 400 mg daily for 2 weeks, then titrated to 400 mg twice daily in patients with an intermediate-risk Sokol score appeared to have benefit with 88% and 91% of patients achieving a complete cytogenetic response at 12 and 24 months.[29] These data require validation with a phase III clinical trial before a widespread use of a higher dose can become standard of care in CP CML.

Accelerated Phase/Blast Crisis

Response rates for patients with AP or BC CML are reduced compared with those in CP. A phase II study evaluating imatinib 600 mg daily in patients with AP CML yielded complete hematologic and complete cytogenetic response rates of 71% and 19%, respectively.[30] Prior to protocol amendments, patients were able to receive imatinib 400 mg daily, but the rates of hematologic response, cytogenetic response, disease progression, and overall survival were inferior to imatinib 600 mg. The toxicity profile between imatinib 400 mg and 600 mg daily was similar.

Traditional therapy for BC has focused on administering cytotoxic chemotherapy in treatment programs similar to acute leukemia induction. Etoposide (VP-16) cytarabine (Ara-C), and carboplatin (VAC-regimen) has demonstrated efficacy in patients with BC CML with a median overall survival of 7 months.[31] Imatinib has demonstrated modest benefit in BC. An open-label, non-randomized trial evaluated imatinib 400 mg daily with dose escalation to 600 mg daily and 400 mg twice daily (for patients not achieving a hematologic response after 1 month).[32] The primary objectives were to assess hematologic response, complete cytogenetic response, and the return to CP CML. Fifteen percent developed a complete hematologic response, 7.4% achieved a complete cytogenetic response, and 18% achieved a second CP. Imatinib 600 mg was an independent predictive factor for the likelihood of a sustained hematologic response. The median overall survival was 6.9 months.

Imatinib Resistance

Despite having high cytogenetic response rates, some patients treated with imatinib will not respond to therapy or will relapse after primary response.[33] The most prominent mechanism of imatinib resistance is the presence of point mutations in one or more areas on the ABL kinase. More than 100 different mutations have been discovered thus far. Many of these mutations can cause a conformational change in the ATP binding site, which greatly decreases the ability of imatinib to bind and inhibit kinase activity.[34] Imatinib binds to *BCR-ABL* by establishing a series of hydrogen bonds with side changes of amino acids within the kinase domain. Mutations which alter this surface can decrease the affinity of imatinib for *BCR-ABL*, potentially preventing binding entirely. The kinase domain of *BCR-ABL*, which encompasses amino acids 225–400, can be subdivided into ATP and imatinib binding site (P loop), the catalytic site where the phosphate from ATP is transferred to the substrate protein, and the activation domain which determines the state of the kinase (open or closed). The imatinib binding site is located in the region of amino acids 300–325. Resistance is caused by point mutations in one or more of several areas on the Abl kinase. The T315I mutation occurs directly within the imatinib binding site and completely disrupts imatinib binding.[35] This mutation has gained notoriety by conferring resistance not only to imatinib but also to second-generation *BCR-ABL* kinase inhibitors.

The other known clinically relevant mechanism of resistance is *BCR-ABL* gene amplification. The *BCR-ABL* gene is overexpressed to such an extent that the typical 400 mg daily dose of imatinib is insufficient to inhibit the activity of the kinase. Reports of clinically significant resistance have been published owing to *BCR-ABL* gene amplification, multiple copies of Ph, or both. The largest series published this far included 66 patients, in whom only two

had confirmed *BCR-ABL* genomic amplification.[35] Other proposed mechanisms of resistance to imatinib include differential binding to alpha-1 acid glycoprotein in serum, overexpression of p-glycoprotein induced drug efflux and clonal evolution to acquisition of additional cytogenetic abnormalities.[36]

Imatinib Monitoring

Imatinib therapy should be frequently monitored to assess response or disease progression. Recommendations for monitoring include baseline molecular and cytogenetic assessment. A complete hematologic response is expected within 3 months of starting imatinib in patients with CP CML. *BCR-ABL* transcripts should be evaluated by RT-PCR every 3 months and bone marrow cytogenetics performed at 6 and 12 months following the start of therapy.[16–18] If the patient has achieved a cytogenetic response at 6 months, then it is not necessary to repeat bone marrow cytogenetics at 12 months. However, if a patient has not yet achieved a cytogenetic response at 12 months then bone marrow cytogenetic should be repeated at 18 months and as clinically indicated.

If a patient develops an increase in *BCR-ABL* transcripts (a 1-log increase) the following measures should be implemented: assess patient adherence, repeat *BCR-ABL* in 1 to 3 months for patients with a prior major molecular response, obtain bone marrow cytogenetics in patients without a previous major molecular response and consider mutation analysis for the *BCR-ABL* tyrosine kinase.[16]

Side Effects and Drug Interactions

Imatinib-induced myelosuppression is one of the most common adverse events. Moderate-to-severe myelosuppression occurs in approximately 5% to 10% of patients with CP CML and in 50% to 60% of patients in AP or BC.[12] The myelosuppression typically occurs within the first 4 weeks of therapy and is more common in patients with advanced disease (i.e., high blastic involvement of the bone marrow) and those with a low hemoglobin. Hematopoiesis in patients with CML depends on the amount of Ph-positive progenitors, although some degree of myelosuppression should be expected when the malignant clone is suppressed. However, imatinib also suppresses normal hematopoiesis, which suggests that myelosuppression associated with imatinib is probably related to effects on the Ph clone and normal hematopoietic cells.[4] Patients should have complete blood counts drawn every 1 to 2 weeks to assess for myelosuppression while receiving imatinib. Appropriate initial management of myelosuppression is to interrupt imatinib treatment, not dose reduce, as dose reductions below 300 mg daily do not fully inhibit *BCR-ABL* and may lead to the emergence of imatinib resistance.[16]

Nonhematologic toxicities associated with imatinib include gastrointestinal complications, fluid retention, mylagias/arthralgias, rash, and hepatotoxicity. Nausea and vomiting is the event most commonly reported and can be managed by administering the drug with food. Higher doses of imatinib may be split in half and taken twice daily to reduce gastrointestinal side effects. Diarrhea may be dose related and can be controlled with antidiarrheal medications such as loperamide or diphenoxylate/atropine. Fluid retention most often manifests as periorbital swelling or peripheral edema. Rarely, fluid retention can be severe, leading to pulmonary and cerebral edema. Risk factors for edema include female gender, age older than 65 years, and a history of heart or kidney disease. Approximately 20% to 40% of patients complain of musculoskeletal symptoms, which tend to occur during the first month of therapy and decline in severity over time. Calcium and magnesium supplementation may provide symptomatic relief. Drug rash frequently occurs but is usually mild and can be managed with antihistamines or topical steroids. Severe rash, while uncommon, has been reported as an important cause for discontinuation of therapy. Algorithms for desensitization for patients that have experienced serious imatinib-associated rash have been published.[37] Hepatotoxicity can occur with imatinib, and the drug should be withheld if liver function tests exceed 5 times the upper limits of normal. After the liver function tests normalize, imatinib can be restarted at a reduced dose of not less than 300 mg per day. Imatinib is then dose escalated to the initial dose if liver function tests do not rise during 6 to 12 weeks of treatment. Death as a consequence of liver failure has been reported in a patient receiving large doses of acetaminophen concomitantly with imatinib. It is recommended that patients on imatinib limit their use of acetaminophen to 1,300 mg daily.[16] Use of other medications that are known to be hepatotoxic should be used with caution while patients are treated with imatinib.

Imatinib is metabolized primarily via CYP3A4 and inducers of this enzyme may decrease imatinib concentrations. Other isoenzymes CYP1A2, CYP2D6, CYP2C9, CYP2C19 play a minor role in metabolism. During the phase I trial of imatinib, a patient who received concurrent phenytoin therapy developed a suboptimal response and was found to have a 75% reduction in plasma imatinib concentrations as compared to patients not receiving phenytoin. The clinical significance of this interaction was confirmed when disease control was acquired with the discontinuation of phenytoin.[24] Imatinib may increase the concentrations of other drugs that are substrates or inhibitors of CYP3A4, 3A5, 2D6, and 2C9. Imatinib has been reported to increase blood levels of cyclosporine and simvastatin. Other agents that should be closely monitored include aprepitant, dexamethasone, St. John's wort, voriconazole, and warfarin.

SECOND-GENERATION TYROSINE KINASE INHIBITORS

Dasatinib (Sprycel®) and nilotinib (Tasigna®) are approved second-generation tyrosine kinase inhibitors used for the treatment of CML in patients who are resistant or intolerant to imatinib therapy; both drugs are also approved for first-line treatment of CP CML. Dasatinib is an oral *BCR-ABL* tyrosine kinase inhibitor that was FDA approved in 2006 for the treatment of imatinib-resistant CML. Dasatinib is an oral tyrosine kinase inhibitor of *BCR-ABL,* the SRC family (SRC, LKC, YES, FYN), c-KIT, EPHA2, and platelet-derived growth factor receptor. Preclinical data show that dasatinib is 300 times more potent than imatinib and has inhibitory activity in imatinib-resistant clones, with the exception of the T315I.[38] Dasatinib received accelerated approval based on hematologic and cytogenetic responses seen in imatinib-resistant or imatinib-intolerant patients.

Dasatinib has been evaluated in patients with imatinib-resistant or -intolerant CP, AP, and BC CML. In a phase II trial of 186 patients in CP CML receiving dasatinib 70 mg orally twice daily a hematologic response and major cytogenetic response were noted in 90% and 52% of patients, respectively.[39] Kantarjian et al. evaluated imatinib 400 mg twice daily compared to dasatinib 70 mg twice daily in patients who developed resistance or were intolerant to imatinib 400 mg daily dosing. At 2 years' follow-up, patients receiving dasatinib were more likely to achieve a complete hematologic response (93% vs 82%; $P = 0.034$), major cytogenetic response (53% vs 33%; $P = 0.023$), and an increased estimated progression-free survival at 2 years, suggesting that dasatinib is superior to imatinib dose escalation in disease progression.[40] A trial evaluating different dosing strategies of dasatinib showed that 100 mg given once daily was as efficacious as dasatinib 70 mg twice daily, 50 mg twice daily or 140 mg once daily but with decreased adverse events such as pleural effusions.[41] Standard dose dasatinib for patients with CP CML is now accepted to be 100 mg daily.

Dasatinib is able to induce responses in patients who are resistant or intolerant to imatinib with advanced disease CML. Patients with AP CML were administered dasatinib 70 mg twice daily with 45% achieving a complete hematologic response, 39% achieved a complete cytogenetic response, 66% had progression-free survival, and 82% were alive 2 years.[42] A phase III trial comparing dasatinib 70 mg twice daily to 140 mg once daily resulted in similar efficacy at 15 months follow-up, but an improved safety profile that established dasatinib 140 mg once daily is the preferred dosing in AP CML.[43] Dasatinib induced a hematologic response in 35% and a major cytogenetic response in 33% of patients with BC CML. Median overall survival for patients receiving dasatinib in BC CML is 11.8 months.[44]

Dasatinib has been evaluated as first-line therapy in a phase III trial of 519 patients with CP CML.[45] Patients were randomized to dasatinib 100 mg once daily or imatinib 400 mg once daily. The rate of complete cytogenetic response at 12 months was significantly higher with dasatinib as compared with imatinib (77% vs. 66%, $P = 0.007$). The rate of major molecular response was also significantly higher in the dasatinib group (46% vs. 28%, $P < 0.0001$). Toxicities were similar between the two treatment groups, with the exception that 10% of dasatinib-treated patients developed grade 1 or 2 pleural effusions.

Nilotinib has 20 to 30 times the inhibitory activity of the *BCR-ABL* tyrosine kinase with activity against c-KIT and platelet-derived growth factor receptor (but not SRC kinases) due to a modification of the methylpiperazinyl structure of imatinib. Nilotinib has inhibitory activity against imatinib-resistant mutants with the exception of T315I. In a phase II trial of 280 patients with imatinib-resistant or -intolerant CP CML, nilotinib 400 mg twice daily resulted in 48% of patients achieving a major cytogenetic response.[46] In AP CML, nilotinib achieved a complete hematologic response of 26% and major cytogenetic responses of 29% were achieved with nilotinib 400 mg or 600 mg twice daily.[47] For front-line treatment of CML, results of a randomized trial in 846 patients comparing nilotinib at two doses (300 or 400 mg twice daily) to imatinib 400 mg once daily have been published.[48] The primary endpoint of the trial was major molecular response at 12 months. Both nilotinib arms had a significantly higher major molecular response rate at 12 months (43% and 44% for nilotinib 300 and 400 mg twice daily, respectively) as compared to imatinib (22%, $P < 0.001$ for both comparisons). The nilotinib arms also had a significant improvement in the time-to-progression to the AP or BC, as compared to the imatinib arm. The number of patients discontinued from treatment was similar in all three treatment arms. Nilotinib provides an alternative to dasatinib in patients with imatinib-resistant or -intolerant CP or AP CML and is one of several options in front-line treatment of CP CML.[16]

The side-effect profile of the second tyrosine kinase inhibitors is similar to imatinib. Reversible myelosuppression is the most common side effect seen with dasatinib and nilotinib, and may require interruption of therapy. Side effects unique to dasatinib include fluid retention and pleural effusions, which appear to be related to peak drug concentrations.[39–44] Edema and plural effusions can be managed by dasatinib drug holiday, diuretics, or short courses of steroids. Nilotinib can be associated with indirect bilirubin elevations in 10% to 15% of patients.[46,47] Nilotinib may prolong the QTc interval (block box warning) and patients should have an electrocardiogram at baseline, at 7 days following initiation of therapy, and periodically thereafter.

Like imatinib, dasatinib and nilotinib are metabolized by CYP3A4. Clinicians need to be aware of possible drug interactions with inducers and inhibitors of the CYP3A4 pathway such as phenytoin, azole antifungals, or macrolide antibiotics. Dasatinib and nilotinib may prolong the QTc interval and patients should avoid concomitant therapy with other drugs that are known to prolong the QTc interval, such as antiarrhythmics, macrolide antibiotics, azole antifungals, and fluoroquinolones. In vitro data also suggest that long-term suppression of gastric acid decreases dasatinib absorption; therefore, patients should refrain from taking concomitant H_2-blockers or proton pump inhibitors, if clinically feasible. The bioavailability of nilotinib is increased when given with a meal and should be taken on an empty stomach, whereas dasatinib should be taken with food.

Dasatinib and nilotinib have an established role in patients who have failed imatinib either because of disease resistance or drug intolerance. The 2011 NCCN guidelines recommend dasatinib or nilotinib as viable treatment options for patients who do not achieve a complete hematologic response in 3 months or cytogenetic response in 6 months. If patients continue to have a partial response or have disease progression while on imatinib, then a change in therapy to dasatinib or nilotinib is warranted in the absence of an immediate allogeneic HSCT option.[16] Limited treatment data are available with the use of a third tyrosine kinase inhibitor due to disease progression and patients should be considered for a HSCT.[49]

INTERFERON ALFA

Prior to the introduction of imatinib, IFN-α was the preferred agent in the treatment of CML. The role of IFN-α has since been relegated to patients who fail tyrosine kinase inhibitor therapies and are not candidates for HSCT.

The interferons are a family of glycoproteins involved in many of the functional aspects of the hematopoietic system. Two recombinant forms of IFN-α are currently marketed: IFN-α_{2a} (Roferon® A) and IFN-α_{2b} (Intron® A). Two polyethylene glycol conjugated products of IFN-α (PEG-IFN-α_{2b} and PEG-IFN-α_{2a}) can be administered weekly as compared with daily administration for the non-pegylated formulation.[50,51] The pegylated dosage forms of IFN have similar efficacy and toxicity profiles relative to the conventional formulation.

4 Use of IFN-α in the treatment of CP CML was based on reports that 20% to 50% of patients achieve a major cytogenetic response, which led to prolonged survival.[7] In the 10% to 15% of patients achieving a complete cytogenetic response, the median survival was more than 10 years.[16] Patients enrolled on the IFN-α arm in the IRIS trial had a complete cytogenetic response of 14%, as compared with 76% of patients treated with imatinib.[15] Historically, those who achieved a cytogenetic response with IFN-α typically continue to receive the drug as maintenance therapy. The 2011 NCCN guidelines recommend IFN-α only for post-transplant relapse.

IFN-α use is also limited by its toxicity profile because it is associated with both short-term constitutional toxicities and potentially dose-limiting long-term toxicities.[52] In the IRIS trial, 26% of patients discontinued IFN-α as a result of intolerable side effects.[15] The most predictable early toxicity is a flu-like syndrome characterized by fever, chills, myalgia, headache, and anorexia. These dose-dependent effects may be a result of IFN-α–induced leukocytosis and release of inflammatory cytokines. This acute flu-like syndrome can be ameliorated by starting IFN-α dosing at 50% of the final dose during the first week, giving the drug at bedtime, and co-administering acetaminophen or indomethacin with each IFN-α dose.[52] Reduction of initial WBC counts to below 10,000 cells/mm^3 (10×10^9/L) with hydroxyurea may also reduce these symptoms. Despite supportive care approaches to ameliorate the flu-like syndrome, it remains a formidable morbidity occasionally requiring termination of the drug. Cardiovascular toxicities (tachycardia, hypotension) are seen in approximately 15% of patients in the first few weeks. Long-term adverse effects include weight loss, alopecia,

neurologic effects (paresthesia, cognitive impairment, depression), and immune-mediated complications (hemolysis, thrombocytopenia, nephrotic syndrome, systemic lupus erythematosus, hypothyroidism) are documented in approximately 5% to 20% of patients.

Despite falling out of clinical favor, IFN-α still remains a disease-modifying agent and ongoing clinical trials are investigating the use of imatinib and IFN-α in combination for the treatment of CML.[53]

HEMATOPOIETIC STEM CELL TRANSPLANTATION

5 Allogeneic HSCT remains the only therapy proven to cure patients with CML, with many patients alive and disease-free decades after transplant. Patients undergoing allogeneic HSCT from a human leukocyte antigen (HLA)-matched sibling donor have 5-year survival rates ranging from 60% to 80% and long-term survival of approximately 50%.[54,55] In most long-term survivors, the *BCR-ABL* translocation is absent in all diagnostic tests including RT-PCR. Prognostic risk factors associated with survival outcomes include age, phase of disease and disease duration. Increasing age is associated with poorer prognosis, with higher transplant-related mortality in patients older than age 50 years. Patients with early disease who receive transplantations have better outcomes than those in accelerated phase or blast crisis. The time from diagnosis to transplantation also affects outcomes. Patients who undergo matched-sibling allogeneic HSCT within the first year of diagnosis have a better 5-year survival rate than those who undergo transplantation more than 1 year after their diagnosis (70%–80% vs 50%–60%).[54,55] This data was reported prior to the use of imatinib as first-line therapy for CML.

The major impediment for broad application of HSCT is that fewer than 30% of patients who are transplant-eligible will have an HLA-matched sibling donor. The most practical approach is to utilize an HLA-matched unrelated donor, if available. Matched unrelated donor HSCT has an overall 5-year survival reported to be 40% to 70%, which approaches overall survival data results reported for matched-sibling donor transplantations.[9,54,55]

The advent of imatinib as first-line therapy has resulted in fewer transplants for CML and has stimulated debate as to which, if any, subgroup should be treated with allogeneic HSCT as primary therapy. The difficulty lies in identifying those patients who will have suboptimal responses and might benefit from early transplantation. A recent study by the German CML Study Group reported that survival with drug therapy (IFN-α or imatinib) is superior to early allogeneic HSCT for low-risk patients, but no difference in survival was observed in high-risk patients.[56] Recent studies show that imatinib use prior to transplantation does not negatively affect transplant-related mortality.[57,58]

Patients who should be considered candidates for allogeneic HSCT are those who are healthy enough to tolerate the procedure and who have an HLA-matched related or unrelated donor; patients who have not achieved a hematologic remission within 3 months of therapy; patients who do not achieve a cytogenetic response after 6 to 12 months; and patients who are in AP or BC CML. With the median age of onset for CML being in the seventh decade of life and the high risk of mortality in patients older than 50 years of age, more than half of CML patients will be excluded from allogeneic HSCT based on age alone. Even when all the criteria are met (matched donor and younger age), 100-day mortality from allogeneic HSCT is between 10% and 20% in established transplant centers. Historically, improved outcomes have been observed when a patient undergoes transplantation within the first 2 years of diagnosis. Consequently, with HSCT being relegated to salvage therapy after primary treatment with tyrosine kinase inhibitors, long-term follow-up is needed to ascertain if delayed HSCT adversely affects outcomes.

Treatment options in patients who relapse after transplantation are limited. Graft-versus-leukemia (GVL) effect, tyrosine kinase inhibitors, IFN-α, or a clinical trial are reasonable options. The infusion of donor lymphocytes function as a form of adoptive immunotherapy can induce a GVL effect. In relapsed CML, donor lymphocytes induce durable responses and these responses strongly correlate with the development of graft-versus-host disease (GVHD).[59] Tumor burden also predicts the likelihood of response to donor lymphocyte infusion in relapsed CML. A study by Raiola et al. stratified the response rate of donor lymphocyte infusion according to relapse type. The response rate to donor lymphocytes was 100% in patients with molecular relapse, 90% in patients with cytogenetic relapse, 75% with relapsed CP CML, and 35% in patients with relapsed AP or BC CML.[60] The dose, timing, and method of administration of donor lymphocytes may also impact effectiveness. In one study, a significantly lower incidence of GVHD was observed with escalating doses of donor lymphocyte infusion (fractionated dosing) rather than single-dose donor lymphocytes while maintaining a similar 70% to 90% complete cytogenetic remission rate.[61] The optimal method of administering donor lymphocytes remains unclear, but these data suggest it may be possible to partially separate the GVL effect from GVHD.

Imatinib has been used in patients who have residual disease after allogeneic HSCT. Most patients respond to imatinib with complete molecular response of 70% without development of acute GVHD, which is often associated with donor lymphocyte infusions.[62] Use of imatinib or other tyrosine kinase inhibitor therapies require further study to determine the magnitude of benefit when applied in the post-HSCT setting.

The role of nonmyeloablative transplants in CML is evolving, but preliminary results suggest comparable outcomes to myeloablative transplants. The experience of German registry data suggests that 17% of all transplants for CML are using a reduced intensity conditioning regimen.[63]

CLINICAL CONTROVERSY

The controversy of whether to use allogeneic HSCT or second-generation tyrosine kinase inhibitor therapy as second-line treatment for patients that have progression or are intolerant to imatinib is ongoing. Dasatinib keeps 90% of CP patients treated first-line with imatinib free from disease progression with a median follow-up of 15 months. For patients that have progressed to AP, dasatinib and nilotinib can produce hematologic response in approximately half of patients and major cytogenetic responses in close to one-third of patients. At one year, three out of four patients will still be alive. It is unknown what efficacy of second-generation tyrosine kinase inhibitors will confer as a long-term treatment option. Allogeneic HSCT remains an option for patients with a suitable donor, younger age, and good performance status.

EVALUATION OF THERAPEUTIC OUTCOMES

Current standard of care is for patients with newly diagnosed CP CML to receive imatinib or one of the second-generation tyrosine kinase inhibitors. The goal of disease monitoring in CML is to differentiate patients who have optimally responded to an initial course of imatinib or one of the second-generation tyrosine kinase inhibitors from those at high risk for treatment failure. A suboptimal response is defined as no complete hematologic response at 3 months or lack of a complete cytogenetic response at 9 to 12 months. Recently published guidelines suggest that monitoring

of *BCR-ABL* transcripts at 3-month intervals is currently the best available test to monitor disease response.[17,18] An escalation in *BCR-ABL* transcripts allows practitioners to identify patients who have progressive disease and may need a therapy adjustment. Imatinib dose escalation, dasatinib, nilotinib, or allogeneic HSCT are therapy options in patients who do not respond or fail to maintain a molecular response.[16]

CHRONIC LYMPHOCYTIC LEUKEMIA

EPIDEMIOLOGY AND ETIOLOGY

CLL is a lymphoproliferative disorder characterized by accumulation of functionally incompetent clonal B lymphocytes.[64] CLL is the most common form of leukemia in the United States, but is rare in other countries, such as Japan and China. It is estimated that 14,990 new cases of CLL will be diagnosed in the United States in 2010 with 4,390 deaths.[1] Occasional family clusters have been recognized, and first-degree relatives of patients with CLL are at 3 times the risk of developing a lymphoid malignancy as compared with the general population. CLL is a disease of the elderly, with a median age of 72 years, although 20% to 30% of CLL occurs in patients who are younger than 55 years of age.[2] Male sex, Caucasian race, family history, and advanced age are known risk factors for the disease.

CLINICAL PRESENTATION OF CLL

Constitutional Symptoms

- Fever, fatigue, weight loss

Physical Examination

- Lymphadenopathy (87%)
- Splenomegaly (54%)
- Hepatomegaly (14%)

Laboratory Tests

- Peripheral blood
  - Lymphocytosis
  - Coombs-positive autoimmune hemolytic anemia
  - Hyper- or hypogammaglobulinemia
  - Monoclonal gammopathy
  - Anemia
  - Thrombocytopenia
- Bone marrow
  - Hypercellular
  - Increased mature lymphocytes
  - Increased megakaryocytes
- Molecular markers
  - Cytogenetics (17p-)
  - ZAP-70 mutations

PATHOPHYSIOLOGY

CLL cells are believed to be a neoplastic clone of $CD5^+$ cells, which express low levels of surface-membrane IgM and IgD compared to normal peripheral blood B cells. Normal $CD5^+$ B lymphocytes are present in the lymph nodes and in the blood. Neoplastic $CD5^+$ cells accumulate in the lymph nodes and spleen because of the loss of apoptosis by either the overexpression of an oncogene, such as *bcl-1* or *-2*, or loss of a tumor suppressor gene, such as *RB1*.[64] The bcl-2 protein is a major regulator of apoptosis or programmed cell death. Evidence is emerging that antigenic stimulation and cytokines drive the proliferation of the CLL cells.

A monoclonal population of B cells with a similar surface antigen phenotype as CLL cells has been recently identified in patients up to several years prior to diagnosis of the disease.[65] This phenomena, termed monoclonal B-cell lymphocytosis (MBL) appears to be predictive as to whether a patient is at risk for developing CLL over time. In a population of 77,000 patients enrolled in a cancer screening trial, 45 patients were diagnosed with CLL throughout the duration of the study. Baseline blood samples collected upon enrollment of the screening trial were analyzed for the patients that developed CLL. MBL was present in 44 of 45 of the patients by either flow cytometric or molecular analysis (i.e., RT-PCR assay) and confirmed in 41 of 45 of these patients by both methods. Samples predated the diagnosis of CLL in a time period ranging from 6 months to 6.4 years. This finding opens the door for potentially earlier diagnosis and intervention for CLL.

Cytogenetic abnormalities correlate with disease progression in CLL. Approximately 80% of patients with CLL have a karyotypic abnormality. The chromosomes that are most frequently involved include chromosomes 13, 12, 11, and 17.[66] Additional cytogenetic abnormalities may be acquired during therapy, particularly with deletions of chromosome 17, which have an adverse effect on survival.[67]

Four percent of patients with CLL have a risk of developing an aggressive histology non-Hodgkin lymphoma (diffuse large B cell), which is termed Richter syndrome. Richter syndrome may be triggered by accumulation of additional cytogenetic abnormalities in the malignant clone of lymphocytes or by viral infections, such as Epstein-Barr virus.[68]

STAGING AND PROGNOSIS

Survival times for patients with CLL are widely variable, with some patients dying within 3 years and others living into a second decade from the time of diagnosis. The Rai and the Binet staging systems are commonly used in CLL with the Rai being favored in the United States and the Binet in Europe. The Rai staging system has been combined into a risk classification scheme: low risk (stage 0), intermediate risk (stages I and II), and high risk (stages III and IV) with median survivals of greater than 10 years, 7 years, and 2 to 4 years, respectively.[69]

The disease course for CLL varies within each stage such that one patient may have an indolent course with long survival time, while another patient may have more aggressive disease and a relatively short survival time. The Rai and Binet staging systems incompletely predict for individual patients who may experience more rapid disease progression. Patients with Richter syndrome will have a rapidly advancing disease course that mimics diffuse large B-cell non-Hodgkin lymphoma. However, successful treatment of the diffuse large B-cell non-Hodgkin lymphoma with combination chemotherapy will not eradicate the underlying clone of CLL cells and patients will ultimately relapse.[68]

Biomarkers such as CD38 expression and ZAP-70 expression have been explored as prognostic factors for CLL. CD38 is a cell-surface antigen that is associated with early progression, significantly shorter overall survival and a poor response to fludarabine.[70–72] ZAP-70 is an intracellular protein with tyrosine kinase activity. Once considered as simply a surrogate marker for the unmutated variable region of the immunoglobulin heavy chain gene (IgVH), elevated ZAP-70 expression appears to predict for rapid CLL disease progression and independently correlates with prognosis.[70,73,74]

Cytogenetic changes such as deletion of the short arm of chromosome 17 (17p-), which corresponds to p53 silencing, are a robust

determinant of patients with disease that is poorly responsive to therapy. A prospective study showed that newly diagnosed patients with 17p- had a median time to progression following first-line therapy with either fludarabine or fludarabine/cyclophosphamide of 10 to 12 months.[67] Patients with chromosomal abnormalities of 13, 12, 11, and 17 have reported median survivals of 133 months, 114 months, 79 months, and 32 months, respectively.[66]

CLINICAL CONTROVERSY

Certain molecular and cellular markers have been identified that may predict CLL disease progression. ZAP-70 expression, CD38 expression, IgVH mutations, and 17p- are associated with a more aggressive clinical course of CLL. Controversy surrounds whether or not treatment should be based on these biologic markers alone. 17p- is the most consistent poor prognostic marker and results in a loss of the tumor suppressor gene, *p53*. Consensus guidelines now delineate treatment options for patients based on the presence of 17p-. If a patient has 17p- more aggressive regimens that contain immunotherapy and purine analogues (e.g., fludarabine, cyclophosphamide, and rituximab) are recommended as first-line treatments. For second-line therapy, regimens with multiagent chemotherapy combined with immunotherapy (e.g., oxaliplatin, fludarabine, cytarabine, and rituximab) are considered standard therapy.

TREATMENT

GOALS OF TREATMENT

6 The primary goals of treatment for CLL are to improve survival duration and minimize treatment-related toxicity. The management of patients with CLL is highly individualized with some patients receiving therapy upon diagnosis, while other patients with early-stage disease are managed expectantly. Indications for starting treatment include disease-related symptoms (fatigue, night sweats, weight loss, fever), threatened end-organ function, bulky disease, doubling of lymphocyte doubling time in less than 6 months, progressive anemia and platelet count less than 100,000 /mm^3 (100 × 10^9/L).[75,76,77] Consideration of initial treatment options is based on several factors including age of the patient, disease stage, and high-risk prognostic factors, such as 17p-.

Most stage 0 patients do not require treatment and can be managed with observation. In patients with stage I disease, treatment is controversial. A consistent survival benefit from early therapy has not been reported in asymptomatic patients.[76,78] Cytotoxic chemotherapy in early stage CLL is usually reserved for patients who have disease characteristics consistent with a more aggressive course, such as short lymphocyte doubling times and presence of biologic markers such as ZAP-70 or high-risk cytogenetics. In stages II through IV disease, treatment is required, with the goal of achieving a partial or complete remission. Overall survival is improved in patients that achieve a complete response with initial treatment. Table 143–4 reviews the regimens used to treat newly diagnosed and previously treated CLL.[69,70,72,73]

CYTOTOXIC CHEMOTHERAPY

Orally administered alkylating agents such as chlorambucil and cyclophosphamide either given alone or with corticosteroids historically have been used as primary treatment for CLL. Results from a meta-analysis involving 2,048 patients from six randomized controlled studies evaluated low-dose alkylating agents in CLL.[78]

TABLE 143-4 Treatment for Newly Diagnosed and Previously Treated Chronic Lymphocytic Leukemia

Treatment	Overall Response	Complete Response
Chlorambucil		
Untreated	37%	4%
Fludarabine alone		
Untreated	60%–80%	20%–30%
Previously treated	13%–59%	3%–37%
Fludarabine + cyclophosphamide		
Untreated	80%–90%	25%–40%
Previously treated	60%–70%	10%–15%
Rituximab alone		
Untreated	50%–60%	10%–20%
Previously treated	80%–90%	20%–40%
Fludarabine + rituximab		
Untreated	80%–100%	30%–50%
Previously treated	80%–90%	20%–40%
Fludarabine + cyclophosphamide + rituximab		
Untreated	95%	70%
Previously treated	73%	25%
Alemtuzumab alone		
Untreated	80%–90%	20–30%
Previously treated	30%–50%	0–20%
Alemtuzumab + fludarabine		
Previously treated	83%	17%–30%
Oxaliplatin + fludarabine + cytarabine + rituximab		
Previously treated	33%	6%

Adapted from Abbott,[69] Zenz et al.,[75] Robak et al.,[81] and Tsimberidou.[99]

That analysis showed that delayed treatment with alkylating agents in asymptomatic patients did not adversely affect 10-year survival. More importantly, if only deaths caused by CLL were considered, significantly longer survival was observed when treatment was deferred. Chlorambucil continues to be widely used in elderly, symptomatic patients as initial treatment for CLL, but its use is based on a small number of studies with no demonstrable survival advantage.[69] Commonly used dosing schedules for chlorambucil are intermittent pulse dosing of 15 to 40 mg/m^2 orally every 28 days or daily doses of 4 to 8 mg/m^2/day.[79] The dose of chlorambucil is often titrated to circumvent myelosuppression.

Cyclophosphamide produces a similar response rate as chlorambucil (overall response rate: 40%–60%; complete response: 4%) and can be used in patients who cannot tolerate chlorambucil or in whom response is not optimal. Some patients who do not respond to chlorambucil will respond to single-agent cyclophosphamide. Cyclophosphamide is typically given orally at a daily dose of 1 to 3 mg/kg. Oral cyclophosphamide is less commonly used compared to chlorambucil because of the risk of hemorrhagic cystitis and bladder cancer with prolonged treatment.

Fludarabine-based therapy is a common initial treatment in CLL. It is particularly useful in younger patients and in those patients who can tolerate immunosuppressive chemotherapy. Fludarabine, along with the other purine analogs, 2-chlorodeoxyadenosine (cladribine) and 2-deoxycoformycin (pentostatin), are highly active in CLL, with fludarabine being the most widely studied agent in the class in the treatment of CLL.[79,80] Most patients receive fludarabine 20 mg/m^2 intravenously daily for 5 days when used as a single agent. Cladribine and pentostatin have similar activity, although head-to-head trials comparing these three nucleosides have not been conducted.[79,81,82]

Fludarabine was initially studied in CLL patients who were refractory to chlorambucil. Several trials reported overall response rates to fludarabine in previously treated patients ranging from 13% to 59% and complete response rates of 3% to 37%.[83] Based on these

encouraging results in patients with refractory disease, fludarabine was studied in chemotherapy-naïve patients. Three large phase II trials conducted in symptomatic, untreated CLL patients confirmed the efficacy of fludarabine. In these trials, fludarabine produced higher overall response rates and complete remissions than did alkylating-based therapies. In one of the randomized studies that compared fludarabine to chlorambucil in chemotherapy-naïve patients, fludarabine-treated patients had a higher complete remission rate as compared with chlorambucil (20% vs 5%).[84] However, the higher complete remission rate did not translate into a significant difference in overall survival and patients treated with fludarabine had a higher rate of severe neutropenia and infection. The study allowed chlorambucil failures to cross over to fludarabine, which may have hampered the ability to show a survival advantage in the fludarabine arm. A recent review of younger patients enrolled in a large phase III trial showed that 33% of patients receiving fludarabine or fludarabine-based therapy had infectious complications.[85] An increase in *Pneumocystis* infections was not observed, but a 6% increase in herpes and varicella zoster infection was documented. Dose reductions occurred frequently as a result of the infectious episodes. Based on the increased risk of infectious complications, some practitioners recommend antiviral and antibacterial prophylaxis be given with treatment.[77,85]

Bendamustine is an alkylating agent that contains a purine-derivative benzimidazole ring in its chemical structure that yields a compound that is non–cross-resistant with other alkylating agents. Bendamustine induces cell death via single and double-stranded cross-links.[86] It was approved for treatment of CLL and relapsed indolent non-Hodgkin lymphoma in 2008. Efficacy for bendamustine was established as first-line agent in Binet stage B or C CLL in a phase III trial that randomized 319 patients to bendamustine or chlorambucil.[87] Complete response rates of 31% vs 2% and an overall response rate for 68% vs 31% were observed for bendamustine and chlorambucil respectively. The median progression-free survival was 21.6 vs 8.3 months favoring bendamustine. Adverse events reported for bendamustine includes hematologic toxicity in approximately 25% of patients, gastrointestinal and cutaneous toxicity.

BIOLOGIC THERAPY

Monoclonal antibodies, such as rituximab and alemtuzumab, are increasingly being used in the treatment of CLL. Rituximab is a chimeric monoclonal antibody that targets the CD20 antigen expressed on B lymphocytes. Rituximab was initially approved for patients with indolent non-Hodgkin lymphoma and later for aggressive non-Hodgkin lymphoma. Rituximab received FDA approval for the treatment of CD20-positive CLL in 2010. The results from early trials of rituximab in CLL showed limited efficacy, with a 10% to 15% partial response rate.[88] This finding was attributed to the lower CD20 expression on the surface of the CLL cells as compared to non-Hodgkin lymphoma and a more rapid clearance of rituximab in CLL, possibly through shedding of CD20.[89] When rituximab was used as the sole therapy in CLL, higher doses than those used in indolent non-Hodgkin lymphoma had to be given to overcome these biologic features. Subsequent studies with higher rituximab doses (up to 2,250 mg/m^2) have reported increased overall response rates to 40% to 75% in previously treated patients.[75,88,89]

7 Alemtuzumab is a monoclonal antibody that targets the CD52 antigen found on both B and T lymphocytes. It was FDA approved in 2001 for the treatment of patients with CLL who had been treated with alkylating agents and had failed fludarabine therapy. Alemtuzumab has generally been reserved for CLL patients who are refractory to other available therapies, although data as first-line therapy are accumulating.[90] Alemtuzumab is titrated to a maintenance dose of 30 mg intravenously given 3 times a week for 12 weeks. As a single agent, alemtuzumab has produced response rates from 33% to 53% in patients with refractory disease, but complete response rates are infrequent.[90,91]

Results from a randomized phase III trial comparing alemtuzumab to chlorambucil in chemotherapy-naïve patients with symptomatic CLL showed higher complete response rates with alemtuzumab than with chlorambucil, 24% vs 2%, respectively.[91] These differences in response rate translated into a significant difference in progression-free survival (hazard ratio, 0.58; 95% confidence interval, 0.43-0.77, $P < 0.0001$). Based on these results, alemtuzumab received FDA approval in 2007 as first-line treatment for CLL.

Infusion-related reactions are one of the most frequently reported toxicities with alemtuzumab. The reactions experienced with intravenous administration include fever, rigors, and hypotension. Alemtuzumab is associated with serious, potentially life-threatening toxicities, including pancytopenia, infusion reactions, and opportunistic infections. Because of alemtuzumab's profound immunosuppression, the 2010 NCCN guidelines recommend antibacterial and antiviral prophylaxis to prevent *Cytomegalovirus* reactivation and *Pneumocystis* infections.[77] Prophylaxis with trimethoprim-sulfamethoxazole and famciclovir or valacyclovir is recommended with the use of alemtuzumab.[92] Alemtuzumab is FDA approved for intravenous administration, although the use of subcutaneous alemtuzumab has been explored to reduce the frequency of these reactions. In a study by Lundin et al., 41 patients received 30 mg of subcutaneous alemtuzumab 3 times a week for 12 weeks which yielded a response rate of 87%.[93] Major adverse event were grades 1 and 2 skin reactions in 90% of patients; fever, rigors, and hypotension were infrequent. Approximately 10% of patients had reactivation of *Cytomegalovirus* and required ganciclovir treatment. Similar to intravenous administration, antiviral and antibacterial prophylaxis is warranted when alemtuzumab is given via the subcutaneous route.[93]

Ofatumumab is a fully human monoclonal antibody to CD20 that was approved as single-agent therapy in 2009 for patients with CLL that is refractory to fludarabine and alemtuzumab. The drug was granted accelerated approved based on 54 patients who had either failed to response to or had progressed within 6 months of both fludarabine and alemtuzumab.[94] Ofatumumab is administered as an IV infusion with an initial dose of 300 mg then 4 weekly doses followed by 4 monthly doses of 2,000 mg. An overall response rate was reported of 42% (no complete responses) with patients achieving a median time-to-progression of 6.5 months. Adverse events reported in greater than 10% of patients included anemia, bronchitis, cough, diarrhea, dyspnea, fatigue, nausea, neutropenia, pneumonia, pyrexia, rash, and upper respiratory infections. Infusion-related events were reported in 44% of patients with the first infusion and 29% with the second infusion which is less than most literature reports of infusion-related hypersensitivity events with rituximab. Serious toxicities such as fatal infections, progressive multifocal leukoencephalopathy, and hepatitis B reactivation have been reported.

COMBINATION THERAPY

The single-agent activity of fludarabine has led to incorporation of fludarabine in combination regimens in patients with CLL. The most widely studied combination is fludarabine with cyclophosphamide, which produces complete response rates between 25% and 40% in treatment-naïve patients as compared with 20% to 30% for single-agent fludarabine.[75,81] Although improved response rates and progression-free survival have been reported with fludarabine and cyclophosphamide combinations compared with fludarabine alone, no benefit in overall survival has yet been observed.

8 The combination of fludarabine and rituximab has promising activity. In vitro studies suggest that rituximab is synergistic with fludarabine and cyclophosphamide and has led investigators to evaluate this combination in clinical trials. Results from an uncontrolled trial of fludarabine, cyclophosphamide, and rituximab (FCR) reported a complete remission rate of 70% in previously untreated CLL patients.[95] FCR has documented a complete remission rate of 25% in previous treated patients. Preliminary results of two phase III trials comparing FCR with fludarabine and cyclophosphamide documented a progression-free survival benefit (30 vs 20 months with 26 months' median follow-up) in patients treated with FCR in patients with refractory disease and an overall survival benefit (87.2% vs 82.5% with 38 months' median follow-up) in patients with newly diagnosed disease.[96,97] The results of these phase III trials led to FDA approval of rituximab with fludarabine and cyclophosphamide in CLL.

Combinations with alemtuzumab have also been studied. The combination of fludarabine and alemtuzumab achieved an overall response rate of 83% in heavily pretreated patients.[98] Patient selection is critical given the high risk of serious infection. Younger patients will be candidates for fludarabine-monoclonal antibody–based combination therapy. Symptomatic elderly patients with aggressive disease who can tolerate immunosuppressive therapy may also be candidates for this regimen.[76]

The novel combination of oxaliplatin, fludarabine, cytarabine, and rituximab was piloted in a phase I/II trial in 55 patients with either fludarabine-refractory CLL or Richter syndrome.[99] This regimen was developed on the basis of preclinical work that oxaliplatin produced synergistic cell kill when given with fludarabine plus cytarabine and that fludarabine administered prior to cytarabine increases the intracellular concentrations of the active metabolite of cytarabine, cytarabine triphosphate. The overall response rate and 6-month overall survival was 33% vs 50% and 59% vs 89% in fludarabine-refractory and Richter syndrome patients, respectively, with a median follow-up of 9 months. Virtually all patients developed neutropenia, anemia, thrombocytopenia, and fatigue with five treatment-related deaths reported.

HEMATOPOIETIC STEM CELL TRANSPLANTATION

9 There is limited experience with the use of HSCT in CLL. Patients treated with allogeneic HSCT achieve higher remission rates and appear to have a longer disease-free survival, but at the expense of high treatment-related mortality which approaches 40%. Contrary to the high mortality reported in most studies, a randomized phase II study of high-risk CLL patients comparing allogeneic and autologous HSCT reported 100-day mortality of 4% in both arms. After 6 years of follow-up, no difference in overall survival (58% autologous and 55% allogeneic) was observed.[100] This low early mortality must be interpreted carefully, given that only 25 carefully selected patients received allogeneic HSCT as compared with 137 who received autologous transplantation. T-cell depletion was performed on the allogeneic grafts, which may reduce 100-day mortality at the cost of increased relapse, infectious complications, or post-transplant lymphoproliferative disorders as a consequence of reduced GVL effect.[100]

Although allogeneic HSCT may offer the potential of cure in CLL, the advanced age of most patients, limited donor availability and the high treatment-related mortality precludes the routine application in the management of this disease. Allogeneic HSCT is a more viable option for younger patients with aggressive disease. Older patients who are not candidates for full-intensity allogeneic HSCT may be candidates for nonmyeloablative allogeneic HSCT.

EVALUATION OF THERAPEUTIC OUTCOMES

CLL is an incurable disease and the goal of therapy is to optimize remission duration while minimizing the burden of treatment-related adverse effects. The 2010 NCCN guidelines segregate treatment options based on the presence of 17p-, age older than 70 years, and first- and second-line regimens.[77] Preferred first-line therapy options for patients younger than 70 years without 17p- are aggressive chemoimmunotherapy regimens such as fludarabine, cyclophosphamide, rituximab; and pentostatin, cyclophosphamide, and rituximab. Patients who are older than 70 years without 17p- may be treated with chemotherapy (bendamustine, chlorambucil, and cyclophosphamide/vincristine/prednisone) or immunotherapy (rituximab) or milder chemoimmunotherapy (fludarabine/rituximab). Second-line therapeutic options for patients without 17p- are again divided by the age of 70 years. Regimens recommended for younger patients consist of chemoimmunotherapy (fludarabine/cyclophosphamide/rituximab, pentostatin/cyclophosphamide/rituximab, and oxaliplatin/fludarabine/cytarabine/rituximab) or traditional regimens used for aggressive non-Hodgkin lymphoma (cyclophosphamide/doxorubicin/vincristine/prednisone) with rituximab. For patients who have 17p-, first-line therapy options consist primarily of more aggressive chemoimmunotherapy (fludarabine/cyclophosphamide/rituximab) regimens. Second-line regimens are similar to those outlined above for patients younger than 70 years.

Supportive care for patients undergoing active treatment for CLL is crucial for ensuring a successful outcome. Patients may become hypogammaglobinemic as a consequence of disease progression or treatment will need routine monitoring of serum IgG. If the serum IgG falls below 500 mg/dL (5 g/L), then monthly replacement doses of 300 to 500 mg/kg of intravenous immune globulin is warranted. Antibiotic prophylaxis for patients receiving fludarabine-based regimens or chemoimmunotherapy should be considered for herpes virus and *Pneumocystis*. Patients that are treated with alemtuzumab will require monitoring for CMV antigen every 1 to 2 weeks while on therapy and for 2 months after or be given prophylaxis with valganciclovir.

TREATMENT SUMMARY OF CHRONIC LEUKEMIA

The treatments used for CML and CLL are strikingly different with tyrosine kinase inhibitors use expanding in CML and monoclonal antibodies, either with or without chemotherapy, playing an increasingly important role in CLL. Front-line treatment for CML is imatinib or one of the other second-generation tyrosine kinase inhibitors with second-line options including dasatinib, nilotinib, and allogeneic HSCT being selected on the basis of patient-specific factors. Allogeneic HSCT is distinguished among other therapies as the only known treatment intervention in CML that achieves long-term cure. IFN-α is now used sparingly for CML and can be considered a treatment option for patients who are intolerant of tyrosine kinase inhibitors without an HSCT option.

The goal in the treatment of CLL is to prospectively identify patients with poor prognostic features and individualize intensity of therapy based on the likelihood of rapid disease progression. Observation is appropriate in asymptomatic patients with early-stage disease. In patients with advanced disease, stratification by presence of 17p- and age will help to decide whether to initiate treatment with chemoimmunotherapy compared to chemotherapy or immunotherapy alone. Monitoring for hypogammaglobinemia and instituting appropriate infectious prophylaxis is critical to prevent the emergence of opportunistic infections during and for months following treatment.

ABBREVIATIONS

AP: accelerated phase

BC: blast crisis

CLL: chronic lymphocytic leukemia

CML: chronic myelogenous leukemia

CP: chronic phase

FCR: fludarabine, cyclophosphamide, rituximab

GVHD: graft-versus-host disease

GVL: graft-versus-leukemia (effect)

HLA: human leukocyte antigen

HSCT: hematopoietic stem cell transplantation

IgVH: immunoglobulin heavy chain gene

IFN-α: interferon alfa

IFN-α_{2a}: interferon alfa$_{2a}$

IFN-α_{2b}: interferon alfa$_{2b}$

IRIS: International Randomized study of Interferon vs STI571 trial

MBL: monoclonal B-cell lymphocytosis

NCCN: National Comprehensive Cancer Network

Ph: Philadelphia chromosome

RT-PCR: reverse transcriptase-polymerase chain reaction

WBC: white blood cell

ZAP-70: zeta-associated protein 70

CHAPTER 144

Multiple Myeloma

TIMOTHY R. MCGUIRE AND CASEY B. WILLIAMS

KEY CONCEPTS

1. Multiple myeloma (MM) is a cancer that develops in plasma cells leading to excessive production of a monoclonal immunoglobulin (M protein).
2. Most patients have skeletal involvement at the time of diagnosis with associated bone pain and fractures. Anemia, hypercalcemia, and renal failure may also be present. A bone marrow biopsy with 10% or more plasma cells and a M-protein spike on plasma or urine electrophoresis confirm the diagnosis.
3. Most patients will require treatment after diagnosis but treatment can be deferred in patients with smoldering (asymptomatic) MM. In patients with symptomatic disease, treatment produces benefits in various measures of survival and quality of life.
4. Thalidomide, lenalidomide, or bortezomib plus dexamethasone are commonly used induction regimens. They produce higher complete remission rates as compared with the classic regimen of melphalan plus prednisone and vincristine, doxorubicin, dexamethasone. The increased response is at the risk of significant grades III and IV toxicity which can include venous thromboembolism and neuropathy depending on the regimen used.
5. Bortezomib is commonly used to treat relapsed MM and increasingly as initial therapy combined with dexamethasone or chemotherapy. Bortezomib activity is maintained in patients with high-risk cytogenetics.
6. Lenalidomide is more potent and better tolerated than thalidomide and is becoming the most common drug used in induction regimens.
7. Melphalan plus prednisone is not used in transplant candidates as part of induction but commonly used in transplant ineligible patients combined with thalidomide, lenalidomide, or bortezomib.
8. Autologous hematopoietic stem cell transplantation (autoHSCT) is used after induction in patients with reasonably good performance status to maximize complete remissions and prolong survival.
9. The quality of induction responses may be important, including in those receiving autoHSCT to maximize clinical benefit.
10. The use of myeloablative allogeneic hematopoietic stem cell transplantation (alloHSCT) produces high early mortality, but the use of nonmyeloablative alloHSCT may offer a chance for long-term disease-free survival.
11. Bisphosphonates are used to treat bone disease associated with MM, which results in decreased pain and skeletal-related events and improvement in quality of life.
12. Salvage therapy for patients with relapsed or refractory MM can include any of the prior listed therapies, depending on performance status of the patient, risk category of the patient, and prior treatments used for induction.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Multiple myeloma (MM) is a relatively common hematologic malignancy that develops in plasma cells or immunoglobulin-producing B lymphocytes.[1,2] The plasma cells produce excessive monoclonal immunoglobulins that can be measured in the plasma or urine. Because of the various bone-mobilizing cytokines secreted from the MM clone and bone marrow stromal cells, patients often have skeletal involvement at diagnosis. MM is initially sensitive to chemotherapy but drug resistance develops relatively rapidly. Although therapy is not curative, several new agents have been developed that have improved the duration and quality of life of MM patients. Disease progression is influenced by cytokines and adhesion molecules which are part of an abnormal bone marrow microenvironment. Cytokines are able to stimulate plasma cell growth and angiogenesis. Several of these cytokines, including interleukin 6 (IL-6), basic fibroblast growth factor (bFGF), tumor necrosis factor alfa (TNF-α), and vascular endothelial growth factor (VEGF), have become targets for therapies such as thalidomide, its congener lenalidomide, and bortezomib.

EPIDEMIOLOGY AND ETIOLOGY

In the United States, it is estimated that 20,180 cases of MM will be diagnosed in 2010, with 10,650 deaths. It is a disease that affects older adults with a median age at diagnosis of 70 years. MM occurs more frequently in males and African Americans.[1–3]

No cause can be identified in most patients. Exposure to high doses of radiation increases the risk of developing MM.[1,2] Although not proven, there may be a hereditary component to MM, given the reports of familial associations. The relationship between viral infection and risk of MM is controversial. Human herpes virus 8 is often reported to be a likely candidate virus for development of MM.[1] However, investigators were unable to isolate human herpes virus 8 from patients with MM and it is unlikely that this virus is an etiologic agent in MM.[4] Patients with HIV-1 infections have 4.5 times the risk of developing MM, which suggests a role for HIV-1 as

a viral cofactor. HIV-1–positive patients develop MM at an earlier age and with disease that has aggressive characteristics leading to poorer outcomes.[5]

PATHOPHYSIOLOGY

MM presents a very complex picture of multistep malignant transformation. A precursor condition called monoclonal gammopathy of undetermined significance (MGUS) is associated with monoclonal immunoglobulin in the blood (≤3 g/dL [≤30 g/L]) without clinical manifestations of the complications of MM.[6,7] The conversion rate of MGUS to MM is approximately 1% per year. The molecular changes associated with the conversion of MGUS to MM are not clear, but genome-wide studies have identified several candidate genes associated with disease progression.[8] Distinct from MGUS, which is a pre-malignant syndrome, smoldering MM is asymptomatic disease with low tumor burden and an indolent course.[1,9] In patients with smoldering MM, the risk of progression is approximately 10% per year for the first 5 years after diagnosis, approximately 3% per year for the next 5 years, and approximately 1% per year for the next 10 years.[9]

In early MM, the balance between apoptotic and antiapoptotic genes is disrupted with overexpression of antiapoptotic genes.[10] As the disease progresses, a greater number of gene products that confer resistance, such as mutated *p53*, are over expressed.[11] Molecules such as IL-6 and the transcriptional regulator nuclear factor kappa B (NF-κB) also stimulate clonal growth and promote resistance to therapy. Given their imprecise but important role in initiation and progression of MM, IL-6 and NF-κB are targets for both old and new therapies.[12,13]

1 MM is characterized by the accumulation of malignant plasma cells in the bone marrow and the production of a monoclonal immunoglobulin (M protein). These proteins, secreted by the malignant clone, are frequently referred to as paraproteins.[1,2] Both MM and normal plasma cells are produced from differentiated B cells after antigen stimulation. Normal plasma cells will die within days to weeks after differentiation, whereas MM plasma cells are immortalized.[1,2] MM cells are seldom seen in large quantities in the peripheral blood because of their interaction with bone marrow stromal cells. This interaction between MM cells and bone marrow stroma is mediated by adhesion molecules within an abnormal bone marrow microenvironment and is required for growth and disease progression.[13] Figure 144–1 shows several of the factors involved in disease pathogenesis and progression and potential targets for the newer agents thalidomide, lenalidomide, and bortezomib.

One of the major targets for the newer therapies is NF-κB. The effects of NF-κB are pleiotropic and integral to MM progression. NF-κB is activated in MM and results in the production of MM growth factors such as IL-6 and adhesion molecules in the bone marrow. Thalidomide is a potent inhibitor of TNF-α, which is a cytokine with important NF-κB–inducing activity. Thalidomide also directly inhibits NF-κB by conserving the inhibitor of NF-κB (IκB) in the cytosol. Lenalidomide has similar mechanisms of action as thalidomide but is significantly more potent. Thalidomide and lenalidomide also activate important antimyeloma immune responses. Bortezomib is the most specific of the NF-κB inhibitors. Through its inhibition of the protease complex, the proteasome, bortezomib prevents IκB degradation and terminates the NF-κB signal. Understanding the targets of these newer agents has led to a better understanding of the pathophysiology of MM.[13]

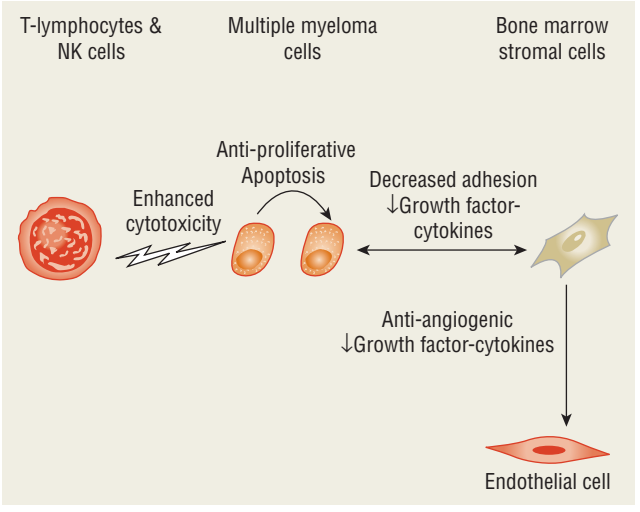

FIGURE 144-1. Sites of action for thalidomide, lenalidomide, and bortezomib.

CLINICAL PRESENTATION

2 Most patients with MM present with complaints of bone pain and fatigue at diagnosis. Approximately 10% to 20% of patients are asymptomatic at the time of diagnosis, and have what is called smoldering MM.[14,15] Most patients show evidence of end-organ damage at the time of diagnosis. Initial laboratory evaluation often reveals hypercalcemia, renal insufficiency, anemia, and abnormalities in various disease markers, such as albumin and β_2-microglobulin. Skeletal evaluation shows gross abnormalities in most patients. Bone scans show abnormalities that often include lytic lesions, osteoporosis, and fractures. This group of findings (hypercalcemia, renal insufficiency, anemia, and bone lesions) is often referred by the acronym CRAB.[6] A bone marrow biopsy with 10% or more plasma cells and an M-protein spike on plasma or urine electrophoresis confirms the diagnosis.[14] Immunofixation is more sensitive and identifies the M-protein isotype being secreted. In a minority of patients, no M protein can be detected in the plasma but is found in the urine, requiring that urine be examined as part of a complete diagnostic workup. Approximately 60% of patients will have intact monoclonal immunoglobulin G (IgG), 20% will have monoclonal IgA, and the remaining 20% will secrete only monoclonal light chains. Antibodies are composed of two light chains where antigen binds and two heavy chains. Light-chain immunoglobulin alone can be secreted by the MM clone. Free monoclonal light chains in the urine are called Bence Jones proteins because they were first described by Dr. Henry Bence Jones and are primarily responsible for MM-associated renal failure.[1,14] In addition, serum IgG light chain can be measured with an FLC assay (Freelite). This new assay may have certain advantages compared to serum protein and urine electrophoresis particularly increased sensitivity and light chain ratio which may add valuable information on likelihood of disease progression.[16]

As discussed above, the skeleton is involved at the time of diagnosis in most patients with MM.[17] The effects of MM on the skeleton result from abnormal production of cytokines including IL-1, IL-6, TNF-α, and the receptor for activation of NF-κB ligand (RANK-L). Bone disease is the net effect of the activation of osteoclasts and inhibition of osteoblastogenesis.[18] In addition, patients are frequently anemic from infiltration of the bone marrow with the MM clone and poor erythropoietin response. Patients can have clinically important hypercalcemia, which results from calcium mobilization from the bone. Renal failure can occur as a result of high protein load from the monoclonal protein secretion as well as dehydration.

CLINICAL PRESENTATION OF MULTIPLE MYELOMA

General Criteria

- 80% of patients present with symptomatic disease

Signs and Symptoms

- Bone pain (fractures, lytic lesions)
- Fatigue (anemia)
- Infection (reduced polyclonal response)
- Neurologic symptoms (nerve compression)
- Polyuria (hypercalcemia)
- Nausea and vomiting (hypercalcemia)

Laboratory Parameters

- Elevated paraproteins
  - Plasma electrophoresis
  - Urine electrophoresis
  - Immunofixation
- Elevated serum creatinine
- Hypercalcemia
- Low hemoglobin
- Low albumin
- Elevated β_2-microglobulin
- Elevated C-reactive protein

Bone Marrow

- ≥10% plasma cells

Cytogenetics

- Chromosome 13 deletion
- Translocation (4;14)
- Del (17p)

STAGING AND PROGNOSTIC FACTORS

Some patients with MM are asymptomatic and have no evidence of end-organ damage at the time of diagnosis. These patients are categorized as having smoldering (asymptomatic) MM.[1,9] Most patients will have evidence of end-organ damage (hypercalcemia [>10.5 g/dL (>2.63 mmol/L)], renal impairment [>2.0 mg/dL (>177 μmol/L)], anemia [<10 g/dL (<100 g/L; 6.21 mmol/L) or >2 g/dL (>20 g/L; 1.24 mmol/L) below normal], or bone disease) at the time of diagnosis and are categorized as having active (symptomatic) disease. Patients with asymptomatic disease have an indolent course, with a median survival of approximately 5 years.[9]

The International Staging System (ISS) uses serum β_2-microglobulin and albumin concentrations to stage patients.[19] These two routine laboratory tests are powerful prognostic discriminators. The ISS predicts survival in patients treated with either conventional treatment or autologous hematopoietic stem cell transplantation (autoHSCT). An older staging system, Durie-Salmon, uses hemoglobin, serum calcium, bone involvement, and M protein to categorize patients in one of three stages. Table 144–1 describes the ISS and median survival for each of the three ISS stages.

Several adverse prognostic factors have been proposed for MM, including chromosome 13 deletion and other cytogenetic abnormalities, elevated β_2-microglobulin, elevated C-reactive protein, high plasma cell labeling index, low albumin, and high bone marrow microvessel density.[1] These prognostic factors generally represent the underlying pathologic changes associated with MM including genetic damage (chromosome 13 deletion), proinflammatory changes (C-reactive protein), tumor load (β_2-microglobulin) and dysregulated cellular growth (labeling index and marrow microvessel density).

TABLE 144-1 The International Staging System (ISS) for Multiple Myeloma

Stage	Characteristics	Median Survival (Months)
I	Serum β_2-microglobulin <3.5 mcg/mL (<3.5 mg/L) Serum albumin ≥3.5 g/dL (≥35 g/L)	62
II	Not stage I or stage III	44
III	Serum β_2-microglobulin ≥5.5 mcg/mL (≥5.5 mg/L)	29

From Greipp PR, Miguel JS, Durie BG, et al. International staging system for multiple myeloma. J Clin Oncol 2005;23:3412–3420.

TREATMENT

OVERVIEW OF INITIAL THERAPY

3 MM is not currently a curable disease. The role of therapy is to prolong progression-free and overall survival and improve quality of life. Patients with more active (symptomatic) or advanced disease (stages II and III) require therapy.[1,14,20] In patients with smoldering MM, watchful waiting is the general practice despite a systematic review that suggests early treatment with chemotherapy slows disease progression and may decrease vertebral compression.[21] These benefits are offset by the absence of convincing evidence that early treatment improves overall survival and important toxicities associated with therapy. The National Comprehensive Cancer Network (NCCN) guidelines recommend watchful waiting for smoldering MM.[14]

Initial management of symptomatic MM depends on the presence or absence of high-risk features of the disease (cytogenetics), patient age, renal function, performance status, and whether autoHSCT is planned. Although current treatments are not curative, median survival has increased significantly from about 7 months to 24 to 36 months, primarily as a result of improved treatment of symptomatic MM and supportive care.[1] There is no standard initial or induction therapy for the treatment of symptomatic MM. Table 144–2 lists commonly used regimens, which are categorized based on whether or not the patient is an autoHSCT candidate. The age restriction for autoHSCT has changed because of low transplant-related mortality, but autoHSCT is generally reserved for patients ≤65 years of age.

The choice of induction therapy in autoHSCT candidates include VAD (vincristine, doxorubicin, and dexamethasone) or VAD-like chemotherapy, dexamethasone combined with thalidomide, lenalidomide, or bortezomib, and bortezomib combined with lenalidomide or thalidomide and dexamethasone. The practice of using VAD chemotherapy prior to autoHSCT has become largely obsolete given data which suggest superior outcomes in those patients receiving newer drug combinations.[22,23] Melphalan should be avoided in patients who are eligible for autoHSCT because of its adverse effect on stem cell mobilization. When autoHSCT is not an option, melphalan plus prednisone has been an acceptable choice for induction therapy but now thalidomide (MPT) or bortezomib (MPB) is frequently added to the melphalan and prednisone backbone. Based on the results of randomized controlled trials that show significantly higher response rates and longer progression-free survival with MPT or MPB when compared with MP, these new combinations are listed as acceptable first-line therapies in the

TABLE 144-2 Drug Therapy in Newly Diagnosed Multiple Myeloma

Induction Regimen	Level of Evidence
Regimens in non-autoHSCT candidates	***Category***
Dexamethasone	2B
Vincristine + doxorubicin + dexamethasone (VAD)	2B
Lenalidomide + low-dose dexamethasone	1
Lipo doxorubicin/vincristine/dexamethasone (DVD)	2B
Thalidomide + dexamethasone	2B
Melphalan + prednisone (MP)	2A
Melphalan + prednisone + thalidomide (MPT)	1
Melphalan + prednisone + bortezomib (MPB)	1
Regimens in autoHSCT candidates

TABLE 144-3 Definition of Clinical Response in Multiple Myeloma

Type of Response	Definition[a]
Partial response (PR)	• ≥50% decrease in serum M protein • Reduction in 24-hour urine light chain by ≥90%
Very good partial remission (vgPR)	• Serum and urine M protein detected on immunofixation but not electrophoresis
Complete remission (CR)	• Negative immunofixation on serum and urine • No soft-tissue plasmacytomas
Stringent complete response	• <5% plasma cells in the bone marrow • CR definition • Normal free light chain ratio • Absence of clonal cells in the bone marrow

[a]Maintained for a minimum of 6 weeks.

NCCN guidelines (category 1 evidence). In addition, lenalidomide plus low-dose dexamethasone has been given a category 1 recommendation based on a phase III study showing high response rates and acceptable toxicity in MM patients, including some who were too old to receive autoHSCT.[14,20]

Clinical response to therapy is generally defined by a reduction in paraprotein in blood and urine.[1] Clinical complete response is defined as elimination of plasma paraprotein, as measured by electrophoresis and immunofixation, and plasma cells (≤5%) in the bone marrow. A specialized type of complete remission (CR), called stringent CR, is defined by negative-free light chain and immunofixation. Complete remissions are uncommon in MM and lesser responses, including, partial response (PR), near complete response (nCR), and very good partial response (vgPR), are more commonly attained. While the nCR term is less commonly used in current trials, it was used in several important studies. These lesser responses can be important because they may correlate with improved survival. Table 144–3 describes the most common types of responses that are used clinically.[14]

DRUGS USED IN THE MANAGEMENT OF MULTIPLE MYELOMA

Conventional Chemotherapy

Two of the common conventional chemotherapy regimens used historically to treat MM are melphalan plus prednisone (MP) and VAD.[1,2] Despite more active combinations, MP and VAD remain listed as options as initial therapy in patients with MM.[14] Since conventional-dose melphalan has an adverse effect on stem cell mobilization and subsequent autoHSCT, the use of melphalan is limited to patients ineligible for autoHSCT. Melphalan may also lead to the development of myelodysplastic syndrome.[24] The use of VAD chemotherapy as initial treatment became more common because of these concerns with melphalan. However, the slightly higher response rates with VAD and similar combination chemotherapy did not translate into improved survival as compared with MP, and VAD is now rarely used in MM.[25]

Dexamethasone accounts for most of the antimyeloma activity of VAD (Table 144–4), which led to the use of dexamethasone alone as initial therapy. However, one study reported that MP produced similar response rates and survival as compared to dexamethasone. The higher rate of infection and CNS toxicity in patients treated with dexamethasone led these investigators to conclude that high-dose dexamethasone be used with caution as initial therapy, particularly in older patients who are not eligible for autoHSCT and who would usually receive MP.[26] Increasingly, patients receive newer agents (thalidomide, bortezomib, lenalidomide) combined with dexamethasone or the MP backbone to maximize initial response rates.[27]

Thalidomide (Thalomid®)

Thalidomide was first used clinically in Europe in the late 1950s as a sedative and antiemetic but its use was largely abandoned when teratogenicity was reported. Its immunomodulatory effects became evident with its use in Hansen disease (or leprosy), and it continues to be used for this rare indication. These clinical benefits are thought to be related to the anti-TNF activity of thalidomide. Because of the role of inflammatory cytokines in the pathophysiology of MM, thalidomide was first studied in refractory MM in 1999. The observation that thalidomide had activity against myeloma rejuvenated it as an important therapeutic agent.[28]

Thalidomide has multiple immune effects including inhibition of inflammatory mediators, antiangiogenic activity, and T-cell modulating activity.[29] Thalidomide destabilizes TNF-α messenger RNA, which leads to increased destruction of the transcripts and reduction in TNF-α production. One potential explanation for thalidomide's antimyeloma activity is inhibition of TNF-mediated NF-κB activation, which results in increased apoptosis of the MM clone. Thalidomide also has TNF-independent effects on NFκB; it protects the cytosolic inhibitor of NFκB (IκB) and prevents signal transduction to the nucleus, resulting in a decline in MM growth factors.[28,29]

Myeloma bone marrow has a high rate of neovascularization, which makes it susceptible to antiangiogenic therapy. Bone marrow microvessel density has been identified as an independent prognostic factor in MM.[30] One explanation for the angiogenesis that occurs in MM is the paracrine release of TNF-α by the myeloma clone and bone marrow stromal cells, which leads to the release of angiogenic factors, including VEGF, IL-8, bFGF, and IL-1, through NF-κB induction. Thalidomide treatment can reduce bone marrow microvessel density, which may contribute to its antimyeloma activity.

The role of TNF-α inhibition is supported by the observation that TNF-α polymorphisms may predict for thalidomide response in patients with MM.[31] High producers of TNF-α had significantly higher response rates and improved survival with thalidomide therapy as compared to patients without the hypersecretory phenotype. These results may be explained by inhibition of TNF-α as

TABLE 144-4 Initial Therapies for Multiple Myeloma

Regimen	Type of Response (%)		
	OR	*CR*	*CR + nCR or VgPR*
Melphalan + prednisone[26,37–39]	40–50	1–2	5–10
Dexamethasone[26,36]	40–50	1	
Thalidomide[34]	34–40

alloHSCT, allogeneic hematopoietic stem cell transplantation; autoHSCT, autologous hematopoietic stem cell transplantation; CR, complete response; OR, overall response (at least PR); RI, reduced intensity; VAD, vincristine, doxorubicin, and dexamethasone.

a required growth factor in patients with the TNF-α hypersecretory phenotype. The authors commented that larger studies are required to confirm and explain these results. Figure 144–1 shows that thalidomide inhibits proliferation and angiogenesis, stimulates T lymphocytes, and modifies the cytokine-secreting ability of bone marrow stromal cells.

Single-agent thalidomide has been extensively evaluated in refractory MM where it produces overall response rates (includes minor responses) in about 30% of patients.[32] Although minor and partial responses are the most common types of responses, these endpoints result in improvement in survival.[33]

4 With the activity of thalidomide in refractory MM established, subsequent studies evaluated its activity in newly diagnosed patients and in combination with other therapies, including dexamethasone and chemotherapy. Partial response rates with single-agent thalidomide in untreated patients are approximately 30% to 40%.[34] When dexamethasone is added to thalidomide in untreated patients, response rates (≥PR) increase to approximately 70% to 80%.[35] The higher response rate with thalidomide plus dexamethasone makes this an attractive combination for initial therapy. However, the higher rate of thromboembolism with this combination (15%–20%) when used in newly diagnosed patients is a concern.[35,36]

The addition of thalidomide to chemotherapy also increases response rates (Table 144–4). Two published randomized controlled trials in newly diagnosed MM showed that the addition of thalidomide to MP improved response.[37,38] In the first randomized trial, the overall complete response rate with MPT was about 15% as compared to 4% with MP. With a median follow-up of about 3 years, patients in the MPT group had significantly improved progression-free survival but not overall survival.[37] The second randomized trial was stopped early because MPT showed clear improvements over the other treatment arms. Results of that trial also showed significantly improved median progression-free (27.5 vs 17.8 months) and overall survival (51.6 vs 33.2 months) with MPT.[38] A third trial was recently published where MPT was compared with MP in patients older than 75 years of age. Patients on MPT had superior progression-free and overall survival at the cost of increased peripheral neuropathy and neutropenia.[39] Based on these impressive results, some have recommended that MPT be the new standard induction therapy in older patients ineligible for autoHSCT. However, it is not possible to define a single standard regimen in this setting because of the number of highly active combination regimens and the lack of head-to-head comparative trials. The increased response rate of MPT is at the expense of higher rates of grades III and IV toxicity, particularly venous thromboembolism (VTE), peripheral neuropathy, and infection.[38,39]

The combination of thalidomide, dexamethasone, and pegylated liposomal doxorubicin produces a high overall response rate of 98% and a complete remission rate of 34%. The major grades III and IV toxicities were VTE (14%) and infection (22%). Toxicity was acceptable, even in patients older than 65 years of age.[40] Although the activity of doxorubicin plus thalidomide compares favorably with other combinations, one disadvantage of this regimen is that pegylated liposomal doxorubicin requires intravenous administration. The high response rate of thalidomide plus pegylated liposomal doxorubicin combinations needs to be confirmed in a randomized trial that compares it with an accepted standard.

Thalidomide dose correlates with response and toxicity. In one large trial of single-agent thalidomide, a higher response rate was observed when more than 42 g of thalidomide was administered over a 3-month period, which is equivalent to a daily dose of about 450 mg.[33] As expected, the higher dose was associated with higher rates of thalidomide-related toxicity. When thalidomide is combined with chemotherapy, thalidomide doses of 100 mg/day are associated with high complete remission rates.[37,40] Neuropathy, one of the important dose-limiting toxicities, may correlate with cumulative thalidomide doses. Thalidomide-induced neuropathy is usually, but not always, reversible and is associated with demyelinating changes in peripheral neurons. Approximately 10% to 20% of patients are unable to tolerate thalidomide and neuropathy is often the toxicity associated with discontinuation of therapy.[33,39] Unfortunately, no effective methods have been identified to prevent or treat thalidomide-induced neuropathy.

Other common toxicities associated with thalidomide include constipation, sedation, and rash. While these toxicities can be problematic, they rarely require discontinuation of thalidomide treatment. Stimulant laxatives can be used to prevent severe constipation. The severity of constipation and sedation declines over time in many patients.[41]

The rate of VTE with single-agent thalidomide is relatively low (<5%) and may not exceed the baseline incidence for MM patients. VTE prophylaxis is not recommended in patients receiving single-agent thalidomide.[42] When thalidomide is combined with dexamethasone, MP, or doxorubicin, the risk of thrombosis is elevated. The underlying mechanism for thrombosis in these patients is unknown but rates in several studies of combination therapy were as high as 10% to 30%.[37–39,43] VTE prophylaxis is recommended and preventive strategies include therapeutic doses of warfarin or low-molecular-weight heparin (LMWH). Warfarin is associated with bleeding complications particularly in patients with thrombocytopenia and should be reserved for patients unable to adhere to LMWH therapy.[43] Aspirin (81 mg or 325 mg) may be beneficial in preventing thrombosis, but large, well-controlled studies are required. Aspirin should be reserved for those patients at high risk of bleeding on warfarin or LMWH and low-to-moderate risk of developing VTE.[43,44]

Bortezomib (Velcade®)

5 Bortezomib is a proteasome inhibitor approved for use in newly diagnosed and relapse/refractory MM. The proteasome is a protease complex responsible for degrading cytosolic proteins that are conjugated to ubiquitin. Ubiquitin is a 8.5-kilodalton polypeptide that tags various proteins for destruction.[45] By reversibly binding to the chymotrypsin site in the catalytic core of the 26S proteasome, bortezomib inhibits the degradation of these targeted proteins.

In MM, NF-κB activity is increased, resulting in increased transcription of inflammatory cytokines such as IL-6 and TNF-α, which are involved in the pathogenesis and progression of MM. In the cytosol, NF-κB is bound to and inhibited by IκB. The proteasome degrades IκB. When the proteasome is inhibited with bortezomib, cytosolic concentrations of IκB remain high and NF-κB is retained in the cytosol as an inactive complex. The resulting inhibition of the NF-κB signal leads to a reduction in cytokine production and growth inhibition of the MM clone. Other proteins involved in cell-cycle regulation and apoptotic signaling that may be affected by bortezomib include p53, JNK proteins, and capase 3.[45]

In phase I studies in patients with refractory hematologic malignancies, bortezomib was administered twice weekly for two consecutive weeks followed by a week of rest. The responses observed in those studies included a complete response in 1 of 8 patients who completed the first course of therapy and minor responses in two patients. These responses were impressive for a phase I trial and confirmed the promising activity in preclinical studies.[46]

Patients with refractory MM were then enrolled into a phase II trial and received 1.3 mg/m^2 of bortezomib twice weekly for 2 weeks followed by a week of rest. Patients received up to eight cycles. The overall response rate was 35% (includes minor responses) with 7 (3.6%) patients achieving a complete response.[47] Based on the phase I and II studies, bortezomib was approved in May 2003 under the FDA's accelerated approval process for relapsed or refractory MM in patients who had failed at least two prior therapies.

Subsequently, a large phase III study (Assessment of Proteasome Inhibition for Extending Remissions [APEX] trial) demonstrated that bortezomib had superior activity as compared with high-dose dexamethasone in relapsed MM.[48] Bortezomib-treated patients had higher complete and partial response rates (38% vs 18%), longer median time-to-progression (6.2 vs 3.5 months), and improved 1-year overall survival (80% vs 66%) as compared to patients receiving dexamethasone. The differences in each of these endpoints were statistically significant. The results from this study led to expanded FDA approval in 2005 to include patients who had relapsed after one therapy.

Combination therapy with bortezomib has shown promising results in relapsed MM. It was reported that relapsed patients who had suboptimal response to bortezomib alone may respond after the addition of dexamethasone. Subsequent studies reported improved results with the combination of bortezomib and corticosteroids with the complete and nCR rate ranging between 5% and 15%.[49] The inclusion of bortezomib in three to four drug combinations which may include doxorubicin, melphalan, thalidomide, and lenalidomide produce CR and nCR rates of 10% to 50% in relapsed MM.[45,49]

There are a number of studies investigating bortezomib in newly diagnosed patients (Table 144–4). Bortezomib alone produces about a 40% response rate (complete remission plus partial response) with approximately 3% of patients obtaining a complete remission. When combined with dexamethasone, the overall response rate increases to approximately 90% (complete remission plus partial response) with complete remissions of 5% to 20%.[50,51] In a phase II study of bortezomib combined with MP (MPB) in newly diagnosed elderly MM patients, the overall response rates of 89% and complete remission rates of 32% are among the highest reported with induction therapies.[52] Subsequently MPB was compared with MP in the large phase III VISTA (Velcade as Initial Standard Therapy in multiple myeloma) trial. The overall response and CR rates, time-to-progression, and overall survival were significantly better in the MPB group. Based on these results, bortezomib received FDA approval in 2008 as first-line therapy in newly diagnosed patients with MM. The improvement in response came at the expense of greater serious adverse effects including neuropathy, gastrointestinal toxicity, and herpes zoster. However, treatment-related mortality was not different between MPB and MP groups.[53]

Bortezomib can cause significant toxicity the most common being mild-to-moderate fatigue and gastrointestinal toxicities. Neuropathy occurs frequently and is the most common cause for discontinuation of therapy. In the VISTA trial, the rate of neuropathy was 44% in the MPB group vs 5% in the MP group.[53] However, MPB and MP groups had similar rates of therapy discontinuation at about 15%. Other important toxicities included thrombocytopenia, fever, neutropenia, and infection. An increased risk of shingles has been reported in bortezomib-treated patients, and the NCCN guidelines recommend that herpes zoster prophylaxis be considered.[14] VTE prophylaxis is not required with bortezomib when it is combined with MP, based on the results of the VISTA trial which reported low rates of VTE and nearly identical rates in the MPB versus MP group.[53]

Lenalidomide (Revlimid®)

6 Lenalidomide is a thalidomide analog that shares a similar mechanism of action with thalidomide, but is significantly more potent than thalidomide. Because of differences in the toxicity profile, the use of lenalidomide is likely to increase. In phase I studies, patients with relapsed, refractory MM were found to have a maximum tolerated dose of lenalidomide of 25 mg/day and this dose was the most commonly used dose in subsequent phase II and III studies.[54]

The addition of lenalidomide to high-dose dexamethasone has been shown to increase response rate and prolong survival in patients with relapsed MM. In 2006, lenalidomide received FDA approval in relapsed-refractory MM based on the results of two recently published randomized controlled trials.[55,56] One trial was conducted in North America while the other trial was conducted outside of North America. In both trials, patients were randomized to receive a combination of either lenalidomide (25 mg/day on days 1 to 21 of a 28-day cycle) and high-dose dexamethasone or an identical lenalidomide placebo and high-dose dexamethasone. In the North American trial, patients in the lenalidomide and dexamethasone group had overall (complete, near-complete, or partial) and complete response rates of 61% and 14%, as compared with 20% and 0.6% in the dexamethasone alone group (P <0.001).[55] These improved response rates translated into longer median overall survival in the lenalidomide and dexamethasone group (29.6 vs 20.5 months). Similar results were reported in the trial conducted outside of the United States.[56]

Lenalidomide has been studied as initial therapy in newly diagnosed MM (Table 144–4). Preliminary results of phase I and phase II studies of lenalidomide plus dexamethasone report an overall response rate of 90% and a complete response rate of 18%.[41,57] These rates may be higher than those reported with thalidomide plus dexamethasone. Lenalidomide causes less neurotoxicity and constipation but more myelosuppression than thalidomide.[42,58] When used as part of combination therapy, the risk of VTE with lenalidomide is similar to that observed with thalidomide and VTE prophylaxis is recommended. Results from a phase III trial in newly diagnosed MM reported that patients randomized to lenalidomide plus high-dose dexamethasone had a 26% incidence of VTE as compared with a 12% rate in those randomized to the lenalidomide plus low-dose dexamethasone arm.[59] That trial also reported a superior 2-year overall survival in the lenalidomide plus low-dose dexamethasone group (87% vs 75%) and this regimen could become the new standard induction regimen for older patients ineligible for autoHSCT. The improved survival in the low-dose dexamethasone arm comes from a lower mortality from adverse events, particularly VTE. Excess deaths in the high-dose dexamethasone group usually occurred in the first 4 months and in elderly patients. The low risk of VTE in the lenalidomide plus low-dose dexamethasone arm may allow for VTE

prophylaxis with aspirin alone.[59] These results have led to a category 1 NCCN recommendation. A reasonable strategy is to use high-dose dexamethasone plus lenalidomide in younger patients who are transplant candidates and use low-dose dexamethasone plus lenalidomide in older patients ineligible for transplant.[14]

Summary of Newer Therapy Combinations as Initial Therapy

7 In patients ineligible for autoHSCT, thalidomide, lenalidomide, or bortezomib is being added to chemotherapy as initial therapy. MP can be the backbone to which these newer drugs are added if the patient is not a candidate for autoHSCT. As previously discussed, MPT produces high response rates and bortezomib added to MP (MPB) produces similar results.[37,38] Based on the results of phase III trials demonstrating superiority of MPT over MP, many experts suggested that MPT was the preferred induction regimen in patients who are ineligible for autoHSCT. However, the results of the recently published VISTA trial support the addition of MPB as another preferred induction regimen. Both MPB and MPT are listed as NCCN category 1 recommendations.[53,14] MPB may be particularly useful in MM patients with high-risk cytogenetics (chromosome 13 deletion, t(4;14), and 17p-).

A phase II study has reported good activity with MP combined with lenalidomide (MPR) in newly diagnosed patients.[60] Results from randomized controlled trials for MP combined with lenalidomide are not available in full form but a recent abstract of a phase III study demonstrated superiority of MPR over MP alone.[61] The preferred combination (MPT, MPB, or MPR) is currently unclear and will require head-to-head comparisons between these combinations.

If autoHSCT is planned after induction therapy, melphalan should be avoided, and thalidomide, bortezomib, or lenalidomide can be added to dexamethasone or VAD-like chemotherapy. The NCCN guidelines lists several induction therapies (Table 144–2). Because there is no standard induction regimen, clinicians can select from a wide range of possible induction regimens. Many clinicians recommend lenalidomide and dexamethasone or bortezomib, lenalidomide, and dexamethasone in patients who are autoHSCT candidates. Patients with chromosome 13 or 17p deletion, which are adverse prognostic factors, may benefit from bortezomib-containing induction regimens because of its activity in these high-risk patients.[20,14] Because patients with high-risk cytogenetics may have poorer outcomes after autoHSCT, bortezomib-containing regimens should be considered in this group of patients, regardless of their eligibility for autoHSCT.[20,14]

CLINICAL CONTROVERSY

For patients who are autoHSCT candidates, induction therapy has historically involved the administration of four months of VAD. High-dose dexamethasone alone was also an option, given that most of the activity of VAD resides with dexamethasone. Newer agents, such as thalidomide, bortezomib, or lenalidomide combined with dexamethasone are now routinely used as induction therapy. There is growing evidence that the higher response rates associated with these newer regimens improve outcomes in patients undergoing autoHSCT. There is no standard choice for induction and choices are made based on individual characteristics of the patient. For example, a patient with high-risk cytogenetics may benefit from a bortezomib-containing induction regimen and may not respond as well to thalidomide-based therapy. Lenalidomide may remain an option in patients with high risk cytogenetics but may also negatively effect stem cell collections. This has led to recommendations that lenalidomide induction be limited to four months to reduce the chance of this negative effect on stem cell mobilization an effect not seen with thalidomide or bortezomib. Patients with renal dysfunction, a relatively common diagnosis in myeloma patients, require dose adjustment of lenalidomide to avoid severe myelosuppression. To better guide the selection of induction prior to autoHSCT studies need to be performed on the above described subgroups.

AUTOLOGOUS HEMATOPOIETIC STEM CELL TRANSPLANTATION

Although MM is a chemosensitive tumor with significant response rates after treatment with conventional chemotherapy, complete remission rates have historically been low and response durations have been short. In an attempt to improve outcomes with chemotherapy, high-dose chemotherapy regimens with stem cell support have been used after initial induction therapy. The intent of the induction therapy prior to transplant is to reduce tumor load. With the newer combinations being used as induction, high rates of quality responses (CR, VgPR) can be obtained and recent data suggest that obtaining quality responses during induction improves the outcomes associated with autoHSCT.[62]

8 Several well-designed, randomized, controlled trials have evaluated the role of high-dose chemotherapy followed by autoHSCT. In these trials, previously untreated patients were randomized to induction therapy alone versus the same induction therapy followed by high-dose chemotherapy and autoHSCT. The results generally showed that autoHSCT improved progression-free survival with a more variable effect on overall survival.[63–65] No survival plateau was observed in the group treated with autoHSCT, which suggests that few, if any, patients are cured of their disease. Despite these variable effects on overall survival, MM has become the leading indication for autoHSCT worldwide.

A systematic review of autoHSCT in newly diagnosed MM was published in 2007.[65] The review pooled results from nine studies comprising 2,411 patients randomized to either autoHSCT or standard dose chemotherapy. The combined hazard ratio for overall survival with autoHSCT was 0.92 (95% confidence interval [CI], 0.74-1.13) and for progression-free survival was 0.75 (95% CI, 0.59-0.96). These results indicate that high-dose therapy with autoHSCT significantly improves progression-free survival but does not significantly improve overall survival. This benefit in progression-free survival was at the risk of greater transplant-related mortality. Patients who received autoHSCT had a 3-fold higher risk of treatment-related death as compared to conventional dose chemotherapy. The authors concluded that for every 26 patients who received a transplant, there would be one excess death from autoHSCT as compared to conventional chemotherapy. It should be noted that these trials used an induction of VAD or VAD-like chemotherapy which is inferior to the modern induction therapies described previously.

Two of the randomized trials comparing autoHSCT to standard therapy in newly diagnosed MM included in the systematic review were updated and illustrates the divergent results seen with autoHSCT. Barlogie et al. reported that progression-free and overall survival were equivalent between high-dose and conventional-dose groups.[66] This is different than the conclusions of the systematic review, which reported a significant improvement in progression-free survival. The Barlogie study has been criticized for using total-body irradiation plus melphalan rather than the more commonly used high-dose melphalan alone. However, several other

studies that used total-body irradiation in addition to melphalan have reported variable results, which suggest that the differences in the preparative regimen do not fully explain these negative results. In the second updated study, Fermand et al. reported a benefit in event-free survival but no benefit in overall survival. These results were consistent with the systematic review. This study used standard high-dose melphalan and compared it with conventional therapy in previously untreated patients.[67]

Although the use of autoHSCT as consolidation therapy has become standard of care in patients younger than age 65 years, it is associated with higher treatment-related mortality and there is no convincing evidence that it improves overall survival. The widespread adoption of autoHSCT as standard therapy is related to the significant improvement in progression-free survival. But as conventional therapy continues to improve, response rates and progression-free survival are likely to approach those seen with autoHSCT without the low but present elevated risk of transplant-related mortality.

The role of autoHSCT as consolidation therapy has been questioned because newer combinations such as lenalidomide plus dexamethasone produce results similar to transplantation without the risk of mortality. However, many investigators believe that the use of autoHSCT as a scheduled sequential therapy after induction therapy, even in those patients who achieve a CR, is a logical next step in the evolving approach to treating MM. This controversy will continue until the results of several ongoing trials comparing these new combinations to autoHSCT have been completed.[68]

9 Preliminary results have shown that induction regimens containing at least one of the novel agents can make a significant difference in outcomes after autoHSCT. Also the use of these novel agents in induction may reduce the number of patients who require a second transplant because of the higher proportion of patients achieving major responses (CR, nCR, or VgPR) after the combination of novel induction regimen and the first transplant. A randomized phase III trial performed by the French group compared bortezomib in combination with dexamethasone with VAD as induction prior to autoHSCT.[69] Patients were randomized to one of four arms which included either bortezomib plus dexamethasone or VAD. All arms underwent autoHSCT with melphalan preparation (200 mg/m^2). Post-induction CR/nCR rates were 15% in the bortezomib-containing arms as compared to 6% in those receiving VAD. The progression-free survival was superior in the patients where autoHSCT was preceded by bortezomib plus dexamethasone induction. Also, the proportion of patients requiring a second transplant was significantly lower in the bortezomib plus dexamethasone arm due to the higher rates of acquiring at least a VgPR in the bortezomib plus dexamethasone group.

Most patients are treated with autoHSCT as consolidation therapy after a short course of induction chemotherapy. However, a smaller number of patients receive autoHSCT as salvage therapy after patients have failed conventional treatments. A study in the early 1990s compared autoHSCT with chemotherapy in previously treated MM patients.[70] The results of that study showed that high-dose therapy was no better then VAD alone. However, more recent studies report benefit from autoHSCT in both primary treatment failures and relapsed MM.[71,72] The NCCN guidelines list autoHSCT as one of the acceptable options in the salvage setting. Responses to autoHSCT in the salvage setting can occur even in patients who have relapsed after prior successful autoHSCT.[14]

The optimal timing of autoHSCT (early vs late) in MM was investigated in a randomized controlled trial. Patients were randomized to early (n = 91) or late transplantation (n = 94) and no significant difference in 5-year overall survival was observed between the groups.[73] Event-free survival, however, was significantly longer in the early transplantation group (39 months vs 13 months). In an analysis that factors in the time without symptoms, treatment, or treatment toxicity (TWisTT), patients receiving early transplantation had a longer time in a state associated with good quality of life (27.8 vs 22.3 months). The results of this study support early autoHSCT because of its effects on event-free survival and quality of life. The often long period of disease response after autoHSCT without ongoing treatment must be considered as newer combinations are considered as upfront therapy to replace autoHSCT. While these new combinations may produce equivalent responses, they require prolonged treatment which may lead to decline in quality of life and can make these therapies more expensive than autoHSCT.

A specialized form of autoHSCT, tandem transplantation, involves the use of two separate autoHSCT procedures separated by a rest period of several months. In a recent meta-analysis, six randomized controlled trials (N = 1,803) were included and the authors concluded that while overall response was superior with tandem transplant, overall survival was not superior compared to single transplant. Higher transplant related mortality was observed in patients receiving tandem transplant.[74]

Transplant-related mortality is generally low for autoHSCT but is higher in patients receiving tandem transplants (2.7% vs 4.8%). Approximately 10% to 15% of patients who did not achieve a complete remission with the first transplant attained it with the second transplant.[75] Because of this increased risk of mortality with tandem transplants, it would be helpful to identify those patients who would benefit most. Two French studies reported that patients who did not achieve at least a very good partial response after the first transplant benefited most from the second transplant.[76,77] One of these studies reported an estimated 7-year overall survival of 21% in the single-transplant arm and a 42% survival in the double-transplant arm.[76]

The primary conclusion from the current data on autoHSCT as consolidation therapy in MM is that it should be used in younger patients with good performance status.[14] Prior to transplant, all patients should receive induction therapy to reduce tumor burden. Because of higher transplant-related mortality, a second autoHSCT should only be considered in patients who do not achieve a very good partial response or better with the first autoHSCT.

Maintenance

Even with recent advances in induction therapy and autoHSCT, most patients will eventually progress within 3 to 5 years, suggesting that effective maintenance therapy is needed to control or delay disease progression. Variable results and high toxicities have been reported with interferon-α (IFN-α) and dexamethasone and neither drug can be recommended outside of a clinical trial.[78] IFN-α at one time was considered to be maintenance of choice after autoHSCT, based on data from a randomized trial showing superior progression-free and overall survival after autoHSCT.[79] A later meta-analysis supported the benefit of IFN-α maintenance.[80] The major limitation of IFN-α is its high toxicity, which has limited its widespread use in maintenance. A randomized trial conducted by the Southwest Oncology Group evaluated the benefit of prednisone maintenance therapy in 125 patients.[81] Patients who received high-dose steroids had significantly longer progression-free and overall survival. While IFN-α or corticosteroids maintenance has not been widely adopted due to toxicity, these therapies served as proof of principle and led to phase III trials evaluating thalidomide.

Thalidomide has also been studied as maintenance after autoHSCT. To date, results of three separate phase III studies show that thalidomide improves overall survival. In the largest study to date, 597 patients were randomized to receive either no maintenance, pamidronate alone, or the combination of thalidomide plus pamidronate. Patients randomized to the thalidomide group had significantly longer event-free and overall survival as compared

with those who received no thalidomide.[82] The median duration of thalidomide maintenance was 15 months and the average dose was 200 mg/day. Nearly 40% of patients had to discontinue thalidomide as a consequence of toxicity. In a subgroup analysis, patients with deletion of chromosome 13 did not benefit and other maintenance therapies may need to be evaluated for this high-risk group.

In another approach, investigators at the University of Arkansas used thalidomide in both induction and maintenance as part of the Total Therapy II trial.[83,84] Thalidomide increased CR and VgPR rates. In addition, event-free survival was improved in the thalidomide arm, including patients with adverse cytogenetics. An update by this group indicated that outcome with thalidomide was not related to cumulative dose, which may allow clinicians to limit the duration of thalidomide therapy and therefore reduce toxicity.[84]

Thalidomide maintenance has also been used after induction in elderly patients who were not candidates for autoHSCT. The results in this setting are not clear and remain controversial. Despite evidence that thalidomide maintenance after autoHSCT can improve outcomes, it is not widely used due to the adverse toxicity profile.[85]

Maintenance with bortezomib and lenalidomide may be more effective, particularly in high-risk MM patients. Bortezomib and lenalidomide are likely to be better tolerated than thalidomide. The NCCN guidelines indicate that there is no consensus on the use of dexamethasone and IFN-α maintenance. Thalidomide is given a category 1 recommendation in the NCCN guidelines.[14] Lenalidomide maintenance is given a category 2A recommendation, based on preliminary results of randomized trials showing that lenalidomide maintenance is superior to placebo. Recommendations for bortezomib maintenance will require completion of ongoing trials.

ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

AlloHSCT uses a stem cell source other than the patient themselves and is therefore a transplant across immunologic barriers. The major post-transplant complications associated with transplanting across these barriers are graft failure and acute and chronic graft-versus-host disease. Acute or chronic graft-versus-host disease may be associated with a graft-versus-myeloma effect. The graft-versus-myeloma effect, which is mediated by antitumor effector cells from the graft-versus-host disease reaction, reduces relapse risk and may offer the patient the best chance for long-term disease-free survival.[86] Unlike autoHSCT, which is simply a method of increasing the dose-intensity of chemotherapy, alloHSCT is a form of immune therapy. This is best illustrated by nonmyeloablative alloHSCT where reduced-intensity preparation provides immunosuppression so the graft is not rejected but little or no antitumor activity yet cures can be achieved as a result of graft-versus-tumor effect.[87]

⑩ Despite data reporting lower relapse rates in MM patients, myeloablative alloHSCT produces high transplant-related mortality (20%–50%), leading to overall survival rates similar to autoHSCT.[72] The reasons for the high transplant-related mortality in alloHSCT are not entirely clear. One possible explanation is that MM patients come to transplantation heavily pretreated, at an older age, and with greater existing organ damage as compared to other cancers. However, a study was closed prematurely in MM patients younger than 55 years of age with minimal pretreatment because of unacceptably high transplant-related mortality (~50%) suggesting these explanations do not completely account for the high mortality.[75]

With the high transplant-related mortality associated with myeloablative alloHSCT, the use of nonmyeloablative alloHSCT is an attractive option to reduce early post-transplant mortality. Several conclusions can be made based on the available data regarding the use of nonmyeloablative alloHSCT in MM patients. First, the transplant-related mortality associated with nonmyeloablative alloHSCT is lower than that reported with myeloablative alloHSCT. Second, the cytoreductive activity of the reduced-intensity preparation may be insufficient for the graft-versus-myeloma effect to have its full impact. Most immune therapies, including the graft-versus-myeloma reaction, are most effective when patients have minimal residual disease and nonmyeloablative alloHSCT may have insufficient antitumor activity to achieve important tumor reduction. The need for cytoreduction may be accomplished by autoHSCT preceding the reduced-intensity alloHSCT procedure. The trials investigating this novel approach have produced conflicting results. These studies compared tandem autoHSCT with single autoHSCT followed by reduced-intensity alloHSCT. Garban et al. reported no differences in event-free or overall survival between tandem autoHSCT and single autoHSCT followed by reduced-intensity alloHSCT.[88] A more recent trial reported significantly improved event-free and overall survival when autoHSCT was combined with reduced-intensity alloHSCT.[89] These conflicting results may relate to the inclusion of particularly high-risk patients and the use of more aggressive immunosuppression in the negative trial. In both trials, transplant-related mortality was not higher in the combined autoHSCT and reduced-intensity alloHSCT arm when compared with tandem autoHSCT.[88,89] More recently, Rosinol et al. found a nonsignificant improvement in progression-free survival and no improvement in overall survival in patients receiving combined autoHSCT and nonmyeloablative alloHSCT. The lack of benefit on overall survival may be explained by higher transplant-related mortality in the nonmyeloablative arm.[90] Because of the variability of these results, the combined use of auto and alloHSCT should be performed as part of an investigational protocol.

SUPPORTIVE CARE

Bisphosphonates

Along with anti-MM therapy, supportive care measures are aggressively used to stabilize skeletal abnormalities. Bisphosphonates have been used for more than a decade in the management of MM. Once a well-accepted standard of care, the optimal use of bisphosphonates is more controversial because of reports of osteonecrosis of the jaw (ONJ), a rare but serious adverse effect of bisphosphonate use.

⑪ Bisphosphonates have a major role in the treatment of bone-related complications associated with MM. Bone resorption is a manifestation of the disease process and is mediated in part by inflammatory molecules including IL-6, IL-1, and TNF-α.[1] Bone disease is not seen in MGUS but occurs in approximately 80% of MM patients at diagnosis. Although the classic cytokine mediators of bone loss are important, a newer view involves excessive production of RANK-L, which activates NF-κB through its receptor (RANK).[91] As previously stated, NF-κB is a transcriptional regulator that increases the production of various inflammatory molecules. Normally, RANK-L mediated activation is in equilibrium with osteoprotegerin, which inhibits NF-κB by serving as a decoy receptor for RANK-L.[91] In the bone marrow of MM patients, excess RANK-L is produced particularly from stromal cells, which, when coupled with a decline in osteoprotegerin from both stromal cells and osteoblasts, leads to osteoclast activation and bone destruction. Macrophage inflammatory protein α_1, macrophage colony-stimulating factor, and VEGF may also play important roles in MM bone disease by stimulating the production and activation of osteoclasts.[92] Macrophage inflammatory protein α_1 is also an important chemotactic factor released by MM cells; it attracts osteoclast precursors, enabling myeloma cells to influence the maturation and activation of osteoclasts, which suggests that antimyeloma drugs can have a

beneficial effect on MM bone disease.[92,93] Although MM bone disease may involve many cell types and many soluble and cell-bound molecules, it is useful to simplify its pathophysiology and consider it to be an imbalance between RANK-L and osteoprotegerin.

Activation of osteoclasts leads to a net loss of bone mass and to many of the common clinical features of MM, including fractures, hypercalcemia, and bone pain. The bone resorption is influenced by the MM cells in proximity to the osteolytic lesions and is associated with recruitment of osteoclasts.[94] The disruptive effect on skeletal integrity can lead to direct mortality, but more commonly has a major impact on morbidity and quality of life.[1]

Bisphosphonates are analogs of endogenous pyrophosphate but are more resistant to hydrolysis than pyrophosphate. Like endogenous pyrophosphate, the bisphosphonates bind to crystalline calcium in the bone and are then phagocytized by osteoclasts.[95] The best described effect of the bisphosphonates is the inhibition of osteoclast activity, which likely occurs by direct osteoclast cytotoxicity.[96] In addition to osteoclast inhibition, bisphosphonates may also promote apoptosis in MM cells. This effect may result from the inhibition of the mevalonic acid pathway, which produces several molecules required for growth of the MM clone.[97] In addition, other potential antimyeloma effects of bisphosphonates may include modifying the cytokine microenvironment, inhibiting the adhesion of MM cells to bone marrow matrix cells, and inhibiting angiogenesis.[98] Although it is possible that bisphosphonates have an antimyeloma effect, there is little direct clinical evidence to support this activity.

The use of bisphosphonates in MM is based on the results from two large, randomized, controlled trials. In the pamidronate study, the drug was compared to placebo in a group of MM patients undergoing their first or second course of chemotherapy.[99] Several clinical end points were found to be positively impacted by pamidronate therapy. The investigators reported that patients in the pamidronate group had a lower risk of skeletal-related events, lower pain scores, and improved quality of life. Importantly, a survival advantage was observed in the pamidronate-treated patients who had already received one or more courses of antimyeloma chemotherapy. This finding of improved survival in subgroup analysis is part of the circumstantial evidence to propose an antimyeloma effect for the bisphosphonates.

Guidelines for the use of zoledronic acid in MM are based largely on a randomized study in MM and breast cancer. In patients with bone metastases, zoledronic acid was compared to pamidronate with the intent of demonstrating clinical equipoise.[100] The study did show equivalence between pamidronate and zoledronic acid. The lack of a placebo arm because of ethical concerns complicates interpretation of this study. Despite this limitation, pamidronate and zoledronic acid appear to have equivalent clinical benefit in stabilizing the skeleton.

Other randomized, controlled trials have been conducted, and the results of these trials were pooled in a systematic review.[101] Eleven randomized trials were included, which accounted for 1,113 MM patients receiving bisphosphonate therapy along with 1,070 MM patients in a control arm who received no bisphosphonate therapy. The risk of vertebral fractures was significantly lower in the bisphosphonate-treated patients as compared to controls (odds ratio = 0.59; 95% CI, 0.45–0.78). Pain scores were also reduced (odds ratio = 0.59; 95% CI, 0.46–0.76). Given that the aggregate data in the systematic review agreed with the large controlled studies described above, the effect on vertebral fractures and pain are well-supported benefits of bisphosphonate therapy.

Clinical practice guidelines for the use of bisphosphonates in MM were updated by an expert panel under the auspices of the American Society of Clinical Oncology Health Services Research Committee.[17] The evidence-based guidelines recommend that symptomatic MM patients be placed on bisphosphonate therapy at the time of diagnosis to reduce pain and skeletal-related events, and to improve quality of life. No firm recommendation was made on the duration of bisphosphonate therapy and which of the two agents should be used. However, the expert panel suggested a duration of bisphosphonate use of 2 years in those patients with responsive or stable disease. Reinstituting bisphosphonate therapy at relapse or progression is at the discretion of the clinician.[17]

CLINICAL CONTROVERSY

Although bisphosphonates are indicated in MM patients with bone disease, controversies surrounding the selection of the best agent and duration of therapy remain. Because of recent reports of ONJ in MM patients, a more cautious approach on bisphosphonate use is being considered. ONJ is associated with patients undergoing dental procedures, those receiving the more potent bisphosphonates, and those receiving longer than two years of bisphosphonate therapy. Clinical practice guidelines developed by clinicians at the Mayo Clinic recommend that all dental procedures be performed prior to the administration of bisphosphonates, that therapy be given for no more than 2 years, and that pamidronate rather than zoledronic acid be used in newly diagnosed patients. Given the benefit of bisphosphonates on skeletal-related events, limiting therapy to 2 years remains controversial. The preference of pamidronate over zoledronic acid is also controversial given that ONJ has also been reported with pamidronate and the higher risk of ONJ with zoledronic acid is based on observational studies and not head-to-head randomized comparisons. Because of effects on the bone marrow microenvironment including effects on osteoblastogenesis, ostoclast inhibition, and differentiation of mesenchymal stem cells, bortezomib and lenalidomide combinations may be an alternative for or supplement to bisphosphonate therapy to prevent progression of myeloma bone disease. While markers of bone formation are positively affected by bortezomib, studies are required to describe this potential clinical benefit on MM bone disease.

Although a good case can be made for the use of bisphosphonates early after the diagnosis of MM, many controversies remain, including whether an antimyeloma effect exists, how long patients should remain on this expensive therapy, and, most importantly, the risk of ONJ. The association between bisphosphonates and ONJ suggests a more cautious approach with bisphosphonate therapy.

ONJ is characterized by an area of exposed necrotic bone and often affects the mandible and the maxilla, but can also affect the soft palate. The development of ONJ may be related to dental disease and tooth extraction, and appears to be more common with zoledronic acid than with pamidronate. The relationship with zoledronic acid is sufficiently strong to lead the Mayo Clinic to recommend that pamidronate be used in newly diagnosed MM patients.[102] The incidence of ONJ is unknown but may be as high as 10% in MM patients receiving zoledronic acid for extended periods of time. Because the risk of ONJ during the first 2 years of pamidronate appears to be very low, the Mayo Clinic guidelines recommend monthly infusions of pamidronate for 2 years after diagnosis.

A recent longitudinal cohort study supported many of the conclusions of the Mayo Clinic recommendations. These investigators concluded that ibandronate and pamidronate were safer alternatives and that dental procedures and dentures were risk factors for the development of ONJ. They recommended a comprehensive dental exam with management of dental problems prior to initiating bisphosphonate therapy but made no recommendation on which agent is preferred.[103]

Pamidronate and zoledronic acid are usually well tolerated. Flu-like symptoms can occur following the administration of bisphosphonates. Acute renal impairment can occur with both agents and is related to both infusion time and dose. For zoledronic acid, the risk of acute renal impairment is higher with the 8-mg dose (vs 4 mg) and when the duration of infusion is 5 minutes (vs 15 minutes). Patients with moderate renal impairment (creatinine clearance: 30–60 mL/min [0.5 to 1.0 mL/s]) should have their dose of zoledronic acid adjusted downward by 25% (3 mg). This recommendation was included in the zoledronic acid package insert and is based on a greater renal toxicity in patients with preexisting renal impairment.[17] Randomized studies suggest that renal effects are similar between pamidronate and zoledronic acid, and patients on bisphosphonate therapy should have serum creatinine measured at baseline and then periodically thereafter.[17,104]

SALVAGE THERAPY

12 A variety of factors must be considered when determining the most appropriate therapy for an individual who relapses including the type and duration of previous therapies, presence or absence of adverse prognostic factors, toxicity of prior therapies, and how much time has elapsed from initial response to relapse. The same drugs used to treat MM initially can also be used as salvage therapy in MM patients who have relapsed. Patients who relapse more than six months after initial induction therapy can have that induction therapy repeated. Bortezomib is an effective salvage therapy. When bortezomib was compared to high-dose dexamethasone, response rates were 38% versus 18%, respectively.[48] The activity of bortezomib in patients with high-risk cytogenetics is particularly useful because these high-risk patients are more likely to relapse and require salvage therapy. Lenalidomide plus dexamethasone is also approved for treating patients in the salvage setting, based on the results of two phase III trials.[55,56] Thalidomide can also be used at relapse with overall response rates that appear somewhat lower than bortezomib and lenalidomide.[33] Thalidomide, bortezomib, and lenalidomide can be combined with chemotherapy in the salvage setting to improve responses.

The combination of bortezomib and pegylated liposomal doxorubicin is another active regimen in relapsed or refractory MM. In a published phase III trial, patients randomized to the bortezomib and pegylated liposomal doxorubicin arm had significantly longer median time-to-progression (9.3 vs 6.5 months; hazard ratio = 0.55; 95% CI, 0.43- 0.71) and 15-month survival (76% vs 65%) as compared with patients randomized to receive bortezomib alone.[105] It is interesting to note that the overall (complete and partial) response rate was only slightly higher in the bortezomib and pegylated liposomal doxorubicin group (44% vs 41%). Based on the results of this study, the combination of bortezomib and pegylated liposomal doxorubicin received FDA approval in 2007 for patients with previously treated MM and is listed as a category 1 recommendation in the NCCN guidelines.[14] As expected, patients who received the combination experienced more adverse effects. A recent phase III trial suggests that bortezomib with or without dexamethasone had activity in relapse/refractory disease even in patients with prior thalidomide therapy or autoHSCT.[106]

As previously discussed, questions remain on the optimal timing for autoHSCT. For patients who are eligible for autoHSCT and did not receive transplant as part of initial therapy, it is appropriate to offer autoHSCT at first relapse. It is important to emphasize that while higher quality of life was realized when autoHSCT was used as consolidation therapy, there was no difference in overall survival based on timing of transplant. In patients with relapsed or refractory MM, autoHSCT followed by nonmyeloablative alloHSCT has potential benefit but at the expense of increased transplant-related mortality requiring treatment only be performed as part of a clinical protocol.

TABLE 144-5 Salvage Therapy in Multiple Myeloma

Regimen	Level of Evidence *Category*
Bendamustine	2B
Bortezomib	1
Bortezomib + dexamethasone	2A
Bortezomib + lenalidomide + dexamethasone	2B
Bortezomib + liposomal doxorubicin	1
Cyclophosphamide-VAD	2A
Dexamethasone	2A
Dexamethasone + cyclophosphamide + etoposide + cisplatin (DCEP)	2A
Dexamethasone + thalidomide + cisplatin + doxorubicin + cyclophosphamide + etoposide (DT-PACE)	2A
High-dose cyclophosphamide	2A
Lenalidomide + dexamethasone	1
Lenalidomide	2A
Repeat primary induction therapy (if relapse at > 6 months)	2A
Thalidomide	2A
Thalidomide + dexamethasone	2A

Category 1: Uniform NCCN consensus based on high-level evidence.
Category 2A: Uniform NCCN consensus based on lower evidence, including clinical experience.
Category 2B: Nonuniform NCCN consensus but no major disagreementç.
Data from NCCN Guidelines NCCN. Clinical Practice Guidelines in Oncology. Multiple myeloma (Version 1.2011). http://www.NCCN.org.

One of the most important questions that remain in the treatment of the relapsed-refractory patient is whether to use multiple active agents at the same time or to use agents sequentially. As an example, the combined use of bortezomib with lenalidomide has not been proven to be superior to each agent combined with chemotherapy or dexamethasone. Until combined bortezomib and lenalidomide is found to be a superior treatment, sequential use of these agents may be able to extend the duration of effective therapy.

Treatment decisions for individual patients with relapsed disease may potentially be improved by taking into account patient-specific information such as the type of previous therapies, adverse cytogenetics, and end-organ dysfunction. For example, in patients with relapsed MM, combined bortezomib and liposomal doxorubicin has shown improved time to progression compared to bortezomib alone including patients who had received prior anthracyclines, lenalidomide, and thalidomide.[105] In contrast, treatment with lenalidomide and dexamethasone resulted in a significantly shorter time to progression in patients that had previously been treated with thalidomide than in thalidomide-naïve patients.[56]

The NCCN guidelines offer many options for salvage, including thalidomide, lenalidomide, or bortezomib with or without dexamethasone or chemotherapy (Table 144–5). In addition, autoHSCT or nonmyeloablative alloHSCT also have a role as salvage therapy in some patients.[14] Careful selection of therapy based on disease and patient risk factors and previous treatment will allow for maximal clinical benefit.

EVALUATION OF THERAPEUTIC OUTCOMES

Because MM is currently not a curable disease, the goals of therapy are to prolong survival and to improve quality of life. Patients with asymptomatic MM are usually followed and not treated. Asymptomatic patients are assessed every 3 to 6 months for disease progression, which would then require therapy. Assessment involves measurement of M protein in blood and urine and laboratory tests

that include complete blood count, serum creatinine, and calcium. Patients are treated as the disease produces symptoms. Disease response is defined by a decline in M protein. After completion of the initial course of therapy and response is obtained, patients should be monitored every 3 months. Bone surveys are performed yearly or as required because of changes in symptoms. Various other tests are performed on an as-needed basis to evaluate disease status, including bone marrow biopsy, magnetic resonance imaging, and positron emission tomography, or computed tomography scan.

CONCLUSIONS

MM remains an incurable disease despite significant therapeutic advances. Lenalidomide plus dexamethasone is a reasonable upfront regimen for both autoHSCT eligible and ineligible patients. Patients who are not candidates for autoHSCT are often older with lower performance status and lenalidomide combined with low dose dexamethasone may be a better tolerated option. Bortezomib plus dexamethasone or chemotherapy may be particularly valuable in patients with MM who have high-risk cytogenetics. Younger patients with good performance status should receive autoHSCT after a short course of induction. The use of maintenance therapy after autoHSCT should be considered as part of a clinical trial. Nonmyeloablative alloHSCT may produce long-term disease-free survival but may require that the patient achieve a minimal residual disease state prior to the transplant procedure. When patients progress after initial therapy, salvage therapy may include regimens that contain thalidomide, lenalidomide, or bortezomib; autoHSCT and alloHSCT may be used in patients who are able to tolerate transplantation. Although there now are multiple therapies that can be used and there has been improvement in survival times and quality of life, MM remains a fatal disease that requires continued treatment advances.

ABBREVIATIONS

alloHSCT: allogeneic hematopoietic stem cell transplantation

autoHSCT: autologous hematopoietic stem cell transplantation

bFGF: basic fibroblast growth factor

IFN: interferon

IL: interleukin

IκB: inhibitor of NF-κB

ISS: International Staging System

LMWH: low-molecular-weight heparin

MGUS: monoclonal gammopathy of undetermined significance

MM: multiple myeloma

MP: melphalan plus prednisone

MPB: melphalan, prednisone, plus bortezomib

MPR: melphalan, prednisone, plus lenalidomide (Revlimid®)

MPT: melphalan, prednisone, plus thalidomide

NF-κB: nuclear factor kappa B

ONJ: osteonecrosis of the jaw

RANK-L: receptor for activation of NF-κB ligand

TNF-α: tumor necrosis factor alfa

VAD: vincristine, doxorubicin, plus dexamethasone

VEGF: vascular endothelial growth factor

VTE: venous thromboembolism

CHAPTER 145

Myelodysplastic Syndromes

JULIANNA A. BURZYNSKI AND TRACEY WALSH-CHOCOLAAD

KEY CONCEPTS

1. Myelodysplastic syndromes (MDS) primarily occur in the elderly, with median age at diagnosis between 75 and 84 years.
2. MDS are associated with environmental, occupational, and therapeutic exposures to chemicals or radiation.
3. The manifestations of MDS are due to immune dysregulation and genomic instability, which creates a dysplastic, clonal population of cells in a milieu unable to support normal hematopoiesis.
4. Most patients with MDS present with fatigue and lethargy or symptoms related to anemia-induced tissue hypoxia.
5. The prognosis of patients with MDS is variable. Overall survival ranges from a few months to several years and can be estimated with the International Prognostic Scoring System (IPSS) or World Health Organization Classification-based Scoring System.
6. Palliation of symptoms and improvement in quality of life are the goals of therapy for most patients.
7. Current guidelines recommend erythropoietin or darbepoetin for management of anemia in patients with MDS.
8. Allogeneic hematopoietic stem cell transplantation (HSCT) offers potentially curative therapy to patients with MDS who have a donor and are healthy enough for the procedure.
9. Hypomethylating agents are appropriate for patients with transfusion-dependent or symptomatic MDS who are not candidates for allogeneic HSCT.
10. Antithymocyte globulin is appropriate treatment for low or intermediate-1 IPSS risk, human leukocyte antigen DR15 positive expressing MDS in patients with symptomatic anemia that is unlikely to respond to erythropoietic agents.
11. Lenalidomide is the recommended initial treatment for low-risk 5q syndrome accompanied by symptomatic anemia.

Myelodysplastic syndromes (MDS) encompass a spectrum of clonal myeloid disorders characterized by ineffective hematopoiesis that results in anemia, thrombocytopenia, leukopenia, or a combination of peripheral cytopenias.[1–3] The hallmark feature of MDS is bone marrow dysplasia in at least 10% of cells of a single myeloid lineage.[3] MDS are frequently associated with clonal chromosomal abnormalities, qualitative disorders of blood cells, and a variable propensity for progression to acute myeloid leukemia (AML). The clinical course of patients with MDS varies along a continuum from a rapid progression to AML to years of slowly progressive bone marrow failure.[4]

CHAPTER 146

Renal Cell Carcinoma

CHRISTINE M. WALKO, NINH M. LA-BECK, AND MARK D. WALSH

KEY CONCEPTS

1. Renal cell carcinoma (RCC) predominantly occurs later in life, with 70% of all cases diagnosed between the ages of 55 and 84.
2. The most established risk factors for RCC are smoking, obesity, and hypertension.
3. Genetic factors contribute to ~15% of cases of RCC; the remaining 85% are believed to be sporadic.
4. Inactivation of the von Hippel-Lindau (VHL) tumor suppressor gene is the hallmark of the most common type of RCC, the clear cell subtype.
5. More than 50% of RCC cases are diagnosed by incidental findings on routine imaging for unrelated reasons.
6. The Memorial Sloan-Kettering Cancer Center Prognostic Factors Model for Survival classifies patients into low-, intermediate- and high-risk groups based on five clinical factors and can predict survival in untreated patients and those treated with immunotherapy and targeted agents.
7. Surgical removal of the primary tumor, either by total or partial nephrectomy, is the preferred initial treatment for all stages of RCC.
8. Immunotherapy used to be considered first-line therapy for metastatic RCC but has largely been replaced by targeted agents because of their improved efficacy and tolerability.
9. Sunitinib is an oral small molecule inhibitor of vascular endothelial growth factor (VEGF) and platelet-derived growth factor (PDGF) and is recommended as first-line therapy for metastatic RCC.
10. Sorafenib is an oral small molecular inhibitor of VEGF, PDGF, and c-kit and is recommended as second-line therapy for metastatic RCC.
11. Temsirolimus is an intravenously administered mTOR (mammalian target of rapamycin) inhibitor indicated for first-line therapy in patients with high-risk metastatic RCC.
12. Ongoing trials with approved and novel targeted therapies either alone or in combination with immunotherapy will elucidate optimal treatment options for RCC.

Renal cell carcinoma (RCC) is a less common malignancy that, until recently, had few treatment options that were poorly tolerated and resulted in few positive outcomes for patients. However, treatment for the disease has been revolutionized by an increased understanding of the pathophysiology of RCC. Clear cell is the predominant subtype of RCC and is the result of inactivation of the von Hippel-Lindau (VHL) tumor suppressor gene on chromosome 3p25, which leads to increased production of growth factors such as vascular endothelial growth factor (VEGF), transforming growth factor (TGF), platelet-derived growth factor (PDGF), and others responsible for angiogenesis and cell growth.[1] Before 2005, the primary therapy option for patients with advanced RCC following nephrectomy was immunotherapy with few responses and high toxicity. However, six new drugs were approved recently either as first- or second-line therapy for RCC: sorafenib, sunitinib, temsirolimus, bevacizumab (in combination with interferon-α), everolimus, and pazopanib.[2–7] Each is an example of targeted therapy against growth factors important in the pathophysiology of RCC and has yielded much needed progress in a disease with few therapeutic options. RCC serves as an example of rational development of targeted agents based on knowledge of tumor biology for the treatment of other malignancies.

CHAPTER 147 Melanoma

CINDY L. O'BRYANT AND JAMIE C. POUST

KEY CONCEPTS

1. Cutaneous melanoma is an increasingly common malignancy, but it is a cancer that can be cured if detected early. Public education about screening and early detection is one strategy for controlling the increase in incidence and the mortality associated with cutaneous melanoma.
2. Surgical resection can cure patients with early-stage melanoma.
3. The toxicities associated with interferon-α_{2b} therapy are significant and require patient education, close patient monitoring, and appropriate dose modification based on toxicity.
4. Patients with locally advanced disease should be evaluated for adjuvant therapy; recommended options include interferon α_{2b} or participation in a clinical trial.
5. High-dose aldesleukin (interleukin 2) is an option for some individuals with metastatic melanoma. The toxicities associated with this regimen are significant and warrant close patient selection. Individuals receiving high-dose aldesleukin require close monitoring and management by an experienced healthcare team. A small subset of patients experience a durable response with this therapy, although the question of risk versus benefit should be assessed on an individualized basis.
6. Metastatic melanoma remains a clinical challenge. At this time, there is not a single standard treatment approach for individuals with metastatic disease. Dacarbazine and temozolomide are considered the most active chemotherapies and can be used as single agents. Combination chemotherapy has not been shown to be superior to single-agent therapy with dacarbazine.
7. As the biology of melanoma has been further delineated, a growing number of potential targets for drug therapy have been identified. Recent work has focused on drugs that target specific pathways of melanoma development and progression.

Melanoma is the sixth most common cancer in the United States. The incidence of melanoma steadily increased from the 1970s to the 1990s and has remained relatively stable since 2000. While nonmelanoma skin cancers (NMSCs) are the most common malignancies of the skin, cutaneous melanoma accounts for up to 75% of all skin cancer-related deaths. With the rise in the number of melanoma skin cancer and the associated mortality, it is essential to consider issues of care beyond that of disease treatment. Skin cancer prevention and screening have a major impact on public health and on the success of treatment for those individuals diagnosed with both NMSC and melanoma. Skin cancers tend to occur more frequently in older individuals. Therefore, as the population continues to age, effective strategies to prevent, detect, and treat individuals with these cancers are needed.

The incidence of melanoma varies worldwide with the highest rates found in Australia, New Zealand, North America, and Northern Europe. In the United States, the lifetime risk of developing melanoma is greater in men (2.6%) than women (1.7%) and varies with ethnicity, whites 2%, Hispanics 0.5 %, and blacks 0.1%.[1] The median age at diagnosis is 59 years old.[2] In 2010 it was estimated that approximately 68,130 new cases of melanoma would be diagnosed in the United States. Unfortunately, this estimate may not be accurate because many superficial and in situ melanomas are managed in facilities that do not routinely report their cases to cancer registries.[1] Childhood and adolescent melanoma is rare with 2% of cases being diagnosed in individuals <20 years old. The incidence in this age group is increasing by 2.9% per year. Young adults between the ages of 15 and 19 years account for approximately three quarters of childhood melanomas. Different than the adult population, the incidence of melanoma appears to be the same between genders except in the 10- to 19-year-old age group where the incidence is higher in girls than boys.[3]

The estimated number of individuals expected to die of melanoma in 2010 in the United States is approximately 8,700. While the 5-year survival rates for melanoma have increased from 82% in 1975 to 92% in 2004, the overall mortality rate has remained stable.[1] Men >65 years old have the highest mortality rates from melanoma. Death rates have declined in younger patients. The stabilization of mortality rates appears to be related to efforts at both primary and secondary prevention of melanoma in addition to advances in the treatment and management of melanoma patients.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

ETIOLOGY AND EPIDEMIOLOGY

The etiology of melanoma, like most other malignancies, is not fully understood. A number of patient-specific factors and environmental factors have been identified (Table 147–1), and it is likely that these factors alone or in combination increase the occurrence of cutaneous melanomas.

Individual physical characteristics can determine responses to UV radiation. White persons with fair-colored hair (red or blond), light-colored eyes (blue or green), high degrees of freckling and those who have a tendency to burn and rarely tan with exposure to sunlight appear especially at risk.[4,5] Clinical and epidemiologic research show a higher rate of melanoma in those who have

TABLE 147-1 Risk Factors for Melanoma

Patient-specific risk factors
Adulthood (age >15 years)
History of cutaneous melanoma
Dysplastic nevi
High density of common nevi and atypical nevi
Cutaneous melanoma in first-degree relative
Immunodeficiency/immunosuppression
High degree of freckling
Sunburns easily/tans rarely
Blonde or red hair
Blue, green, or gray eyes
Socioeconomic status (higher > lower)
Race (white > Hispanics > black)
External risk factors
Intense intermittent sun exposures
History of sunburn
More than four painful sunburns before age 15 years
Recreational sun exposure

extensive or repeated intense sun exposure.[6] Intermittent intense sun exposure, blistering sunburns, and the time of life of exposure to the sun now are believed to be critical factors for development of cutaneous melanoma and individuals with a history of these are at this highest risk. Individuals who have had chronic sun exposure without a history of burning and those with occupational exposure have a lower risk. The risk with sunlight and UV radiation seems to be greatest during childhood and adolescence and is more hazardous than exposure during adult life.

One of the most important risk factors for melanoma is the number of melanocytic nevi (pigmented lesions or moles) on the body. The formation of these nevi has been shown to be directly related to cumulative sun exposure. The relative risk of developing melanoma increases with the greater the number of typical nevi an individual has. A second risk factor is the presence of atypical melanocytic nevi.[4] Atypical nevi may progress from a normal nevus or be dysplastic from the onset. Up to one fifth of melanomas develop from atypical nevi and individuals with these have an increased risk of developing melanoma as compared to the general population. Small congenital melanocytic nevi may be present at birth or within the first few months after birth. Approximately 1% to 3% of newborns are born with pigmented lesions, and the lifetime risk of developing melanoma is related to the size of the nevus.[3]

Immunocompromised patients are at an increased risk for development of cutaneous melanoma.[3,5] Immunodeficiency includes individuals with ataxia telangiectasia, chronic lymphocytic leukemia, Hodgkin lymphoma, and immunosuppression following organ transplant. Acquired immunodeficiency syndrome has been shown to increase the risk of developing cutaneous melanoma, and the disease often is more aggressive.[7] Personal history of nonmelanoma or melanoma skin cancers is a risk factor for subsequent melanoma and may be associated with a poor prognosis. Xeroderma pigmentosum is a rare skin disorder but does carry an increased risk for melanoma.

A rare but important risk for melanoma is maternal–fetal transfer of melanoma. Although melanoma is not the most common cancer in pregnancy, it is the cancer most likely to metastasize to the placenta and the fetus.[3] Maternal–fetal transmission of melanoma is commonly lethal. However, neonates delivered with concomitant placental involvement but without clinical evidence of disease still are considered to be at increased risk for development of disease.

A number of genes have been implicated in melanoma development and progression, and molecular profiling studies have identified several distinct molecular subclasses of melanoma.[8] Familial atypical multiple mole syndrome (FAMMS) or dysplastic nevus syndrome is a hereditary disease characterized by a predisposition to develop dysplastic nevi and cutaneous melanoma. Approximately 8% to 10% of cases of melanoma are associated with a family history or hereditary dysplastic nevus syndrome. Patients with familial atypical multiple mole syndrome suggest a risk for melanoma of 400- to 1,000-fold higher than that seen in the general population. The mode of inheritance is somewhat controversial and is believed to be polygenic.

Genetic studies of this heritable trait in families led to the identification of *CDKN2A* as the familial melanoma gene, located at chromosome 9p21. *CDKN2A* encodes two distinct proteins: inhibitor of cyclin-dependent kinase 4 (INK4A or $p16^{INK4a}$) and ARF (p14ARF). INK4A regulates cell cycle progression at the G_1/S checkpoint by inhibiting the G_1 cyclin-dependent kinases that phosphorylate and inactivate the retinoblastoma protein. ARF inhibits p53 degradation; therefore, loss of ARF inactivates p53. The frequency of *CDKN2A* mutations vary in melanoma but are found more commonly in individuals with familial inheritance patterns and are associated with multiple cases of melanoma in a family, young age at diagnosis, multiple primary melanomas amongst family members, and pancreatic cancer.[9]

One of the major signaling pathways found to be associated with the development of melanoma is the mitogen-activated protein kinase pathway (MAPK) which mediates receptor tyrosine kinases resulting in activation of RAS and downstream BRAF. Activating *BRAF* mutations are the most common somatic genetic event in human melanoma, occurring in 25% to 70% of melanoma patients and primarily noted by a single point mutation *BRAF* (V600E). *BRAF* does not appear to be an inherited disposition gene, but the high prevalence of *BRAF* mutations in cutaneous melanoma appear to be an epidemiologic link between ultraviolet (UV) radiation and melanoma. *BRAF* mutations are common in melanomas arising from skin with intermittent sun exposure and not as common in melanomas in chronically sun-exposed areas. This may be an early event in the damage to the melanocytes as these mutations are also found in benign and dysplastic nevi.[5]

Other genetic alterations involved with the development of melanoma include *MITF* (microphthalmia-associated transcription factor), a gene that is important to the survival of melanocytes and has been shown to play a key role in melanoma signaling. The melanocortin 1 receptor gene (*MC1R*), which is associated with the red hair/fair skin phenotype, is involved in melanin synthesis and is more prevalent in individuals with melanoma. *NEDD9* modulates metastatic activity and has been found to be unregulated in melanoma. These melanoma-specific pathways give better understanding of the biology of the disease and may lead to better more directed treatment. A variety of other molecular pathways and receptor tyrosine kinases are also being studied to identify their role in the development of melanoma.[5]

Sunlight is one of the most important environmental factors in the pathogenesis of melanoma, and the incidence of melanoma has been associated with latitude and the intensity of solar exposure among susceptible populations. Radiation in the ultraviolet B (UVB) range (280 nm to 320 nm) is historically considered to be the critical factor linking sunlight and melanoma, although prolonged exposure to ultraviolet A (UVA) radiation (320 nm to 400 nm) also may be important. Use of older UVB-blocking sunscreens may not be as protective as once thought because they allow more sustained sun exposure without any clinical symptoms of burn (e.g., erythema or pain), ultimately resulting in intense irradiation of the skin by UVA light.

PATHOGENESIS

Melanomas most often arise within epidermal melanocytes of the skin, although they also can arise from noncutaneous melanocytes. Human melanocytes are dendritic pigmented cells that arise from

the neural crest tissue during early fetal development and migrate over a predictable route to a variety of sites within the body, including the skin, uveal tract, meninges, and ectodermal mucosa. In adults, most melanocytes are located at the epidermal–dermal junction of the skin and the choroid of the eye, but they can be found in other tissues such as the meninges and the alimentary and respiratory tract. Primary melanoma can arise in any area of the body with melanocytes. The skin is the most frequent site of melanoma; cutaneous melanoma constitutes 90% of all melanoma. Primary melanoma can arise in the eye (ocular melanoma) and less frequently the mucosa and metastatic disease with unknown primary site.[5]

Normal melanocytes arise from melanoblasts. They undergo a series of differentiation events before reaching a final end-cell differentiation state and can be arrested in their differentiation process at any given state of maturation without loss of their proliferation capacity. Melanocytes adhere to the basement membrane of the epidermis and, despite a resting state, maintain a lifelong proliferation potential. The existence of melanoma stem cells has been suggested from work with cells from melanoma lines.[8]

Melanocytes synthesize melanin to protect various tissues, such as the skin, from UV radiation–induced damage and reach the keratinocytes in the upper layers of the epidermis via dendrites. Tyrosinase is an essential enzyme within melanosomes that synthesizes melanin. They are resistant to severe UV radiation, unlike keratinocytes, and their survival leads to the proliferation of mutated genes.[6]

Skin melanocytes transform from preexisting nevocellular nevi in the development of melanoma. A series of distinct steps are involved in the development and progression of melanoma from melanocytes. The pathologic components of the progression in human melanoma involve a series of morphologic stages: melanocytic atypia, atypical melanocytic hyperplasia, radial growth phase in which limited growth and radial expansion of the nevi may occur without metastatic competence, primary melanoma in the vertical growth phase with or without in-transit metastases, regional lymph node metastatic melanoma, and distant metastatic melanoma.[4] Primary melanoma is characterized by radial growth and limited vertical thickness (<0.75 mm). Primary melanoma demonstrates little tendency to metastasize. Melanoma has a potential for metastasis formation with the onset of a vertical growth phase. Therefore, the thickness of a primary melanoma is an important prognostic factor and is used in the staging classification of cutaneous melanoma. Of note, melanomas can skip steps in this development pathway.

Normal melanocytes require growth factors for proliferation, but melanoma cells can proliferate without growth factors. Melanoma cells secrete a variety of growth autocrine and paracrine factors that may facilitate proliferation. Additionally, with disease progression, melanoma cells increase production of certain growth factors and cytokines. The phosphatidylinositol 3-kinase (PI3K)–AKT pathway often is overactive in melanoma. Integrins and growth factors promote growth and survival of melanoma through these pathways.

Basic fibroblast growth factors (bFGFs) are thought to be important mediators of growth stimulation and cell survival and act as motility factors for melanoma cells as well as upregulate serine proteinases and metalloproteinases. Melanoma cells are strong producers of chemoattractive proteins such as interleukin 8. Vascular endothelial growth factor can be triggered in the vertical growth phase.[10] Most of these changes occur between the radial growth phase and vertical growth phase of primary melanoma, and metastatic cells often show the highest cytokine production.

Understanding the biology of melanoma has provided potential targets for drug therapy.[11,12] For example, the role of bFGF in the pathogenesis of melanoma has led to investigation of antisense oligonucleotides to block bFGF. Other pathways, such as mitogen-activated protein kinase pathway has been targeted by RAF and MEK inhibitors and the PI3K/AKT pathway by mTOR inhibitors. As pathways are identified and as agents that inhibit these pathways enter clinical trials and practice, there is growing excitement about the opportunities to impact treatment of melanoma in new and effective ways.

Immune factors appear to be involved in the progression of melanoma more often than in most other solid tumors.[3,5] Spontaneous cancer regressions are rare but are a well-documented phenomenon seen in melanoma. Focal regression in primary melanoma has been reported. Tumor regression appears to be associated with host immunity.

A number of different tumor antigens have been identified in the cellular membrane and cytoplasm of melanoma cells and are referred to as melanoma-associated antigens. Ganglioside antigens have been of particular interest in the development of immunotherapy for melanoma. A large number of monoclonal antibodies to melanoma-associated antigens have been developed and are being evaluated in clinical trials for diagnosis of and therapy for melanoma.

The humoral and cellular responses of individuals with melanoma who express melanoma-associated antigen have been described and provide the rationale for immunotherapy in the management of metastatic melanoma.[5] Melanoma-directed antibodies have been isolated in the sera of patients with melanoma. The presence of antimelanoma antibodies in the sera of patients correlates with the clinical status of the patients, and the antibodies gradually disappear from the serum as the disease progresses. This phenomenon may be explained by the possible formation of anti-idiotype antibodies directed against the antimelanoma antibodies, an increase in the circulation of soluble tumor antigens that saturate all antibody combining sites, increased levels of immunosuppression, or absorption of antibodies on the tumor mass.

Interest has focused on the role of cell-mediated immune response in melanoma. Specific cell-mediated responses may play a role in tumor regression, but the role of specific cells, such as cytotoxic T lymphocytes (CTLs), is not fully understood. Tumor-infiltrating lymphocytes (TILs) have been shown in vivo and in vitro to possess antitumor reactivity. TILs contain a large number of mature tumor-specific lymphocytes and have been a target for manipulation in immunotherapeutic approaches for melanoma.[5] Two identified targets are cytotoxic T lymphocyte antigen 4 (CTLA-4) and toll-like receptor 9 (TLR9). CTLA-4 is a glycoprotein expressed on the surface of activated T cells that appears to have an inhibitory effect on T cells. Blocking the effect of CTLA-4 could be an effective strategy for increasing the T-cell antitumor response.[13]

HISTOLOGIC SUBTYPES

Cutaneous melanomas are categorized by growth patterns. Four major histologic subtypes or growth patterns of primary cutaneous melanoma have been identified: superficial spreading melanoma, nodular melanoma, lentigo maligna melanoma, and acral lentiginous melanoma. Clinical outcomes of the four major melanoma subtypes are similar, if the comparison controls for depth of penetration or tumor thickness. Any of the four subtypes can present as an amelanotic variant. Amelanotic melanomas appear to be devoid of clinically apparent pigmentation. Two less common types of melanoma include desmoplastic melanoma and lentiginous melanoma. Desmoplastic melanoma is more commonly seen in older individuals and its clinical presentation is similar to that seen in nonmelanoma skin cancers. If a biopsy of the lesion is not obtained, the disease may be mismanaged. Lentiginous melanoma is histologically different than the four major subtypes. Uveal melanoma is considered a separate disease from cutaneous melanoma.

Superficial spreading melanoma is the most common morphologic type of cutaneous melanoma, accounting for approximately 70% of all melanomas.[5] The lesions usually arise from a preexisting nevus, known as a *precursor lesion*, and evolve slowly over 1 to 5 years. At some point, superficial spreading melanoma may progress to a more rapid growth phase. Early in lesion development, the superficial spreading melanoma is flat, but the surface becomes irregular and asymmetrical as the lesion progresses. The lesion enlarges when it enters into a rapid growth phase, and the edges appear notched or lacy. The lesions can be blue, black, or pink. Areas within the lesion may be hypopigmented. These patches of color variation, specifically the hypopigmented areas, are thought to be associated with tumor regression within the lesion or pigment inconsistency. The clinical differential diagnosis of superficial spreading melanoma includes both benign and malignant skin disease. This subtype is sometimes confused with seborrheic keratoses or pigmented basal cell carcinoma. Superficial spreading melanoma may occur at any anatomic site on the body, but they are more commonly seen on the back in men and on the legs in women. This subtype of melanoma is more common in women. The mean age of diagnosis of superficial spreading melanoma is 50 years, which is earlier than that seen for other subtypes. Superficial spreading melanoma usually occurs after puberty.

Lentigo maligna melanoma represents 10% to 20% of melanomas and is commonly found on the head and neck. It is unique from other histologic subtypes because due to its prolonged radial growth phase it does not have the same propensity to metastasize.[5] Lentigo maligna melanoma arises on chronically sun-exposed sites in older individuals and presents as a freckle-like lesion. Lentigo maligna melanomas are generally large (>3 cm), flat, and tan-colored lesions with shades of brown and black. The lesions gradually grow and develop darker, with asymmetric flecks in areas. Lentigo maligna melanoma is uncommon before age 50 years and may have been present for more than 5 years. Only approximately 5% to 8% of lentigo maligna melanoma evolve into invasive melanoma, which is characterized by nodular development within the flat precursor lesion. Lentigo maligna melanoma can be difficult to distinguish from solar lentigo, which typically is a smaller and evenly pigmented flat-appearing lesion.

Nodular melanoma is the second most common growth pattern of melanoma, occurring in 15% to 30% of patients. Nodular melanoma is a pure vertical growth phase disease. In nodular melanoma, a small expansive nodule in the papillary dermis invades the reticular dermis and subcutis. The radial growth phase is absent at all times. Nodular melanomas are more aggressive and develop more rapidly than superficial spreading melanoma. Nodular melanomas are dark blue–black and often uniform in color with a shiny surface, although a small percentage of nodular melanomas are amelanotic and have a fleshy appearance. Nodular melanomas are raised and often symmetric. They can occur at any age, typically around 50 years of age, and are most common on the trunk, head, and neck. Nodular melanomas are more common in men. Of note, nodular melanomas can resemble traumatized nevi.

Acral lentiginous melanoma makes up approximately 5% of melanomas and is most likely not related to UV exposure. It presents as three distinct clinical subtypes: melanoma on the palms of the hands or soles of the feet, subungual melanoma, and mucosal melanoma.[5] Most acral lentiginous melanomas are located on the soles of the feet and look like a large tan or brown stain. The lesions often have irregular convoluted borders. The initial macular component of palmar/plantar melanomas can be masked by the thickened stratum corneum at these sites. Many of these lesions look verrucous in appearance, making them difficult to distinguish from warts by the untrained eye. Suspicious lesions on the palms or soles of the feet should be evaluated. Acral lentiginous melanoma includes subungual melanoma, which arises in the nail matrix or nail bed. The most common presentation is a brown or black line in the great toe or the thumbnail. Mucosal melanoma is rare but can occur on any mucosal surface. Mucosal melanoma occurs most commonly in the oropharyngeal mucosa, followed by the anal/rectal mucosa, genital mucosa, and urinary mucosa. Unfortunately, mucosal melanoma often does not become clinically apparent until the mass is large or the lesion bleeds. Acral lentiginous melanoma occurs in less than 10% of white people with melanoma but is the most common type of melanoma reported in individuals with a dark complexion (e.g., African Americans, Asians, and Hispanics). Like lentigo maligna melanomas, this subtype is characterized by a protracted radial growth phase.

Uveal melanoma is the most common primary intraocular malignancy seen in adults but is an uncommon tumor.[14] Unlike cutaneous melanoma, the frequency and mortality of uveal melanoma have remained steady. This melanoma arises from the pigmented epithelium of the choroid. Iris melanoma is a subset of uveal melanoma and tends to have a more benign course. The risk of metastasis varies with the histologic type and size of the tumor as well as the location in the eye. Metastases occur most frequently in the liver but have been documented in a variety of tissues.

The ability to predict the metastatic potential of melanomas would be a valuable prognostic tool. An attempt to predict the likelihood for metastasis is based on radial and vertical growth phases. Radial growth phase describes the early stage of melanoma when the tumor is thin and primarily intraepidermal in location. By definition, malignant melanoma in situ is a form of radial growth phase melanoma. Vertical growth phase is the stage of melanoma with clear metastatic potential.

CLINICAL PRESENTATION

Benign nevi often occur in sun exposed areas and typically are 4 to 6 mm in diameter (about the size of a pencil eraser), raised or flat, are uniform in color and round in shape. Dysplastic nevi are believed to be a link between benign nevi and melanoma. Dysplastic nevi tend to be larger that the common nevi (>5 mm), appear as flat macules with asymmetry, have a fuzzy or ill-defined shape, and vary in color. Compared to melanoma lesions, dysplastic nevi appear less evolved.

The initial clinical presentation of melanoma often is a cutaneous lesion and is dependent on the histologic subtype as well as the stage of development of the lesion. The lesion can be located anywhere on the body but is most commonly discovered on the lower extremities in women and on the back and trunk in men. The cardinal clinical feature of a cutaneous melanoma is a pigmented skin lesion that changes over a period of time. The clinical features used to describe or evaluate a questionable lesion are highlighted by the mnemonic "ABCDE." Unlike benign pigmented lesions, the shape of a melanoma lesion is often (A) *asymmetric*. Benign lesions tend to have regular margins, whereas melanoma lesions often have irregular (B) *borders*. The (C) *color* of melanoma lesions is often variegated, ranging in color from tan to blue-black, and at times the lesion is intermingled with colors of red, purple, and white. The size or (D) *diameter* of a melanoma lesion is frequently 6 mm or greater when identified, whereas benign lesions usually are smaller. Early melanoma lesions may be diagnosed at a smaller size, and size of a lesion should not be used as "the trigger" to have a suspicious lesion evaluated. Another warning sign of a potential melanoma is the *enlargement* or *evolution* (E) in preexisting nevi. Changes such as a sudden or continuous enlargement of a lesion, an elevation of a lesion, or any change in the skin surrounding a nevus, including redness or swelling, are important clinical signs. Uncommonly, the sensation

of the lesion may become itchy or tender and painful. Friability of the lesion resulting in bleeding or oozing is a danger sign. Perhaps the most important warning sign of danger is the evolution in any characteristic of a lesion.

The diagnosis of melanoma is complicated by the number of pigmented moles (melanocytic nevi) and nonmelanocytic lesions that resemble melanoma. An average of 10 to 40 ordinary nevi can be found on the skin of white adults. Nonmelanocytic pigmented lesions such as seborrheic keratoses, pigmented basel cell carcinoma, and vascular lesions, also can appear similar to a melanoma lesion. In childhood melanoma, commonly the lesions are thicker at the time of diagnosis. This may be in part to the low level of suspicion by pediatricians, the fact that many melanomas associated with congenital nevi develop in the dermis rather than the epidermis, and histological uncertainty.[3]

1 Improved survival rates for melanoma have been attributed to the identification and treatment of disease at an early stage, when the disease is limited and has not yet metastasized. It follows that one strategy to improve survival rates would be to increase efforts to identify early-stage melanoma. The cost-effectiveness of massive screening for all adults by a physician has never been demonstrated. However, routine examination of the skin by physicians is recommended for individuals, adults, or children who are at high risk. The entire cutaneous surface, including the scalp, should be examined.

It has been estimated that approximately 50% of the initial melanoma lesions found are discovered by self-examination. Therefore, one of the most direct strategies to improve early detection would be a method to increase effective skin self-examination (SSE) by the individual, the individual's partner, and/or a caregiver. Identification of early melanoma allows the opportunity to treat the lesions when they are thin and curable. Persons who perform SSE present for care at an earlier stage in the disease process and have 50% less advanced melanoma and lower mortality from the disease.[15] Healthcare individuals who routinely work with the public, such as community pharmacists, have an opportunity to increase public awareness concerning the benefits and appropriate methods for SSE. Educational pamphlets describing SSE (Table 147–2) for the public are widely available through the American Cancer Society, American Academy of Dermatology, and Skin Cancer Foundation. If a newly discovered pigmented lesion is identified or if a preexisting pigmented lesion changes, the individual should be evaluated by a physician immediately.

SSE is of special interest in the elderly. As the population of older adults (≥65 years of age) increases, it is expected that the mortality from melanoma also will increase. Barriers to successful SSE in the elderly, such as failing eyesight, lack of partners, and poor memory, impact the older adult in detecting new or changing lesions. These barriers, coupled with the higher incidence of melanoma in males, present a challenge and an opportunity for the healthcare professional to target education on this growing segment of our population.

A biopsy of the lesion is critical to establish diagnosis of melanoma. Subsequent pathologic interpretation of the biopsy will help provide information on prognosis and treatment options. An excisional biopsy with a 1 to 2 mm margin of normal-appearing skin is recommended for a suspicious lesion and should include a portion of underlying subcutaneous fat for microstaging. For larger lesions where an excisional biopsy is impractical, an incisional or punch biopsy can be performed and should include a core of full-thickness skin and subcutaneous tissue. When excisional biopsies are not appropriate, as with the face or palmar surface of the hands, a full-thickness incisional or punch biopsy is preferred. A shave biopsy is never appropriate because it can underestimate the thickness of the lesion and may not fully remove the lesion, and the scarring may mask the remaining tumor.

Evaluation of any individual with a suspected melanoma includes a complete history and total body skin examination. The focus of the patient history is identifying potential risk factors. Risk-related questions include an assessment of family history of melanoma, personal history of skin cancer and/or nevus excisions, sun exposure, and phenotype. Total dermatologic examination is necessary to determine melanoma risk factors (e.g., mole pattern, mole type, or freckling) and for staging. Melanoma commonly spreads to the lymph nodes, therefore individuals suspicious for advanced disease should have their lymph nodes examined for lymphadenopathy. Any clinical indication of regional lymph node involvement should be confirmed with fine-needle aspiration or on biopsy of the enlarged lymph node. Laboratory and imaging studies (chest x-ray, computed tomography (CT) with or without positron emission tomography (PET) or magnetic resonance imaging (MRI)) can be used in the workup for melanoma. These tests may not be sensitive in detecting occult disease in early-stage (stages I and II) patients and may be optional if an individual is low risk or asymptomatic.[16] Lactate dehydrogenase should be measured as elevated serum levels have been shown to be an independent predictor of decreased survival.[17] Additionally, any other signs or symptoms suggestive of metastatic disease should be completely evaluated.

TABLE 147-2 Self-Examination of Suspicious Moles

1. Examine your body front and back in the mirror, and then right and left sides with arms raised.
2. Bend the elbows and look carefully at the forearms and upper arms and palms.
3. Look at the backs of the legs and feet. Look specifically in the spaces between toes and at the soles of the feet.
4. Examine the back of the neck and scalp with the help of a hand-held mirror; part hair (or use a blow dryer) to lift hair and give yourself a closer look.
5. Check the back and buttocks with a hand-held mirror.

STAGING AND PROGNOSTIC FACTORS

The size of a primary melanoma lesion is associated with the likelihood of metastases. The prognostic factor originally used to determine survival was based on the cross-sectional profile of the primary tumor. The cross-sectional profile could be evaluated if the deepest invasive tumor cells lay above or below the sweat glands. This assessment was further clarified by Clark,[18] who described the relationship of depth of invasion of the cancer cells to the standard anatomic landmarks of the skin (Table 147–3). Clark's classification is a practical approach for patients with more superficial tumors, because tumors classified as Clark levels I through III seldom metastasize. The classification system has been criticized because of problems associated with practical measurements. Melanoma lesions that occur in the presence of lymphoid infiltration, fibrosis, or even the cells of preexisting nevi are difficult to assess with classic reference landmarks.

Breslow[19] replaced Clark's classification of reference landmarks with the use of thickness of the primary melanoma lesion. Tumor thickness is quantified to the nearest tenth of a millimeter with an

TABLE 147-3 Clark's Classification

Clark Level	Anatomic Landmark
N	Epidermis
I	Dermal-epidermal junction
II	Papillary dermis
III	Interface between papillar dermis and reticular dermis
IV	Reticular dermis and subcutaneous fat

ocular micrometer, measuring from the top of the granular layer of the overlying epidermis to the deepest contiguous invasive melanoma cell. The correlation between tumor thickness and probability of tumor metastases is strong but does not include aspects such as tumor satellites, defined rather arbitrarily as skin involvement within 2 cm of the primary lesion, and vascular invasion. It was once thought that the presence of satellite nodule(s) had the same impact on prognosis as a high-risk primary lesion (tumor thickness >4 mm). It is now known that patients with satellitosis have a worse prognosis than patients with thick primary lesions, and prognosis is more similar to that of patients with nodal metastases. A number of prognostic factors, in addition to tumor thickness and level of invasion, are associated with the risk for developing metastatic disease.[20]

The American Joint Committee on Cancer (AJCC) developed a staging system for melanoma that divides patients with localized melanoma into four stages according to microstaging criteria of Breslow and Clark.[21] In addition to consideration of the primary lesion, the AJCC staging system includes aspects of the tumor satellite, extent of lymph node involvement, and presence of metastatic disease.[21] Analysis of several large databases worldwide identified areas in which the AJCC staging system, which was published in 1997, did not reflect the natural history of melanoma. Issues such as the appropriate cutoff values for primary tumor thickness, ulceration of the melanoma, and satellite lesions of the primary tumor should be considered when making decisions about therapy.[20] The cutoff values initially proposed by Breslow for primary tumor thickness were initially used in the AJCC staging system, but it appears that cutoff depths of 1, 2, and 4 mm of thickness may better predict overall survival. Melanoma ulceration is associated with increased mitotic rate within a primary melanoma. The presence of ulceration of the primary lesion has been correlated with poorer survival for patients with very thin or thick lesions, but ulceration of the melanoma was not included in the 1997 AJCC staging system.

The revised AJCC staging system for cutaneous melanoma was published in 2002 and has been used for several years.[21] It is important to carefully examine older clinical trials to determine which staging system was used to determine patient inclusion and exclusion criteria, as results may differ based on these patient criteria. Revisions of the new melanoma staging system include (a) melanoma thickness and ulceration for all tumors (except T_1 tumors); (b) number of metastatic lymph nodes versus gross dimensions and delineation of clinically occult versus clinically apparent nodal metastases; (c) site of distant metastases and presence of elevated serum lactate dehydrogenase for metastatic disease; (d) upstaging of all patients with stage I, II, or III disease when a primary melanoma is ulcerated; and (e) new convention for separating clinical and pathologic staging to include information obtained from intraoperative lymphatic mapping and sentinel node biopsy. Clinical staging includes microstaging of the primary melanoma and clinical and radiologic evaluation. It is used after complete excision of the primary melanoma with clinical assessment for regional and distant metastasis. Pathologic staging includes microstaging of the primary melanoma and pathologic information about the regional nodes after partial or complete lymphadenectomy. At this time, it appears that patients with very limited disease (in situ or stage 0) do not require pathologic evaluation of lymph nodes (Tables 147–4 and 147–5). As with other solid tumors, the presence of regional lymph node involvement is a powerful predictor of tumor burden and patient outcome. In the past, the primary method for determining nodal status was surgical resection and analysis of the lymph nodes via a regional lymph node dissection. The extent of lymph node dissection was determined by the anatomy of the area of the lesion. In recent years, preoperative lymphoscintigraphy and intraoperative sentinel node mapping have become more widely used methods for identifying the first or sentinel lymph node in the direct pathway of lymph drainage from the primary cutaneous melanoma. Sentinel lymph node biopsy (SLNB) is a minimally invasive procedure that determines if a patient is a candidate for a complete lymph node dissection. The rationale for lymphatic mapping and subsequent sentinel node biopsy is based on the observation that regions of the skin have patterns of lymphatic drainage to specific lymph nodes in the regional lymphatic basin. The sentinel lymph node is believed to be the first node in the lymphatic basin into which the primary melanoma drains. Unlike other solid tumors, melanoma appears to progress in an orderly nodal distribution. Evaluation of sentinel nodes has been used for detection of micrometastases in breast cancer and in melanoma. SLNB allows for more thorough examination

TABLE 147-4 Melanoma TNM Classification

T Classification	Thickness	Ulcerative Status
T_X	Primary tumor cannot be addressed (e.g., shave biopsy)	
T_0	No evidence of primary tumor	
T_{is}	Melanoma in situ	
T_1	≤1 mm	A: No ulceration and level II/III B: With ulceration or level IV/V
T_2	1.01–2 mm	A: No ulceration B: With ulceration
T_3	2.01–4 mm	A: No ulceration B: With ulceration
T_4	>4 mm	A: No ulceration B: With ulceration
N Classification	**No. of Metastatic Nodes**	**Nodal Metastatic Mass**
N_X	Regional lymph nodes cannot be assessed	
N_0	No regional lymph nodes	
N_1	1 node	A: Micrometastasis B: Macrometastasis
N_2	2–3 nodes	A: Micrometastasis B: Macrometastasis C: In-transit metastases/satellite(s) without metastatic nodes
N_3	≥4 metastatic regional lymph nodes, matted metastatic nodes, metastatic lymph nodes, or intransit metastatic or satellite lesions in regional nodes	
M Classification	**Site**	**Serum Lactate Dehydrogenase**
M_X	Distant metastases cannot be assessed	
M_0	No distant metastasis	
M_1	Any distant metastasis	
M_{1a}	Distant skin, subcutaneous tissue, or nodal metastatic disease	Normal
M_{1b}	Lung metastases	Normal
M_{1c}	All other visceral metastases or distant metastasis at any site associated with elevated serum lactic dehydrogenase	Elevated

Micrometastases are diagnosed after sentinel or elective lymphadenectomy.
Macrometastases are defined as clinically detectable lymph node metastases confirmed by therapeutic lymphadenectomy or when any lymph node metastasis exhibits extracapsular extension.

of a single sentinel node than is possible when examining multiple lymph nodes with a lymph node dissection and may be most useful for melanomas located in ambiguous drainage sites such as the head and neck areas. SLNB is associated with low false-negative rates and low complication rates.[22] Detection of clinically undetectable disease in a lymph node basin that is not directly adjacent to the primary lesion may allow for upstaging of patients who initially are believed to have node-negative disease.

Reverse-transcription polymerase chain reaction (RT-PCR) is another method used to detect occult micrometastases in biopsied lymph nodes. This technique identifies submicroscopic levels of melanoma-specific genetic material. Initial studies with RT-PCR suggested that individuals who were RT-PCR negative had increased survival. Since these data have not been confirmed in a larger prospective trial, the prognostic value of RT-PCR remains unclear.[5,23] Strategies that combine RT-PCR with other newer detection methods are being evaluated.

The stage of melanoma at the time of diagnosis is one of the primary indicators of natural history of the disease and contributes to prognosis. Tumor thickness, level of tumor invasion and ulceration all contribute to the stage of a patient and their overall outcome. Other factors such as tumor growth pattern or histological subtype, mitotic rate, density of TILs infiltrating the tumor tissue, elevated lactate dehydrogenase, satellite lesions, angiolymphatic invasion, gender, and age also have been reported to have an impact on survival (Table 147–6). The location of the primary tumor on the skin is also important as individuals with tumors of the extremities have an increased survival as compared to those with axial, neck, head, and trunk tumors. In addition, a number of additional prognostic factors have been identified in patients with advanced disease. The number of metastatic sites, disease involvement of the gastrointestinal tract, liver, pleura, or lung, Eastern Cooperative Oncology Group (ECOG) performance status ≥1, male sex, and prior immunotherapy have been associated with poor prognosis.[20]

TREATMENT

Melanoma

Treatment of cutaneous melanoma depends on the stage of disease. Local disease is managed, and often cured, with surgical ablation. Regional disease is treated with surgical resection of the primary lesion and, depending on the risk of recurrence, possibly adjuvant therapy. Use of adjuvant therapy after surgical resection and the role of interferon-α as adjuvant therapy remain controversial. Treatment of disseminated melanoma continues to be a challenge. Although numerous clinical trials have evaluated single-agent and combination chemotherapy, immunotherapy, targeted therapy, and biochemotherapy regimens, there is not a single standard approach for management of the individual with metastatic melanoma.[4,5,16,24]

SURGERY

2 Patients who present with a suspicious pigmented lesion should undergo a full-thickness excisional biopsy, if possible. Sites at which excisional biopsy is inappropriate include the face, palm of the hand, sole of the foot, distal digit, and subungual lesions. A full-thickness incisional or punch biopsy is preferred in these cases to provide microstaging and ultimately to determine therapy.

Localized cutaneous melanoma can often be cured with surgical excision. The cure rates for melanomas <1 mm are as high as 98%.[5] The extent of the excision margin is important in preventing local recurrence and ultimate survival. For melanoma in situ, excision of the visible lesion or biopsy site with a 0.5 to 1 cm border of clinically normal skin and a layer of subcutaneous tissue with confirmation

of histologically negative peripheral margins is recommended. The recommended clinical margin for invasive melanoma depends on the tumor thickness. Excision with a 1 cm margin of clinically normal skin and underlying subcutaneous tissue is recommended for invasive melanomas ≤1 mm thick.[16,25] The appropriate margin of excision for melanomas between 1 and 2 mm in thickness is controversial. A study suggests the risk of locoregional recurrence is higher when melanomas that are at least 2 mm thick are excised with a 1 cm margin rather than a 2 cm margin.[26] Current National Comprehensive Cancer Network (NCCN) guidelines recommend a 1 to 2 cm margin for melanoma with tumor thickness of 1.01 to 2 mm.[16] Lesions that are 2 to 4 mm thick should be excised with a 2 cm margin. Primary tumors more than 4 mm thick require at least a 2 cm margin, but whether a larger margin is beneficial is not clear. Surgical management of lentigo maligna melanoma is problematic, as subclinical extension of atypical junctional melanocytic hyperplasia may extend beyond the visible margins. Complete excision of these lesions is important.

When isolated regional lymph nodes are detected via physical examination in the absence of distant disease, therapeutic lymphadenectomy is recommended. The extent of therapeutic lymph node dissection often is modified according to the anatomic area of the lymphadenopathy. Prophylactic lymphadenectomy in all patients is not recommended. Although a subgroup of patients with early-stage melanoma will have microscopic metastatic disease in nonpalpable lymph nodes, prophylactic regional lymph node dissection does not prolong survival or decrease time to relapse in randomized clinical trials.[5,27,28] Selective regional lymphadenectomy performed after scintigraphic and dye lymphographic identification of the affected sentinel draining lymph node(s) is the standard of care for melanomas >1 mm thick. If the sentinel node is found to have micrometastatic melanoma, regional dissection of the involved nodal basin is performed. If the lesion is 0.75 to 1 mm in thickness with ulceration or is Clark level IV or V, lymphatic mapping with sentinel node biopsy may be considered based on patient characteristics such as ulceration of the tumor.[24] Of note, the likelihood of detecting metastatic disease in the sentinel lymph node depends on tumor thickness. The likelihood of detecting metastatic disease is approximately 1% in tumors that are less than 0.8 mm but increases to more than 30% in tumors 4 mm thick.[24] Sentinal lymph node biopsy results are important for accurate staging, therapeutic lymphadenectomy, and to aid in the decision to offer adjuvant treatment.[22,27]

One of the most important aspects of surgical management of cutaneous melanoma is the role of patient followup.[4,16] Postsurgical followup of patients who have had a melanoma excised is essential to monitor for undetected metastatic disease and the development of a second primary cutaneous melanoma or nonmelanoma primary malignancy. Scheduled screening in addition to routine surgical followup are required for any patient with a melanoma; the recommended frequency and duration depend on the stage of melanoma. The optimal duration of followup remains controversial. Most patients who develop recurrent disease will do so in the first 5 years after treatment, but late recurrences more than ten years after surgery have been observed. The increased lifetime risk of developing a second primary melanoma supports lifetime dermatologic surveillance for all patients.

Curative surgery usually is limited to patients with early-stage disease. A patient with stage III melanoma usually has lymph node involvement, but in-transit metastases also may occur. In-transit metastasis is the clinical manifestation of tumor that develops in lymphatics between the primary melanoma and the regional lymph node basin.[5] In-transit metastases are more than 2 cm from the original lesion. In-transit metastases are more common in individuals with thick ulcerated lesion. Surgery is used for management of in-transit lesions, and the goal is complete resection. Unfortunately, subsequent recurrence in the same extremity often occurs after initial resection of in-transit metastases.

The role of surgery beyond that of cure is less clear, although surgery may offer palliation for patients with isolated metastases.[27] Resection of isolated lesions in the brain and lungs may be appropriate in certain cases and should be evaluated based on individual patient criteria. Surgery can be an option in situations where the lesion is accessible and where the lesion may cause problems if not removed. Surgery can extend survival in select patients with metastatic disease. Patients whose metastases can be completely resected may experience improved quality of life, improved overall survival, and occasionally long-term disease control.[27]

Brain metastasis is a frequent complication of advanced melanoma. Approximately 20% to 50% of patients with stage IV disease will develop clinically apparent central nervous system involvement. Surgical resection, with or without radiation, has been used in select individuals. More recently, high control rates of brain metastases have been achieved with focal radiation therapy such as linear accelerator-based stereotactic radiosurgery or gamma-knife technologies.[29,30] Melanoma in the gastrointestinal tract can lead to bowel obstruction, and appropriate resection or bypass may allow the patient significant relief of symptoms. Despite the lack of controlled clinical trials, the impact on palliative surgery should be evaluated in the context of a patient's comfort and quality of life. Surgery may be an appropriate option if the perceived outcome is to provide patient comfort. On the other hand, surgery may constitute a significant physical challenge or financial burden to a patient with a limited life expectancy. The clinical scenarios involving surgical resection should be fully evaluated in terms of overall quality of life.

The risk of relapse and death after resection of a local or regional cutaneous melanoma is the primary determinant for use of adjuvant therapy after primary resection. Adjuvant trials have focused on patients at intermediate or high risk for recurrence.

IMMUNOTHERAPY

Melanoma is considered one of the most immunogenic solid tumors, and it appears to interact with and respond to the immune system of the host in which it arises. Spontaneous regressions of melanoma suggest the importance of the immune system in disease modulation. Lymphoid infiltration into the primary melanoma also suggests that immunomodulation may impact the biology of melanoma. Early work showed that nonspecific immunomodulators, such as levamisole and bacillus Calmette-Guérin, for treatment of melanoma were associated with some regression of the tumor, although many of these responses were limited and short lived. Because melanoma is one of the cancers most resistant to traditional treatment modalities such as radiation and chemotherapy, immunotherapy offers an avenue of treatment. Although the complete response rate seen in patients with melanoma treated with biotherapy is relatively low, the durability of responses in individuals who respond can be significant. Remaining unanswered questions include what is the best approach to biotherapy in a patient with melanoma and can biotherapy be combined with other available and emerging antineoplastic therapy.

Interferon

One of the oldest, and most controversial, immunotherapy approaches for the treatment of melanoma is the use of interferons (IFN).[4] The *interferons* are a group of proteins with diverse immunomodulatory and antiangiogenic properties. A number of

studies have evaluated various doses and schedules of recombinant interferon for treatment of metastatic melanoma. Response rates in metastatic melanoma range from 10% to 30%, and overall response rates are approximately 15% for IFN-α. Unfortunately, the optimal dose, treatment schedule, and treatment combinations/regimens have not been established for management of metastatic melanoma.[5]

In clinical trials of interferon therapy for patients with metastatic melanoma, response rates were highest in patients with minimal disease. Responses were seen at all sites of disease but were most frequent in subcutaneous, lymph node, and pulmonary metastases. The success of interferon in patients with minimal disease encouraged investigators to evaluate the role of adjuvant interferon after curative surgical resection in patients who were at high risk for recurrent disease (bulky disease or regional lymph node involvement). Early trials of short-term or low-dose regimens of IFN-α did not demonstrate a survival benefit in the adjuvant setting. In an attempt to optimize response in the adjuvant setting, maximum tolerated doses of IFN-α were administered for 1 month, followed by prolonged therapy of IFN-α at more tolerable doses for 48 weeks. The rationale for the intensive induction phase was to provide peak interferon levels sufficient to inhibit tumor growth and avoid the development of anti-interferon antibodies. A large, multicenter cooperative group trial (E1684) of adjuvant IFN-α_{2b} versus observation was designed for 287 patients with high-risk (stages IIB and III disease based on the 1997 AJCC staging criteria) melanoma following curative surgical resection.[31] IFN-α_{2b} was given intravenously as an induction therapy at maximum tolerated doses of 20 million international units/m^2 per dose 5 days per week for 4 weeks in an outpatient setting; treatment was continued for 48 weeks with subcutaneous IFN-α_{2b} 10 million international units/m^2 per dose 3 times per week at home. This therapy now is often referred to as *high-dose interferon* (HDI). With a median followup of 6.9 years, patients treated with HDI had significantly longer relapse-free and overall survival compared to patients who were observed following surgical resection (1.72 vs. 0.98 years and 3.8 vs. 2.8 years, respectively).[31] Table 147–7 shows 5-year relapse-free and overall survival results. With longer followup (median, 12.6 years), however, the difference in overall survival was no longer significant.[32] Further analysis showed that the greatest reduction in melanoma recurrence occurred during the first few months of treatment. Subgroup analysis of this study indicated that patients with large primary tumors and node-negative disease ($T_4N_0M_0$) did not receive the same benefit from therapy, but the small number of patients in this group made it difficult to draw definite conclusions about the role of interferon for adjuvant therapy in this subgroup.

TABLE 147-7 Results of Eastern Cooperative Oncology Group Trials of Adjuvant High-Dose Interferon-α_{2b} Therapy in Melanoma Patients at High Risk for Recurrence

Trial	Regimen	5-Year Relapse-Free Survival	5-Year Overall Survival	Reference
E1684	High-dose IFN[a]	37%	46%	Kirkwood et al.[31]
	Observation	26%	37%	
E1690	High-dose IFN[b]	44%	52%	Kirkwood et al.[32]
	Low-dose IFN	40%	53%	
	Observation	35%	55%	

[a]High-dose interferon (IFN) 20 million international units/m^2/day IV for 1 month and 10 million international units/m^2 3 times per week subcutaneously (SC) for 48 weeks.
[b]High-dose IFN 20 million international units/m^2/day 5 days per week IV for 4 weeks and 10 million international units/m^2 three times per week subcutaneously (SC) for 48 weeks.

HDI treatment is associated with multiple toxicities, including flu-like syndrome. Other toxicities include depression, nausea, weight loss, fatigue, myelosuppression, elevations in liver function tests, and renal insufficiency. Toxicities of interferon therapy in the adjuvant HDI trials were common and severe, and most patients required dose reductions and/or delays at some point during treatment. Dose modifications were required for dose-limiting constitutional symptoms, myelosuppression, and hepatic toxicities, but 74% of patients were able to complete the year of therapy in an outpatient setting.

One of the strategies for reducing the toxicities associated with interferon was to modify the dose and duration. A subsequent ECOG trial (E1690) of low-dose interferon (LDI; 3 million units per dose given subcutaneously 3 times weekly) for 24 months compared with the HDI regimen described above versus observation did not demonstrate an overall survival advantage of HDI versus observation.[33] At median followup of 52 months, the 5-year estimated relapse-free survival rates for HDI, LDI, and observation were 44%, 40%, and 35%, respectively. Relapse-free survival was significantly longer in the HDI group, prolonging the median time to relapse by 10 months compared to observation and LDI. With longer followup, however, the difference in relapse-free survival was no longer significant.[32] A significant overall survival benefit was not seen for HDI or LDI compared to observation, although the investigators speculated that this analysis of survival was affected by the number of patients in the observation arm who received interferon therapy after disease progression.[33]

The use of interferon in the adjuvant setting remains controversial. Although the HDI regimen is used in the United States, the LDI strategy remains standard in many European countries.[4] In a pooled analysis of 713 patients who participated in two randomized controlled trials (E1684 and E1690), HDI was associated with a significant reduction in relapse-free survival compared with observation (P <0.006).[32] No benefit in overall survival was observed in the pooled analysis. The results of nine randomized clinical trials of adjuvant HDI or LDI versus observation in melanoma were included in a systematic review. The systematic review observed a trend toward reduction of risk of recurrence of melanoma and of death among the interferon-treated patients in nearly all studies.[34] Adjuvant IFN-α has been evaluated in a number of clinical trials in patients with intermediate- to very-high-risk melanoma after surgical resection. A systematic review evaluated nine randomized controlled trials of high- and low-dose regimens.[34] Due to differences in dose, frequency, and duration of IFN-α treatment in the various trials, the review was not able to compare LDI versus HDI. Furthermore, the wide variability in number of patients enrolled, endpoints, patient selection, quality, type of therapy, duration of treatment, and followup precluded statistical analysis of the pooled results. Although the differences in overall survival were not always statistically significant, HDI remains the only adjuvant treatment shown to prolong survival in prospective randomized trials. IFN-α_{2b} is approved by the U.S. Food and Drug Administration (FDA) for treatment of patients with primary melanomas larger than 4 mm (stages IIB and IIC) and in patients with melanoma involving regional lymph nodes who are disease-free following lymph node dissection (stage III).

Although interferon is widely used in the adjuvant setting, there are concerns over the considerable treatment toxicities and the lack of consistent overall survival advantage of a toxic and expensive regimen. In addition, whether the results from the HDI trials should be extrapolated to patients with local recurrences, satellite lesions, or in-transit metastases is not clear. Remaining questions include the following: (a) Are the toxicities associated with HDI treatment worth the potential benefits for patients? (b) What are the mechanism(s) and best approaches to managing interferon toxicity?

(c) Is the regimen/schedule of interferon used in the initial positive trial (HDI) necessary to achieve the benefits seen in this study? Aggressive toxicity evaluation and individualized management are essential to help preserve quality of life in individuals receiving interferon therapy.

3 A mechanism for optimizing the care of patients receiving interferon is to effectively prevent and manage treatment-related toxicities. A common syndrome seen with IFN-α therapy is a diverse group of side effects referred to as *constitutional symptoms*, which can include acute symptoms such as fever, chills, myalgia, and fatigue, and can encompass some of the more chronic toxicities such as fatigue, anorexia, and depression.[35] Acetaminophen can be used to prevent or minimize acute dose-related symptoms such as fever, myalgia, and chills. Opiates, such as meperidine, are often required when patients experience severe chills or rigors, most commonly during the initial month of the HDI induction phase. Nonsteroidal antiinflammatory drugs (NSAIDs) have been used to manage interferon-related myalgia but may have overlapping side effects with interferon, such as a decrease in renal blood flow. NSAIDs, like acetaminophen, may mask fevers that occur in patients who experience neutropenia while undergoing therapy. Additionally, NSAIDs may add to the risk of bleeding in the setting of thrombocytopenia caused by interferon. Fatigue is one of the most frequently observed dose-limiting toxicities seen with interferon therapy occurring in 70% to 100% of patients.[35] The mechanisms of interferon-induced fatigue are not fully understood and may be multifactorial in individual patients. Interferon-induced fatigue appears to be dose related and may worsen with continued therapy. Pharmacologic (e.g., methylphenidate) and nonpharmacologic interventions (e.g., exercise, psychosocial techniques, distraction, energy management, and dietary modifications) for treatment of cancer-related fatigue and now interferon-related fatigue are being evaluated.[35] Depression is common and should be fully evaluated. Contributing factors such as interferon-induced hypothyroidism and/or concomitant interferon symptoms (e.g., nausea and fatigue) should be evaluated concurrently with depression symptoms to optimize treatment decisions.[36] Antidepressants, such as selective serotonin-reuptake inhibitors, have been studied in interferon-induced depression with notable benefit.[35] Anorexia was reported in approximately 70% of patients receiving adjuvant interferon therapy for melanoma and is thought to be mediated through direct effects on hypothalamic neurons, modification of normal hypothalamic neurotransmitters/neuropeptides, or effects from stimulation of other cytokines.[35] Taste alterations may contribute to anorexia. Investigational strategies for ameliorating interferon-induced anorexia include nutritional intervention, use of appetite stimulants such as megestrol acetate, and patient education. Glucocorticoids should not be used for appetite stimulation or as part of an antiemetic therapy because they may adversely impact the immunomodulatory effects of interferon. Other toxicities such as hematologic or hepatic toxicities require monitoring and appropriate dose modification.

Because of the associated toxicity and adverse effects seen with IFN-α therapy, many experts have questioned the usefulness of intensive adjuvant therapy for melanoma despite the possible benefits in relapse-free and overall survival.[37] A subsequent report from the cooperative group study demonstrated a quality-of-life benefit with interferon therapy based on the quality-of-life–adjusted survival analysis.[38] This analysis calculates the quality-of-life–adjusted years gained as a result of IFN-α treatment or the clinical benefit of time without toxicities and without disease. Another approach that has been investigated is the use of a pegylated product. Unfortunately, pegylated interferon has been evaluated in an attempt to improve the benefit-toxicity ratio without much success.[39]

4 The role of interferon as adjuvant therapy is not clear at this time. If adjuvant interferon is given, it is not clear what product (e.g., pegylated interferon), dose, and duration of therapy should be used. The issues of patient side effects and cost must be carefully weighed against the potential disease-free survival benefit. Because HDI is the only therapy to demonstrate benefit in large comparative trials, it should be considered for patients with high-risk disease. The 2010 NCCN guidelines for melanoma list IFN-α as one of several options for select patients with high-risk disease.[16] Other options include observation and probably, most importantly, clinical trials. Individuals should be prescreened for potential problems associated with therapy; relative contraindications to HDI therapy include autoimmune diseases, immunosuppression, decompensated liver disease, severe neuropsychiatric diseases, and life-threatening infection.[35] Efforts continue to better define the optimal treatment regimen for HDI versus other strategies in well-designed clinical trials.

The role of interferon in advanced disease is even less clear, especially for patients who have recurred after treatment with adjuvant interferon therapy. IFN-α has been used as a single agent in patients with metastatic disease who have not received adjuvant therapy and in combination with chemotherapy and/or other biotherapy for metastatic melanoma. The challenges of combination therapy are that many of the toxicities seen with interferon can be exacerbated by concomitant chemotherapy (e.g., nausea, vomiting, and neutropenia).

CLINICAL CONTROVERSY

The role of IFN-α as adjuvant therapy for high-risk patients after surgical resection of melanoma is controversial. Assessment of patient risk factors, availability of clinical trials, and cost of therapy should be evaluated prior to initiation of therapy.

Interleukin 2

Interleukin 2 (IL-2) is a glycoprotein produced by activated lymphocytes.[41] IL-2 was first identified as a T-cell growth factor, but now IL-2 clearly is a growth factor for a variety of cells including lymphocytes, T cells, and natural killer (NK) cells. IL-2 also may be immunosuppressive. The role of each of these effects of IL-2 on disease control in melanoma is not clear.

The precise mechanism of cytotoxicity of IL-2 is unknown. High concentrations of IL-2 have not been shown to have a direct antitumor effect on cancer cells in vitro. In vitro and in vivo, IL-2 stimulates the production and release of many secondary monocyte-derived and T-cell–derived cytokines, including IL-4, IL-5, IL-6, IL-8, tumor necrosis factor (TNF)-α, granulocyte-macrophage colony-stimulating factor, and interferon-γ, which may have direct or indirect antitumor activity. In addition, IL-2 stimulates the cytotoxic activities of NK cells, monocytes, lymphokine-activated killer (LAK) cells, and CTLs. IL-2 also appears to activate endothelial cells, which results in increased expression of adhesion molecules.[41]

5 Based on preclinical studies that demonstrated a dose–response relationship between recombinant IL-2 (aldesleukin) and tumor response, initial clinical trials of aldesleukin in patients with melanoma used relatively high doses of the drug as a single agent or in combination with LAK cells. The response rates seen in these trials ranged from 15% to 25%, and 2% to 5% of patients achieved complete responses, some of which were durable (median response = 70 months).[41] Responses were seen at a number of metastatic sites such as lung, liver, bone, lymph nodes, and

subcutaneous tissue. Based on reevaluation of early clinical trials, aldesleukin received FDA approval for treatment of metastatic melanoma. Overall, objective response rates were approximately 16%, but 4% to 6% of responses were durable and were observed in patients with large tumor burdens.[42] The high doses of aldesleukin used in the initial clinical trials and recommended in the labeling of the drug are associated with serious toxicities and may limit the practicality of therapy for individual patients and broad application in certain healthcare systems. The high-dose aldesleukin regimen used for treatment of metastatic melanoma is 600,000 international units/kg per dose every 8 hours for 14 doses maximum in a 5-day period given for two cycles, with a 10- to 14-day rest period between cycles. At these doses, cytokine-induced capillary leak syndrome is a common problem and often is accompanied by significant hypotension, visceral edema, dyspnea, tachycardia, and arrhythmias. Increased permeability of capillary walls allows for a fluid shift from the intravascular space into tissue. As the patient becomes intravascularly dehydrated, hypotension may occur, resulting in reflex tachycardia and arrhythmias. In addition, the decrease in blood volume may result in decreased renal blood flow and urine output, manifesting as an increase in blood urea nitrogen, serum creatinine, edema, weight gain, and a decrease in urine output (input greater than output). Visceral edema can result in pulmonary congestion, pleural effusions, and edema. The management of patients receiving high-dose aldesleukin requires extensive supportive care medications, careful monitoring, and a staff trained in aspects of critical care such as hypotension management. Although patients initially receiving high-dose aldesleukin are treated in an intensive care unit, most patients can be managed on a designated oncology unit if the staff is familiar with the toxicities and management strategies of the toxicities. Constitutional symptoms are a frequent complication of aldesleukin therapy and become more intense as therapy progresses. Additional side effects seen with aldesleukin include pruritus, eosinophilia, bone marrow suppression including thrombocytopenia, increased liver function tests, neurological disturbances, diarrhea, and nausea.[43]

In an attempt to reduce treatment-related toxicities, a number of studies have evaluated continuous-infusion aldesleukin and lower doses of aldesleukin, given either alone or combined with chemotherapy and interferon therapy. Although initial reports were encouraging, survival has not been significantly affected. At this time, direct head-to-head comparisons of various dosing schedules and regimens are needed to determine the optimum approach to aldesleukin therapy in metastatic melanoma. Coadministration of LAK cells with aldesleukin does not appear to significantly improve clinical response.[44]

One of the greatest treatment challenges in treatment of metastatic melanoma is determining the role of aldesleukin therapy for each patient. Pre-treatment factors such as performance status, site of metastases, and LDH may play a role in who will respond and are currently being assessed in clinical trials. Based on reports of long-term responses (>10 years) experienced by some patients, the risk certainly is worth the benefit for those individuals. Unfortunately, at this time it is difficult to determine which individuals will respond to aldesleukin therapy, as no biologic or immunologic parameters have been found to correlate with response. The decision to treat an individual with high-dose aldesleukin should be based on an analysis of an individual patient's risk versus potential benefit. Patients with inadequate pulmonary function, cardiac function, renal insufficiency, active infection, or poor performance status are poor candidates for this therapy. Aldesleukin can be safely administered with a properly trained healthcare team and is one of only two approved therapies for treatment of metastatic melanoma.

CLINICAL CONTROVERSY

Although aldesleukin has been associated with long-term durable responses in a small subset of patients with metastatic melanoma, the toxicity profile, intensity of therapy, and cost have limited its acceptance in the United States. Patients should be evaluated for treatment prior to initiation of therapy.

CHEMOTHERAPY

A number of antineoplastic agents have demonstrated in vitro activity against melanoma, but only a few drugs have consistently shown a response rate greater than 10% in individuals with metastatic melanoma. Most clinical trials that evaluate new agents in melanoma measure activity in terms of response rates, which often include partial response rates in addition to complete response. It is important to understand that these response rates do not always correlate with survival and do not evaluate benefit to the patient. Complete responses can be durable in a small number of patients.

6 *Dacarbazine*, a cytotoxic drug thought to exert its antitumor effect through alkylation, currently is the most effective single agent for treatment of melanoma. Dacarbazine remains the only FDA-approved chemotherapeutic agent for treatment of metastatic melanoma in the United States.[45] Prospective controlled clinical trials have observed response rates of 10% to 25%, with an average duration of response of 5 to 7 months. Recent randomized trials in large numbers of patients have confirmed that response rates are closer to 7%.[46] Complete responses are uncommon, with less than 5% of patients treated with single-agent dacarbazine sustaining long-term complete responses. There does not appear to be a survival benefit for dacarbazine relative to other treatments or supportive care. Patients with skin, subcutaneous tissue, and lymph node involvement respond most frequently, whereas patients with metastatic disease to the liver, bone, and central nervous system often are unresponsive. The optimum dose schedule of dacarbazine has never been determined; therefore, single-dose regimens are often preferred for patient convenience. Doses of 250 mg/m_2/day for 5 days or 800 to 1,000 mg/m^2 every 3 weeks are seen in practice. Common side effects of dacarbazine therapy include myelosuppression, severe nausea and vomiting, and a flu-like syndrome after large doses. Nausea and vomiting can be prevented and managed with available antiemetics and is not a major complication. At this time, dacarbazine has no defined role in the adjuvant setting.

Temozolomide is one of a series of imidazole tetrazine derivatives that was developed as a potential alternative to dacarbazine.[45] Temozolomide is an oral prodrug of the active metabolite of dacarbazine. Dacarbazine requires hepatic transformation to its active intermediate, whereas at physiologic pH, temozolomide chemically degrades to the cytotoxic monomethyltriazenoimidazole carboxamide (MTIC). Temozolomide is administered orally and appears to be less emetogenic than dacarbazine, although nausea can be a challenging chronic toxicity. Temozolomide appears to cross into the central nervous system and so initially was thought to have benefit for patients with central nervous system metastases. In a phase III trial of chemotherapy-naïve individuals with metastatic melanoma, temozolomide showed efficacy at least equivalent to that of dacarbazine in terms of objective response rates, time to progression, and overall and disease-free survival.[47] Temozolomide appeared to be associated with improvement in some aspects of quality of life, although overall disease control was similar to dacarbazine.[48]

A potential advantage of temozolomide is the convenience of oral dosing, which allows a potentially more effective dosing schedule. Low-dose intermittent dosing schedules with a rest period are being

evaluated. This schedule allows for a threefold increase in drug exposure and may overcome some drug resistance mechanisms. The active metabolite of dacarbazine and temozolomide, MTIC, methylates guanine residues in DNA at the O^6 position. Resistance to agents that produce O^6 methylation is partly due to increased levels of O^6-alylguanine-DNA alkyltransferase. Temozolomide administration results in the depletion of the DNA repair protein O^6-methylguanine-DNA methyltransferase (MGMT), which is a major mechanism of tumor resistance.[49] Clinical evaluations of prolonged administration of temozolomide are ongoing, often in combination with other agents such as interferon.

The *nitrosoureas* are active against melanoma. Nitrosoureas, such as carmustine and lomustine, have antitumor activity similar to that of dacarbazine, with reported response rates between 10% and 20%. Sites of responses are similar to those seen with dacarbazine. It was initially hoped that use of the lipophilic nitrosoureas would provide added benefit against a malignancy that can metastasize to the brain. Unfortunately, despite the ability of these agents to cross the blood–brain barrier, the commercially available nitrosoureas have not been shown to have increased activity against melanoma in the central nervous system. Fotemustine, a nitrosourea available in Australia and some European countries, appears to cross the blood–brain barrier more rapidly than do other nitrosoureas. Response rates of 30% have been reported in previously untreated patients, with response rates of 25% of patients who had cerebral metastases. Fotemustine is considered standard therapy in some countries.[50] The most common toxicities of the nitrosoureas are nausea and vomiting, delayed myelosuppression, particularly thrombocytopenia. Leukopenia and thrombocytopenia may be seen as long as 3 to 5 weeks after drug administration and may limit the inclusion of these agents to multidrug regimens.

Cisplatin and related compounds have been evaluated in the management of metastatic melanoma. The effectiveness of platinum compounds as single agents is limited, with reported response rates of 10% to 15% with a short median duration. The activity of cisplatin in melanoma may be dose dependent, and higher response rates have been seen with higher doses of cisplatin in single-institution studies.[51] The toxicities of cisplatin can be problematic, especially in higher doses, and include acute and delayed nausea and vomiting, renal toxicity, and neurotoxicity. Carboplatin, another platinum analog, has been evaluated in small trials for treatment of melanoma. Results demonstrated similar response rates to cisplatin with differing toxicities.[47] Carboplatin is currently being studied in combination regimens for treatment of melanoma.

Taxanes have demonstrated encouraging results in initial trials of metastatic melanoma. Response rates of 15% to 17% have been seen in initial phase II trials with paclitaxel and docetaxel. Abraxane, the albumin-bound nanoparticle formulation of paclitaxel, has shown encouraging results in a very small phase II trial and is being evaluated in a randomized phase III trial.[52] At this time, these agents are not routinely used as single-agent therapy for melanoma but are being incorporated into multidrug strategies undergoing evaluation for use against metastatic melanoma.

In an attempt to improve the limited responses seen with single-agent chemotherapy, a variety of combination chemotherapy regimens (Table 147–8) have been evaluated in both small and large clinical trials. Response rates as high as 30% to 50% were reported in single-institution phase II trials of patients with metastatic melanoma. The combination of dacarbazine with other chemotherapy, most commonly cisplatin, increased the response rates reported with dacarbazine alone, but the survival benefit has been minimal. Responses often were limited to metastases in soft tissue, lymph nodes, and the lung, the sites most likely to respond to single-agent dacarbazine therapy. The concern with combination chemotherapy is increased toxicity, and any reports of increased response rates should be weighed against the effect of toxicities on overall quality of life. The initial reports with the cisplatin, vinblastine, and dacarbazine (CVD) regimen were exciting, with reported response rates greater than 50%, 4% complete response rate, median response duration of nine months, and acceptable toxicities.[53] Comparisons of this regimen to dacarbazine alone have been conflicting. Subsequent reports showed no difference in response rates or survival.

TABLE 147-8 Combination Chemotherapy Regimens for Metastatic Melanoma

Dartmouth regimen (CDBT): Repeated every 3–4 weeks
Cisplatin 25 mg/m² IV daily × 3 (days 1, 2, and 3)
Dacarbazine 220 mg/m² IV daily × 3 (days 1, 2, and 3)
Carmustine 150 mg/m² IV daily × 1 (day 1)
Tamoxifen 10 mg orally twice a day
CVD
Cisplatin 20 mg/m² IV daily × 4 (days 2, 3, 4, 5)
Vinblastine 1.6 mg/m² IV daily × 5 (days 1, 2, 3, 4, 5)
Dacarbazine 800 mg/m² IV daily × 1 (day 1)

The Dartmouth regimen is a combination that includes carmustine, dacarbazine, cisplatin, and tamoxifen. Initial reports from uncontrolled phase II trials of this combination have demonstrated high response rates of 20% to 50%, but few patients achieve long-term survival. The benefit of tamoxifen to this regimen has been controversial, but a controlled clinical trial from the National Cancer Institute of Canada demonstrated no benefit in response or survival from tamoxifen in this combination.[54] Careful analysis of the initial studies demonstrates that the criteria used to measure response were not consistent with standards used in large multicenter studies. Phase III trials have shown no benefit of the Dartmouth regimen compared to single-agent dacarbazine.[55,56] Response rates were 15%, and median survival was approximately 7 months in both studies. Of concern, toxicities were higher with the combination study and included bone marrow suppression, nausea, vomiting, and fatigue.

BIOCHEMOTHERAPY

Low overall response rates and toxicity have limited the routine use of chemotherapy alone or immunotherapy alone in the management of metastatic disease. Over the past decade, the strategy of a combination of chemotherapy (dacarbazine, platinum agents, or vinka alkaloids) and cytokines, aldesleukin, and/or interferon, often termed *biochemotherapy*, has been a major focus of investigation in the management of metastatic melanoma and more recently in the adjuvant setting. The primary rationale is to combine two therapies with some biologic activity to increase overall activity and perhaps response rates. Additionally, some preclinical trials suggest potential synergistic interactions between cytokines and some chemotherapy agents. As with other treatment strategies in melanoma, the results from initial trials suggested a higher response rate with biochemotherapy than the rates seen with either chemotherapy or biotherapy alone. Although several studies have suggested an increase in response rate with the addition of IFN-α to chemotherapy, results of most studies have shown that the addition of IFN-α does not increase the antitumor effect of dacarbazine but does increase toxicity and cost. Similarly, the combination of aldesleukin to chemotherapy has not been consistently shown to increase response or survival. The most encouraging results have been seen with combination chemotherapy and combination biotherapy, but the results of phase III studies have not demonstrated a clear advantage of biochemotherapy compared with chemotherapy alone.[57] A

recently published meta-analysis of 18 randomized trials of chemotherapy versus biochemotherapy showed that biochemotherapy was associated with a significantly higher response rate in treatment of metastatic melanoma.[58] However, these differences in response rates did not translate into a significant difference in overall survival. Toxicities can be severe and are consistent with the individual agents in the regimen. A more recent strategy for biochemotherapy is substitution of newer agents into the combination. For example, a small phase II trial of patients with metastatic melanoma evaluated the substitution of temozolomide for dacarbazine.[59,60]

One of the problems with most studies of biochemotherapy is the relatively short duration of response. Recurrence rates among patients who respond to therapy are as high as 50% within 18 to 24 months. Strategies such as subcutaneous low-dose aldesleukin are being investigated in an effort to prolong overall survival and time to progression in patients who do respond to treatment. Initial response rates, durable complete remission, and activity in patients in whom HDI therapy was not successful have stimulated interest in evaluating biochemotherapy in the adjuvant setting for high-risk patients with node-positive disease as compared to HDI.

Biochemotherapy is also being evaluated in the adjuvant setting. Phase II data of neoadjuvant provided promising results in terms of response rates, relapse-free survival, and overall survival.[57] Currently, phase III studies are evaluating biochemotherapy compared to interferon as adjuvant therapy in stage III disease.

ENDOCRINE THERAPY

The role of endocrine therapy in the management of melanoma has been debated over the last decade.[5] Initial reports that described high-affinity cytoplasmic estrogen receptors in patients with metastatic melanoma caused some experts to speculate about the possibility that antiestrogens or other hormonal manipulation may be beneficial in modulating the biology of melanoma. Additionally, estrogens have been shown to suppress T-lymphocyte activity and to suppress or stimulate the activities of B lymphocytes, macrophages, and NK cells, supporting a hypothesis that estrogens influence the immunologic mechanisms that appear to be important in melanoma.

In a randomized trial, tamoxifen was shown to have a response and survival benefit when combined with dacarbazine in patients with metastatic melanoma; this benefit was most pronounced in women.[61] Well-designed prospective randomized studies demonstrate that tamoxifen does not significantly enhance the antitumor effect of dacarbazine alone or the combination of dacarbazine with cisplatin and carmustine.[5] As discussed previously, subsequent trials have not been able to confirm the initial reported benefit of the antiestrogen when combined with chemotherapy, and tamoxifen is no longer routinely included in chemotherapy regimens.[45]

VACCINES

The rationale for vaccination as a therapeutic modality is based on the observation that antigens expressed on the surface of tumor cells differ from normal cells and the hope that vaccines might induce effective tumor-specific immune responses with fewer toxicities than conventional chemotherapy or other immunotherapies. Greater knowledge about tumor antigens and the mechanism of antigen presentation and immune response to antigens has led to the development of several vaccination strategies for treatment of early and advanced melanoma.

A variety of melanoma vaccines based on whole tumor cells, peptides, proteins, and tumor lysates have been evaluated for treatment of patients with metastatic disease and for intermediate- and high-risk patients after surgical resection of disease.[62,63] Although tumor responses with some of these approaches have been observed in phase I and II trials, none of the vaccine responses have been confirmed in phase III trials.[63] These early trials have focused on safety, feasibility, and immunogenicity of the vaccine. Vaccines are a promising but still experimental approach in the treatment of melanoma.

Vaccination is a form of active specific immunotherapy directed against a particular cellular target or specific membrane antigen. The ideal tumor vaccine would generate an active, systemic, long-lived immune response in the cancer-bearing host against tumors; protect against primary development or subsequent relapse of cancer; or induce regression of established cancer. Obstacles in the development of a vaccine include identifying appropriate antigens to target and generating immune responses against tumor antigens to which the immune system has been already exposed.

Whole-cell tumor vaccines can be derived from cell lines that are already established (allogeneic vaccines) or from the patient's own tumor cells (autologous). Whole-cell vaccines are challenging to produce for several reasons: a new vaccine must be prepared for each patient, patients must have sufficient tumor available to provide adequate material, and considerable delay may exist between time of tumor removal and vaccine administration. In addition, there are technical challenges to producing the vaccine in the laboratory.[62] Currently, no autologous tumor cell vaccine has been successfully studied in a phase III randomized clinical trial. An example of a whole-cell tumor vaccine that is being studied is Canvaxin. Canvaxin (CancerVax®, Carlsbad, CA) is an allogeneic whole-cell vaccine that uses bacillus Calmette-Guérin as an immune adjuvant. Small trials have shown improvements in survival compared with historical controls, and some objective clinical responses have been seen in patients with metastatic melanoma. The results from two large phase III trials that compared Canvaxin to observation in stage III and IV melanoma demonstrated a survival disadvantage for patients that received the vaccine.[64]

Antigen vaccines use individual antigens to stimulate immune responses, as compared with whole-cell vaccines, which contain many thousands of antigens.[63] These antigens usually are proteins or pieces of proteins called *peptides*. Antigen vaccines may be specific for a certain type of cancer, but they are not made for a specific patient. Vaccines against GM2 ganglioside, a glycolipid expressed on most melanomas, are examples of vaccines targeted against an antigen. Two randomized controlled trials with anti-GM2 vaccines have failed to show any benefit with the vaccine.[63]

Peptide antigen vaccines match the patient's haplotype with the spectrum of immunity that he or she expresses. T cells recognize antigens as peptide epitopes on the surface of major histocompatibility complex (MHC) molecules. Antigenic peptides can be mixed with an immunologic adjuvant and administered with the goal of loading empty MHC molecules in vivo. To date, the most commonly used peptides have shown activity only in patients who express human leukocyte antigen (HLA)-A2. However, many patients would not be eligible for this vaccine because not all patients express this HLA antigen. Additional peptide antigens that are compatible in other haplotypes have been identified, and eventually this disadvantage may be overcome. Peptide vaccination can generate quantifiable and functional tumor-reactive T cells, but clinical responses are rare and do not consistently correlate with CTL response.

Because protein antigen vaccines have a slightly broader spectrum of antigen diversity, all patients with melanoma potentially could be eligible for vaccination with this particular type of vaccine. Proteins intrinsically produced by the cell are presented only to $CD8^+$ T cells, whereas proteins taken up by antigen-presenting cells are presented only to $CD4^+$ T cells. Under certain conditions, antigen-presenting cells can present protein-derived antigens to both $CD4^+$ and $CD8^+$ in a process known as *cross-presentation*.[63]

Tumor lysates can be generated from tumor cells by mechanical disruption or enzymatic digestion. Tumor cells that shed antigens in culture can be purified and used as an antigen source for vaccines. Production of a vaccine from these sources raises concern because standardization of production and verification of purity and biological activity are more difficult.

Vaccines in combination with other biologic therapies are being evaluated. In a randomized trial of 604 patients with resected stage III cutaneous melanoma, LDI combined with an allogeneic melanoma lysate vaccine (2 years) was compared with HDI alone (1 year).[65] Median overall survival was not significantly different between the two treatment arms. Five-year relapse-free and overall survival were similar in the two treatment arms. The incidence of serious treatment-related adverse events was similar in the two arms, but more severe neuropsychiatric toxicity was observed in patients receiving HDI. Although the results of this trial suggest that the vaccine has some activity in melanoma, the study was not powered sufficiently to show either equivalency or small differences in efficacy. HLA typing was optional based on whether the centers were able to perform the typing. With ongoing research additional trials performed with this vaccine, specifically in patients with certain HLA types, may prove promising.

Occasional clinical responses have been observed in clinical trials of melanoma vaccines, which demonstrate the potential of this form of treatment. Many clinical trials with vaccine therapy in melanoma patients are ongoing. The results of completed clinical trials have not yet shown definitive evidence of improved survival. Further research is needed to improve vaccine responses and to determine how to apply treatment to melanoma patients.

TARGETED THERAPY

7 The role of protein kinases in the regulation and proliferation signals in cancer cells is becoming a key focus for anticancer agents. The role of protein kinase inhibitors has emerged as standard therapy for malignancies such as renal cell carcinoma, chronic myelogenous leukemia, and gastrointestinal stromal tumors. As the biology of melanoma continues to unfold, there is increasing excitement about the development of targeted therapies against targets important for the development and progression of melanoma.[13,66] There now is greater interest in identifying potential targets in melanoma and determining the applicability in specific patients and/ or patient subsets.

The mitogen-activated protein kinase (MAPK) pathway and the Akt pathway are involved in tumor cell growth and differentiation and are activated in melanoma. BRAF is downstream in the MAPK pathway. Mutations of BRAF have been described in melanoma cell lines, and it appears that approximately 70% of melanomas exhibit BRAF alteration.[67] Sorafenib is a multikinase inhibitor that inhibits both wild-type and mutant BRAF, in addition to other tyrosine kinases involved in angiogenesis and tumor progression. Preclinical studies demonstrated activity against human melanoma tumor xenografts in preclinical trials, but minimal activity was observed in phase I-II clinical trials in refractory metastatic melanoma. However, sorafenib may be active when given in combination with chemotherapy. In phase I-II studies, 27% of patients responded to sorafenib when given in combination with carboplatin and paclitaxel, and 73% of patients maintained a response at a 6-month followup.[67] Although a phase III trial with this same combination failed to show an improvement in progression-free survival, an ECOG phase III trial is currently evaluating carboplatin, paclitaxel, and sorafenib as first-line treatment for metastatic melanoma.[67] In this study, it will be important to evaluate the efficacy of the addition of sorafenib to the "untested" combination of carboplatin and paclitaxel for treatment of metastatic melanoma.

Other drugs targeted to mutated BRAF have reported encouraging results. In a phase I/II trial, PLX4032, an investigational orally available inhibitor of mutated BRAF, showed activity in patients with melanoma that had BRAF with the V600E mutation. Among the 16 patients with melanoma that had BRAF with the V600E mutation and who received 240 mg or more of PLX4032 twice daily, 10 had a partial response and one had a complete response.[68]

Another agent of interest is imatinib mesylate, an oral agent that inhibits c-*Kit* and PDGFR. c-*Kit* and PDGFR are highly expressed on melanoma cells. Imatinib has been shown to suppress melanoma cell growth in preclinical studies. In phase II trials, imatinib was shown to be inactive in metastatic melanoma despite the downregulation of phosphorylated c-*Kit*, the biologic target, in the tumor.[67]

The anti-apoptotic protein Bcl-2 is overexpressed in melanoma and has been linked to chemotherapy resistance. In a large phase III trial comparing oblimersen, a Bcl-2 antisense, in combination with dacarbazine compared to dacarbazine alone, demonstrated a significant increase in the overall response rate (13.5% vs. 7.5%; $P = 0.007$) but this did not translate into a significant difference in overall survival (9 months vs. 7.8 months; $P = 0.077$) and as a result was not approved by the FDA for the treatment of metastatic melanoma. Other targeted therapies such as toll-like receptor agonists, antiangiogenic agents, heat shock protein 90 inhibitors and m-TOR inhibitors have also been studied in early clinical trials for the treatment of metastatic melanoma and all have modest activity.[67]

OTHER APPROACHES

Dendritic cells are potent antigen-presenting cells that initiate antigen-specific immune responses. Dendritic cells express high levels of MHC class I and class II molecules, which are essential in antigen presentation. Activation of T cells and recruitment of non–antigen-specific effectors, such as NK cells and macrophages, result in a broad immune response. One strategy that uses dendritic cells for inducing antitumor immune responses is peptide-pulsed dendritic cells. Antimelanoma CTLs can be generated from healthy donors and patients with melanoma with dendritic cells pulsed with melanoma-derived peptides. A number of clinical trials are evaluating dendritic cell–based immunotherapy.[62,63]

Monoclonal antibodies have been used for diagnosis and treatment of melanoma. Monoclonal antibodies can be used to target biologic pathways that are associated with tumor progression and as a delivery system for antineoplastic drugs. Monoclonal antibodies have been conjugated to cytotoxic agents, radioisotopes, and toxins such as ricin A.[5,13] More recently, monoclonal antibodies have been developed to target processes that are involved in the host immune response to melanoma. Cytotoxic T-lymphocyte antigen 4 (CTLA-4) is a transmembrane protein expressed on T lymphocytes that is a homodimer which functions as an inhibitory receptor for the costimulatory molecule B7. Crosslinking of CTLA-4 by B7 inhibits T-cell activation, transcription, translation, and transduction. CTLA-4 blockage sustains activation and proliferation of T cells.[69] CTLA-4 blockade may represent a novel approach to enhance the immune response against melanoma antigens. Ipilimumab (MDX-010) and tremelimumab (CP-675206) are two fully human monoclonal antibodies against CTLA-4 currently in phase III clinical trials. Preliminary results of clinical trials show promising activity in malignant melanoma. Results from phase I and II trials with ipilimumab and tremelimumab demonstrate up to 20% response rates in advanced disease.[70] In a phase III trial of 676 HLA-A*0201-positive patients with refractory metastatic melanoma, ipilimumab plus a glycoprotein 100 (gp100) peptide vaccine was compared with ipilimumab

alone or gp100 alone.[71] Median overall survival was significanly longer in patients treated with ipilimumab either alone or combined with gp100 as compared with patients treated with gp100 alone (10.0 or 10.1 months vs. 6.4 months). No difference in overall survival was observed between the two ipilimumab groups. Unfortunately, recent phase III data with tremelimumab showed no difference in overall survival when compared with dacarbazine or temozolamide.[69] CTLA-4 antibodies produce several immune-mediated adverse events that are distinct from the typical adverse events associated with conventional cancer treatments. Many of these adverse effects are autoimmune in nature and can occur in up to 40% of patients.[69] Antibodies against CTLA-4 may cause autoimmune-mediated adverse events by promoting the activation of self-reactive T cells. The most common serious adverse events included dermatitis, enterocolitis, and diarrhea. Less common adverse effects include autoimmune thyroiditis, adrenal disease, or hepatitis.[70,71] Early administration of corticosteroids is important in the management of immune-related adverse effects. In the clinical studies reported to date, patients who have experienced grade III or grade IV autoimmune toxicities have also been the most likely to exhibit tumor regression and increased time to relapse.[69–71] The timing of adverse effects is variable and may occur several months after the cessation of treatment.

Gene therapy of human melanoma is in its infancy but suggests several exciting approaches to management of metastatic melanoma. Several strategies for gene therapy are under investigation for treatment of melanoma. One approach to gene therapy for melanoma is modification of melanoma cells with insertion of one or more cytokine genes and then administration of these altered allogeneic or autologous cells as a vaccine. Cytokine gene transduction has been accomplished with a number of cytokines, including aldesleukin (IL-2), TNF-α, IL-4, and interferon. It is hoped that insertion of cytokine genes into melanoma cells will significantly increase the cells' immunogenicity.

Genes can be transferred in vitro into TILs associated with melanoma in an attempt to potentiate the cytotoxicity of these cells. Rosenberg et al. were the first to attempt to transduce the gene coding for resistance to neomycin into human TILs.[72] This approach has since been used to transfer the tumor necrosis factor gene into TILs.

Thalidomide and thalidomide analogs are being evaluated for management of melanoma. Thalidomide, given either as a single agent or in combination with chemotherapy or cytokines, is being evaluated in a variety of studies. Thalidomide analogs also are being evaluated in an attempt to avoid toxicities associated with the parent compound. The thalidomide analogs are grouped into two classes: selective cytokine inhibitory drugs and immunomodulatory derivatives. Both classes appear to have antiangiogenic and antiinflammatory properties, but the selective cytokine inhibitory drugs are phosphodiesterase inhibitors. Immunomodulatory derivatives also have effects on T-cell stimulation and inhibition of TNF-α. Several of these agents are being evaluated in clinical trials of metastatic melanoma.[45]

RADIATION

The role of radiation for the adjuvant treatment of melanoma is being investigated, based on retrospective data that suggest that patients at high risk for reoccurrence benefit from postoperative adjuvant radiation to the nodal basins. Overall these data demonstrate improvement in locoregional control with reasonable toxicity but with no impact on overall survival. This has been substantiated in one phase II trial. As a result, a phase III trial is currently underway to further elucidate the benefit of radiation in this setting.[5,73] For patients with metastatic melanoma, radiation is limited to the palliative setting to symptomatic areas of disease progression.

LIMB PERFUSION AND LIMB INFUSION

Isolated limb perfusion is a surgical procedure of regional intravascular delivery of chemotherapy and/or biotherapy into an extremity with cutaneous melanoma.[74] When in-transit metastases occur in extremities, local therapy with isolated limb perfusion or isolated limb infusion has been used.[5] Isolated limb perfusion is a method for escalating the dose of chemotherapeutic drugs to a specific region of the body while limiting the systemic toxicities of the agent. Most perfusions can be performed with drug exposures of less than 2%. The most significant side effect of isolated limb perfusion is regional toxicity; all of the skin, subcutaneous tissue, and tissue of the extremity receives the same dose and is subjected to the same perfusion conditions as the tumor located within the extremity. After regional perfusions, objective response rates greater than 50% in treated limbs have been reported, with overall response rates possibly as high as 80%. The role of hyperthermia (39°C to 40°C [102°F to 104°F]) with regional isolated perfusion is not clearly defined. Although most clinical trials have used melphalan, whether the combination of melphalan with other agents may improve results is not known.[75] Agents that have been combined with melphalan include actinomycin D, nitrogen mustard, thiotepa, and cisplatin. Work with biologic response modifiers, such as TNF-α, have been encouraging.[76] A simplified form of isolated limb perfusion, called isolated limb infusion, is a low-flow isolated limb perfusion performed under hypoxic conditions via small-caliber arterial and venous catheters. It has been proposed that the hypoxia that develops during isolated limb infusion may be beneficial with certain cytotoxic agents such as melphalan.

TREATMENT BY STAGE

Treatment of cutaneous melanoma is determined by many factors, including disease-related and patient-related issues. Most available reviews and guidelines provide treatment recommendations based on stage of disease.[16] Most patients present with localized disease.[16] Treatment of localized disease is surgical excision, with the extent of excision based on the tumor size. Wide excision is recommended for in situ melanoma and wide excision with SLNB for stage IA, IB, and II disease. Long-term survival of individuals with early-stage disease and thin tumors (<1 mm) is good, but survival is negatively impacted as tumor thickness increases.

The role of adjuvant therapy in the management of individuals at high risk for recurrence remains controversial. One controversy is determination of which patients are appropriate candidates for treatment after resection of the primary tumor. Although adjuvant therapy has been considered historically in patients with locally advanced disease (stages II and III), it is increasingly being considered after surgical resection of an isolated distant metastases.

Another controversy with adjuvant therapy is the choice of therapy. HDI has the most evidence supporting its use and is FDA approved for this indication. The challenges with this therapy have been discussed, and the therapy has limited worldwide acceptance. The most appropriate option is a clinical trial, if available. New therapies and combinations must be evaluated to help answer the questions that remain about adjuvant therapy in melanoma. Clinical trials of chemotherapy, immunotherapy, vaccines, and emerging therapies are ongoing.

Another treatment challenge is the management of patients with advanced disease. The 2010 NCCN guidelines list a variety of systemic therapies for advanced or metastatic melanoma, including dacarbazine, temozolomide, high-dose aldesleukin, and combination therapies of biochemotherapy that include dacarbazine or temozolomide.[16] Of note, the preferred treatment is participation in a clinical trial. Best supportive care is also an option in some

TABLE 147-9 Options for Sun Protection Sunscreens

		Benzopehnone-6
		Dibenzoylmethanes

individuals. Data suggest that surgical treatment of metastatic melanoma should be considered in select individuals based on the extent and location of disease and performance status.

An important consideration for treatment of melanoma is the presentation of the disease. As discussed, treatment of melanoma isolated to the limb may be most appropriately treated with regional therapy. Treatment options for metastatic uveal melanoma include strategies for managing hepatic metastasis, such as chemoembolization to the liver and intrahepatic chemotherapy.[77]

PREVENTION AND DETECTION

The results of early treatment emphasize the role of early detection and prevention. There are three different strategies for chemoprevention for melanoma. Primary chemoprevention is used to prevent occurrences of melanoma in healthy individuals. Secondary chemoprevention is used to prevent premalignant melanoma precursors from becoming melanoma. Tertiary chemoprevention is used to prevent melanoma recurrence in individuals who were treated for melanoma and have no evidence of disease. The mainstay of melanoma prevention remains strategies to protect individuals from harmful effects of the sun[78] (Table 147–9).

UV light exposure plays a major role in melanoma development. Childhood sunburns and intermittent sun exposure correlate positively with melanoma risk. Studies have shown that a decrease in recreational sun exposure is associated with a reduction of a second primary melanoma in individuals diagnosed with primary melanoma.[79] Education and reeducation about the importance of sun protection have the potential to help decrease the rising incidence of this disease. Strategies, such as sun avoidance, especially during peak hours of sun intensity (10 AM to 4 PM), and staying in the shade when outdoors, are important education concepts for individuals who are in the sun for prolonged periods and/or who are at high risk for burning. Skiers and winter sports enthusiasts should be cautioned about exposure to UV radiation, as the reflection off snow and high altitude contribute to increased UV exposure. There is also the use of protective clothing to minimize damage to the skin for individuals who spend time in the sun. Clothing designed to protect an individual from sun exposure but allows for physical activities such as water sports and hiking are widely available. The clothes are designed for skin protection, but it is important to realize that not all clothing provides sufficient protection from UV radiation. Clothes with tight weaves provide the greatest protection. In addition to protective clothing, wide brimmed hats to protect ears, neck, and nose as wells as sunglasses with both UVA and UVB protection are important. Additionally, the use of tanning beds over the last three decades have led to an increased exposure of individuals to UVA light. Observational studies have shown individuals who spent time in tanning devices before the age of 35 have a 75% increase in risk of melanoma.[80] As a result, the World Health Organization International Agency for Research on Cancer declared in 2009 that ultraviolet light emitted from tanning beds was a human carcinogen.[81]

It is important to counsel patients about the appropriate use of sunscreens to optimize benefits from these products. Sunscreens should be applied 15 to 30 minutes before going into the sun and should be reapplied every 2 hours, after swimming, and after perspiring heavily. About 1 ounce of sunscreen (a "palmful") should be used to cover the arms, legs, neck, and face of the average adult. Sun protection must be used regularly and not limited to times of recreation or anticipated "prolonged" exposure. Times of season changes, when the potential for sun exposure can be perceived as erratic, are possible times for the "first-of-the-season sunburn."

Historically, patients have been counseled that the risk of skin cancer can be limited by the use of sunscreens with a sun protection factor (SPF) of 15 or greater. SPF is a measure of protection from UVB radiation only. Although some studies have found a decreased risk of melanoma in sunscreens users, others have demonstrated no association and even increased melanoma risk with sunscreen use. Methodologic difficulties may explain the discrepancy in study results. Factors that include variables in sun exposure, sunscreen use, and sun sensitivity are very difficult to control in these trials. In addition, all sunscreens are not the same. It is important that people understand that no sunscreen provides complete protections and that the SPF scale is not linear, the higher the SPF, the smaller the difference in sun protection. For example, SPF 15 sunscreens filter out about 93% of UVB rays, while SPF 30 sunscreens filter out about 97%, SPF 50 sunscreens about 98%, and SPF 100 about 99%.

Sunscreens traditionally have been designed to prevent erythema by blocking UVB, leaving users relatively unprotected from wavelengths such as UVA. As a result, the use of sunscreens, especially those with higher SPFs, may lead to the ability of individuals to increase their time in the sun without clinical indication of sunburn. Newer forms of sunscreens combine protection for UVA and UVB. Unfortunately, no currently approved system rates products for UVA protective capabilities; however, the FDA has proposed new sunscreen rules that will establish an UVA testing and labeling system. It is unclear when this system will be put into place. The impact of the use of high-potency sunscreens on the incidence of melanoma is not clear at this time, because the lag time for melanoma is approximately two decades and high-potency sunscreens have only been popular for approximately 10 years.

Thickness and stage of the disease are inversely related to melanoma survival. Early detection can play a large part in the secondary prevention of melanoma. Many healthcare organizations and skin cancer groups recommend monthly self-examination of skin to serve as a mechanism for recognizing moles or marks on the skin that may be melanoma. Patients with a strong family history should additionally have a clinical examination and, in some cases, screening photography to document the size, shape, and location of moles. Both patients and clinicians need to be properly educated in the clinical features of the disease to ensure more appropriate diagnosis. Currently there are no consistent recommendations for the screening and early detection of melanoma.

EVALUATION OF THERAPEUTIC OUTCOMES

The outcome of patients treated with melanoma depends on the stage of disease at presentation. The prognosis of patients with thin tumors (<1 mm in thickness) and localized disease is good, with long-term survival in more than 90% of patients. The risk of regional nodal involvement increases with increasing tumor thickness, so survival rates decrease in patients with nodal involvement. Long-term survival in patients with distant metastases is even lower. Therefore, early diagnosis and appropriate treatment of early

disease are essential. Patients with suspicious pigmented lesions should be evaluated and the lesion excised whenever possible. Treatment is determined by patient factors and stage of disease.

Clinical practice guidelines published by the NCCN and ESMO provide some guidance for followup of patients with melanoma.[16,82] Intensive surveillance has the benefit of early detection of recurrent disease, which may lead to better options of surgical resection. Emphasis on evaluation of locoregional areas is important. For patients with in situ melanoma, periodic skin examinations for life are recommended, although frequency is determined based on patient risk factors. Local recurrence is associated with aggressive tumor biology and frequently is a manifestation of an aggressive primary tumor. If a local recurrence occurs after inadequate primary disease, the patient should undergo a workup based on the lesion thickness of the original melanoma. Patients with nodal recurrence should be evaluated for lymph node metastases. Patients with systemic recurrence should be evaluated and treated in a fashion similar to patients presenting with systemic disease.

ABBREVIATIONS

AJCC: American Joint Committee on Cancer

ARF: alternative reading frame

bFGF: basic fibroblast growth factor

CTL: cytotoxic T lymphocyte

CTLA-4: cytotoxic T lymphocyte antigen 4

ECOG: Eastern Cooperative Oncology Group

CHAPTER 148

Hematopoietic Stem Cell Transplantation

JANELLE B. PERKINS AND GARY C. YEE

KEY CONCEPTS

1. Hematopoietic stem cell transplantation (HSCT) is a process that involves intravenous infusion of hematopoietic stem cells from a donor into a recipient, after the administration of chemotherapy with or without radiation. The rationale is to increase tumor cell kill by increasing the dose of chemotherapy. Immune-mediated effects contribute to the tumor cell kill observed after allogeneic HSCT.
2. Hematopoietic stem cells used for transplantation can come from the recipient (autologous) or from a related or unrelated donor (allogeneic). If the related donor is a twin, the transplant is referred to as a syngeneic transplant.
3. Human leukocyte antigen (HLA) mismatching of allogeneic donor/recipient pairs at either a class I or class II locus correlates with the risk of graft failure, graft-versus-host disease (GVHD), and survival. The ideal donor is matched at HLA-A, HLA-B, HLA-C, and HLA-DRB1.
4. Hematopoietic stem cells are found in the bone marrow, peripheral blood, and umbilical cord blood. Because of their rarity and their similarity to other cells, hematopoietic stem cells are difficult to isolate and measure. These stem cells express the CD34 antigen, and quantification of the number of $CD34^+$ cells has become a clinically useful measure of the number of hematopoietic stem cells.
5. Because of clinical and economic advantages, peripheral blood has replaced bone marrow as the source of hematopoietic stem cells in the autologous and adult allogeneic HSCT setting. Bone marrow continues to be the primary graft source in children undergoing allogeneic HSCT.
6. The purpose of the preparative (or conditioning) regimen in traditional myeloablative transplants is twofold: (a) maximal tumor cell kill and (b) immunosuppression of the recipient to reduce the risk of graft rejection (allogeneic HSCT only).
7. Reduced-intensity conditioning regimens (including those that are nonmyeloablative) reduce early posttransplant morbidity and mortality while maximizing the graft-versus-malignancy (GVM) effect of the allogeneic graft. The advantage of this approach is that patients who otherwise would not be eligible for allogeneic HSCT can be offered a potentially curative therapy.
8. Posttransplant immunotherapy is based on the GVM effect caused by certain subsets of T cells responsible for eradication of malignant cells. Posttransplant immunotherapy includes the use of donor lymphocyte infusions, immunomodulatory cytokines, monoclonal antibodies, or antitumor vaccines.
9. Transplant-related mortality associated with allogeneic HSCT ranges from 10% to 80%, depending on age, donor, and disease status. Major causes of death include infection, organ toxicity, and GVHD. The most common cause of death after autologous HSCT is disease relapse. Transplant-related mortality usually is less than 5%, depending on the conditioning regimen, age, and disease status.
10. Treatment of acute GVHD often is unsuccessful, and the resulting complications can be fatal. Patients undergoing allogeneic HSCT are given prophylactic immunosuppressive therapy, which inhibits T-cell activation and/or proliferation. The most commonly used GVHD prophylaxis regimen is cyclosporine or tacrolimus and methotrexate.
11. Initial treatment of both acute and chronic GVHD consists of prednisone, either alone or combined with cyclosporine or tacrolimus. Treatment of patients with steroid-refractory GVHD is problematic.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

1 Hematopoietic stem cell transplantation (HSCT) is a process that involves intravenous infusion of hematopoietic stem cells from a compatible donor into a recipient, usually after administration of high-dose chemotherapy. Hematopoietic stem cells can be derived from the bone marrow, peripheral blood, or umbilical cord blood. The original rationale for HSCT for treatment of malignant disease is based on studies showing that most anticancer drugs have a steep dose–response relationship and that bone marrow suppression limits the chemotherapy dosage that can be safely administered. Although standard-dose chemotherapy can prolong survival in many cancer patients, most patients are not cured of their disease (Fig. 148–1). Infusion of hematopoietic stem cells allows administration of very high doses of chemotherapy (as much as 10-fold higher). If tumor cells that are resistant to standard doses are sensitive to higher doses of chemotherapy, then tumor cell kill will be greatly increased, and the likelihood of cure would be higher with HSCT. However, the chemotherapy dose cannot be escalated indefinitely because of the risk for death caused by nonhematopoietic toxicity. The success and increasing use of reduced-intensity regimens (including those that are nonmyeloablative) show that immune-mediated effects also contribute to the antitumor effect of allogeneic HSCT.

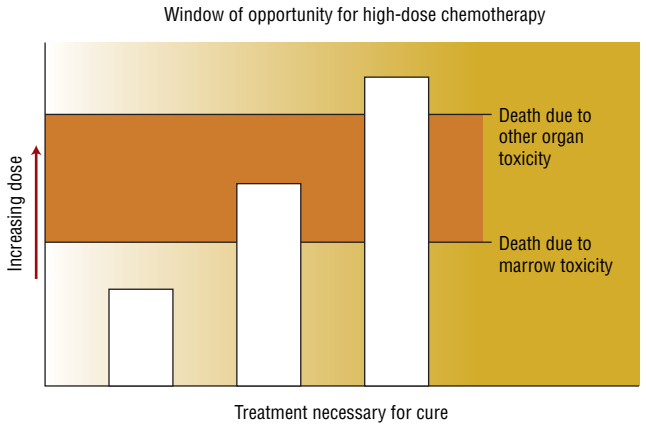

FIGURE 148-1. Patients represented by the middle column are the best candidates for hematopoietic stem cell transplantation because the technique allows for administration of chemotherapy or radiation in doses that otherwise would be intolerable because of severe myelosuppression.

High-dose chemotherapy followed by HSCT has become an important modality for treatment of a variety of malignant and nonmalignant diseases. It is estimated that 50,000 to 60,000 transplants are performed worldwide each year, primarily for malignant diseases.[1] Approximately 40% of these transplants are performed in North America. The number of transplants has grown steadily over the last decade due to an increase in the number of patients receiving umbilical cord blood (UCB) transplants and patients older than 60 years being transplanted after reduced-intensity conditioning regimens.

Historically, the most common type of donor was a genetically nonidentical individual, such as a histocompatible sibling (referred to as allogeneic HSCT). However, the number of autologous transplants in which the patient serves as his or her own donor has increased dramatically, and the number of autologous transplants performed (approximately 35,000) currently exceeds the number of allogeneic HSCTs (approximately 25,000) performed each year.[1] This chapter focuses on the application of HSCT for treatment of malignant disease, but it is important to note that many nonmalignant diseases—including aplastic anemia, thalassemia, sickle cell anemia, immunodeficiency disorders, and other genetic disorders—are potentially curable with allogeneic HSCT. Transplantation is also being investigated as a treatment modality for patients with life-threatening autoimmune diseases, such as rheumatoid arthritis, systemic and multiple sclerosis, and systemic lupus erythematosus.

This chapter summarizes the procedures involved in HSCT and the common complications associated with HSCT. More detailed information on HSCT can be found in published reviews and books.[2–5] Information on HSCT also can be found on several websites, including *http://www.cibmtr.org* (Center for International Blood and Marrow Transplant Research) and *http://www.marrow.org* (National Marrow Donor Program).

DONORS AND HISTOCOMPATIBILITY TESTING

2 Different types of donors are used in HSCT. In *autologous* transplants, patients receive their own hematopoietic stem cells, which were collected and stored before intensive cytotoxic therapy. In *syngeneic* transplants, an identical twin serves as the donor. In *allogeneic* transplants, the donor is genetically not identical to the recipient but shares some common tissue antigens. Immunologic compatibility is evaluated by studies of cell surface antigens (human leukocyte antigens [HLAs]) encoded by genes of the major histocompatibility complex (MHC), which is located on the sixth chromosome.[6] The genes of the HLA system are clustered in three distinct regions designated as class I, class II, and class III. Class I and class II genes encode for antigens that function as major transplantation antigens; products of class III genes have other important roles in the immune system. The major class I loci in humans are referred to as HLA-A, HLA-B, and HLA-C. The one major class II locus is HLA-D. Class II genes encode for the α and β polypeptide chains of the class II molecules. The designation of class II genes consists of three letters: the first (D) indicates the class, the second (M, O, P, Q, or R) the family, and the third (A or B) the chain (α and β, respectively). Class I and class II antigens differ in their tissue distribution, structure, and function. Class I antigens are expressed on virtually all nucleated cells and serve as the primary targets for cytotoxic T lymphocytes. Class II antigens normally are expressed only on macrophages, B lymphocytes, and activated T lymphocytes, and they serve as the primary targets for helper T lymphocytes.

HLA genes are closely linked to one another within the MHC and generally are inherited together. The series of HLA alleles occurring on a single chromosome is termed a *haplotype*. The combination of two parental haplotypes inherited by an individual determines an individual's *genotype*. For a given HLA locus, an individual generally has two different corresponding antigens expressed in their genotype (e.g., HLA-A2 and HLA-A3; HLA-B44 and HLA-B7; HLA-DR4 and HLA-DR2).

Historically, the most important HLA loci in allogeneic HSCT were HLA-A, HLA-B, and HLA-D (or HLA-DR [D-Related]). Typing for HLA-A and HLA-B traditionally was performed by serologic typing with standard microcytotoxicity assays having panels of antisera containing HLA molecules.[7] HLA types determined by this method were reported as the locus (A or B), followed by a number that designated the cell surface HLA antigen (e.g., HLA-A2). Typing for the HLA-D was performed with cellular typing methods, such as the mixed lymphocyte reaction (MLR) or mixed lymphocyte culture (MLC). A "positive" MLR or MLC indicated incompatibility somewhere in the HLA-D region. Individuals who had a low degree of reactivity in the MLR or MLC (expressed as a low percent relative response), and who met other selection criteria, could serve as donors.

Serologic methods of HLA typing have been replaced by DNA-based techniques that use polymerase chain reaction (PCR) amplification of specific HLA genes from genomic DNA. DNA typing methods are categorized by the level of discrimination they provide in defining the sequence of an HLA gene. *Low-resolution* methods provide limited sequence information about a particular HLA gene and allow identification only to the antigen level, much like older serologic methods. Results of low-resolution typing are given in the form HLA-A*02, where the asterisk denotes DNA-based typing and the corresponding serologic equivalent of the antigen is labeled as a two-digit number. Low-resolution typing typically is used to identify sibling donors. However, neither serologic nor low-resolution techniques can distinguish the extremely polymorphic nature of many of the HLA antigens. HLA antigens are characterized by thousands of allelic variations, and each allele may correspond to a unique HLA molecule. Different alleles can be distinguished only by *high-resolution* typing techniques. Results of high-resolution techniques are reported as the corresponding HLA antigen, followed by an asterisk and a four-digit number identifying the allele. For example, the HLA-A*02 antigen may be encoded by alleles HLA-A*0201, A*0202, A*0203, etc. In some cases, the four-digit allele name includes several alleles. For example, HLA-B*4006 includes B*40060101 and B*40060102. Methods that define the HLA type A beyond the serologic level but short of the allele level are termed *intermediate-resolution*. This method might identify the

presence of either HLA-A*0201 or A*0205 but may not be able to discriminate one allele from the other.

3 The degree of HLA mismatching correlates with the risk of graft failure, graft-versus-host disease (GVHD), and survival.[7] In an analysis of 1,874 patients who received HLA-matched unrelated bone marrow donor transplants under the auspices of the National Marrow Donor Program (NMDP), low-resolution mismatches at HLA-A, HLA-B, HLA-C, and HLA-DRB1 were similarly associated with increased risk of GVHD and mortality.[8] The observation concerning the prognostic value of HLA-C was particularly important since until that time the locus was omitted from most matching algorithms. Based on these results, HLA-C typing is now included in standard typing protocols. High-resolution mismatches, particularly at HLA-A and HLA-DRB1, also were associated with increased mortality. In addition, among patients who received transplants from "6 antigen-matched" (HLA-A, HLA-B, and HLA-DRB1 matched) donors, the number of allele mismatches correlated with the risk of grades III to IV acute GVHD and survival. These findings were confirmed in an analysis of over 3,800 unrelated bone marrow donor–recipient pairs in which high-resolution matching for HLA-A, -B, -C, and DRB1 was associated with the best overall survival.[9] That study also showed that mismatches at HLA-DQ or -DP had no effect on survival.

The most common donor for allogeneic HSCT is an HLA-identical sibling. The odds that any one full sibling will match a patient are 1:4. Approximately 30% of Americans have an HLA-identical sibling. In an effort to offer allogeneic HSCT to patients who lack an HLA-identical sibling donor, alternative donors are being used. Rarely, a parent is HLA identical with his or her child. A relative can be a zero- (rare), one-, two-, or three-loci antigen mismatch (assuming testing for HLA-A, HLA-B, and HLA-DR antigens). Although some patients who receive transplants from mismatched related donors experience long-term survival, their risks of graft failure and acute GVHD are higher than for recipients of matched-sibling transplants. It is estimated that only another 10% of patients will have a closely HLA-matched related donor.

The most common type of alternative donor is an individual unrelated to the recipient who is fully or closely HLA-matched. To facilitate identification of these donors, the NMDP (*http://www.marrow.org*) was started in 1986 with initial funding from a U.S. Navy contract. To date, the NMDP has registered more than eight million donors in the United States, and the NMDP has facilitated approximately 40,000 HLA-matched unrelated donor transplants. Patients searching NMDP also have access to an additional four million donors through agreements with international cooperative registries. Approximately one third of the allogeneic HSCTs performed worldwide are from unrelated donors.[1] The NMDP currently requires that the recipient be typed by high-resolution methodology at HLA-A, -B, -C, and -DRB1. The NMDP also suggests typing other DR and DQ alleles when developing a search strategy. Although it is the transplant center's responsibility to select the donor, the NMDP *recommends* that selected donor and recipient be matched at HLA-A, -B, -C, and -DRB1 by high-resolution typing, when possible. To permit an NMDP donor as a source for transplant, the NMDP *requires* a high-resolution match for at least five of six HLA antigens at HLA-A, -B, and -DR for marrow or peripheral blood transplants and four of six for UCB transplants. The following guidelines should be used for unrelated donor selection: (a) assume that HLA-A, -B, -C, and -DRB1 are equally important; (b) avoid antigen mismatches, if possible; (c) accept one allele mismatch over one antigen mismatch; and (d) minimize the number of allele mismatches.[10] If more than one suitable HLA matched unrelated donor is identified, other factors can be used to select the donor, such as younger age, male or nulliparous female, and negative CMV serostatus.

The likelihood of any one unrelated individual being an antigen-level match ranges from 1:100 to 1:1,000,000, depending on the prevalence of the patient's HLA type, race, and ethnic background. With the current size of the NMDP registry, the matching likelihood is higher than 80% for Caucasians. Because most minorities are not as well represented in the program, the likelihood of finding a donor for patients from certain racial or ethnic groups is lower. Agreements between NMDP and international registries may improve the likelihood of finding donors for these patients. Another limitation is the time needed to search for a potential donor. Some donor searches take up to three to four months, and many patients with acute leukemia may relapse while waiting for completion of the search. Cost is also a concern, with the cost for donor search and procurement ranging from $25,000 to $50,000. The clinical results of allogeneic HSCT with unrelated donors are encouraging. With improved HLA typing techniques and better supportive care, most reported outcomes are no longer significantly different than with related sibling donors.[7,11,12]

COLLECTION OF HEMATOPOIETIC STEM CELLS

Hematopoietic stem cells serve as "mother" cells for all blood cells, including erythrocytes, leukocytes, and platelets (see Chap. 95). Stem cells have varying degrees of "stemness." True *pluripotent* stem cells are capable of replicating indefinitely and can give rise to stem and progenitor cells of *all* tissues. *Multipotent* stem cells, such as hematopoietic stem cells, have the capacity for self-renewal and can differentiate into more than one cell type in a particular tissue lineage. Because of their capacity for self-renewal, hematopoietic stem cells are capable of repopulating the recipient's marrow which has been "emptied" by administration of high-dose chemotherapy, either alone or combined with radiation.

4 Hematopoietic stem cells are rare cells, composing less than 0.01% of all bone marrow cells. Isolation and quantitative measurement of hematopoietic stem cells are extremely difficult because of their rarity and their similar appearance to other cells. For these reasons, surrogate markers are used to measure the number of stem cells. Determination of the number of cells expressing the CD34 antigen ($CD34^+$ cells), as determined by flow cytometry, has become the standard method of measuring hematopoietic stem cell content.[13] CD34 is an antigen expressed on hematopoietic stem cells and other early progenitor cells.

Hematopoietic stem cells are found in the bone marrow, peripheral blood, and UCB. Hematopoietic stem cells from the bone marrow are obtained by multiple aspirations from the anterior and posterior iliac crests while the donor is under general anesthesia. The procedure takes approximately one hour and yields 200 to 1,500 mL, depending on the size of the donor. The marrow is transferred into tissue culture medium containing preservative-free heparin. The pooled marrow is passed through a series of stainless steel screens to break up aggregated particles, resulting in an essentially single-cell suspension. In allogeneic HSCT, the marrow stem cells are given to the recipient 12 to 24 hours after harvest. In autologous HSCT, the marrow is frozen and stored until needed. After intravenous infusion, the marrow stem cells enter the systemic circulation and find their way to the bone marrow cavity, where they reseed and grow in the bone marrow microenvironment. Although the donor experiences local soreness for a few days, the procedure usually is well tolerated, with no delayed complications resulting from the marrow aspiration. The major risk of serving as a marrow donor is the risk of undergoing general anesthesia.

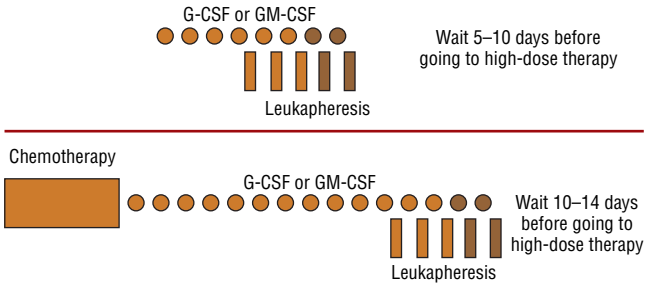

FIGURE 148-2. Schema for collection of peripheral blood progenitor cells after hematopoietic growth factor administration (top) or after chemotherapy and hematopoietic growth factor administration (bottom). Symbols with darker shading represent procedures performed only if adequate numbers of $CD34^+$ cells have not been collected. (G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor.)

Hematopoietic stem cells in peripheral blood (peripheral blood progenitor cells or peripheral blood stem cells [PBSCs]) are found in the mononuclear fraction of white blood cells (lymphocytes and monocytes) and are collected by a procedure called *leukapheresis* (or *apheresis*). In this outpatient procedure, approximately 9 to 14 L of blood are processed over several hours during each daily apheresis session. Most of the blood cells are returned to the donor, and each apheresis yields approximately 200 mL of cells.

The number of hematopoietic stem cells that circulate in peripheral blood normally is too low for this approach to be technically feasible. Without mobilization techniques, at least six aphereses usually are required to collect a sufficient number of PBSCs. Several methods have been used clinically to "mobilize" hematopoietic stem cells from the bone marrow into peripheral blood for use in autologous transplantation.[14,15] Figure 148–2 shows representative schemas for mobilization and collection of PBSCs. With current mobilization techniques, most HSCT centers collect sufficient PBSCs with three or fewer aphereses. One type of mobilization method is administration of chemotherapy, which can briefly increase the number of PBSCs as much as 100-fold. The more commonly used method is administration of a recombinant hematopoietic growth factor such as granulocyte colony-stimulating factor (G-CSF; filgrastim) or granulocyte-macrophage colony-stimulating factor (GM-CSF; sargramostim). Each agent has its own potential advantages and disadvantages.[16] Both agents are FDA-approved for this indication, but G-CSF is the most commonly used growth factor. Dosages are 10 mcg/kg/day (5 to 32 mcg/kg/day) for G-CSF and 250 mcg/m^2/day for GM-CSF. The combination of chemotherapy followed by a hematopoietic growth factor increases the number of PBSCs to a greater extent than either method alone. This approach is more expensive and is associated with more adverse effects than a growth factor alone, but the number of aphereses is reduced and the additional chemotherapy may further reduce the tumor burden before transplant, which may reduce the likelihood of tumor cell contamination in the apheresis collection. Pegfilgrastim has also been evaluated in the mobilization setting, either alone (12 mg) or combined with chemotherapy (6 mg). It appears to be safe and at least as effective as G-CSF. Further studies are needed to evaluate the functional characteristics of cells mobilized by pegfilgrastim as preliminary data suggest that there may be important biologic differences between cells mobilized by pegfilgrastim versus G-CSF.[17]

Plerixafor (AMD3100) is a novel inhibitor of the CXCR4 chemokine receptor that received FDA approval in 2008 as a mobilizing agent. Its approval was based on two multicenter randomized double-blinded trials that compared G-CSF plus plerixafor or placebo as primary mobilization in patients with multiple myeloma or non-Hodgkin lymphoma.[18,19] In both studies, patients received G-CSF 10 mcg/kg/day daily for four days; on the evening of the fourth day, they received either 240 mcg/kg of plerixafor or placebo. Starting on day 5, patients began daily apheresis for up to four days, continuing G-CSF and plerixafor or placebo until at least 5×10^6 $CD34^+$ cells/kg were collected (a minimum of 6×10^6 $CD34^+$ cells/kg were used in the myeloma study). In both studies, a significantly larger proportion of the G-CSF plus plerixafor–treated patients were able to collect the target number of $CD34^+$ cells in no more than two aphereses procedures as compared with the G-CSF plus placebo–treated group. In addition, more patients with both diagnoses were able to reach the target with just one apheresis when given plerixafor. The most common adverse events related to plerixafor were gastrointestinal complaints and injection site reactions. Neutrophil and platelet engraftment post-transplant were similar between treatment groups in both studies. Due to the high cost of plerixafor, many transplant centers are developing mobilization protocols to define its appropriate role. The general trend is to evaluate peripheral blood $CD34^+$ counts after 4–5 days of G-CSF (but prior to apheresis); if this count does not meet a pre-specified level, plerixafor is initiated. Patients who are identified as high risk for primary mobilization failure are often given plerixafor in combination with G-CSF as initial mobilization therapy.

Several studies show that the number of $CD34^+$ cells infused correlates significantly with the rate of neutrophil and platelet recovery after high-dose chemotherapy.[13–15] Rapid neutrophil recovery usually is observed in patients who receive at least 2×10^6 $CD34^+$ cells/kg (body weight of recipient). More rapid platelet recovery is observed when at least 5×10^6 $CD34^+$ cells/kg are transplanted compared to lower cell doses. As a result, most transplant centers use 2×10^6 $CD34^+$ cells/kg as a minimum number to collect for autologous transplant, with an optimal target of 5×10^6 $CD34^+$ cells/kg. For patients with multiple myeloma undergoing tandem transplants, cells for both transplants are collected prior to the first transplant. A minimum of 4×10^6 $CD34^+$ cells/kg are required and generally the entire cell dose collected is divided into two approximately equal aliquots, one for each transplant.

There may be clinical and economic benefits associated with infusion of higher $CD34^+$ cell doses.[20–21] Although the difference in the *median* number of days to neutrophil or platelet recovery usually is no more than 1 to 2 days in patients who receive more than 5×10^6 $CD34^+$ cells/kg compared with those who receive less than 5×10^6 $CD34^+$ cells/kg, fewer patients who receive more than 5×10^6 $CD34^+$ cells/kg have delayed engraftment. This small effect may be important because patients with delayed engraftment consume a disproportionate share of healthcare resources, such as additional transfusions, hospital days, and drugs (e.g., antibiotics and growth factors).

In some otherwise-eligible transplant candidates, an optimal number of $CD34^+$ cells will not be obtained with standard mobilization methods. Risk factors associated with poor mobilization include the amount (greater than six cycles) and type of prior chemotherapy (alkylating agents), lenalidomide use, and prior radiation therapy.[14,15,22] Older age and some diagnoses also are associated with poor mobilization. Several strategies for overcoming the obstacle of poor mobilization have been evaluated, including remobilization with the same or higher doses of the same hematopoietic growth factor, a combination of hematopoietic growth factors, or a combination of chemotherapy and a hematopoietic growth factor. Bone marrow harvest is an option but often is of limited value. Plerixafor has also been evaluated in patients who have failed primary mobilization. In a study of 115 patients who had failed at least one previous mobilization attempt, plerixafor and G-CSF were given with the objective of collecting

at least 2×10^6 $CD34^+$ cells/kg.[23] Depending on diagnosis, approximately 60% to 75% of patients successfully mobilized with this regimen, which compares favorably with other secondary mobilization strategies.

5 Use of peripheral blood instead of bone marrow as a source of hematopoietic stem cells offers several clinical and economic advantages. The most clinically important advantage is that patients who receive mobilized PBSCs experience more rapid hematopoietic engraftment. Although engraftment of all lineages is more rapid when PBSCs are used, the most significant effect is observed with platelet recovery. Patients who receive mobilized PBSCs experience platelet recovery as much as two to three weeks earlier and require fewer platelet transfusions than those who receive bone marrow stem cells. As a result, patients usually are discharged earlier from the hospital, so the overall cost of autologous HSCT is reduced with the use of PBSCs. Another advantage is that the donor does not experience the discomfort associated with marrow aspirations and is not exposed to the risk associated with general anesthesia. PBSCs may be less likely to be contaminated with malignant cells as compared with marrow stem cells. Finally, because PBSCs are collected from the mononuclear cell fraction, a fraction that also contains immunocompetent cells (e.g., natural killer [NK] cells and T lymphocytes), some investigators believe that infusion of PBSCs represents a form of "adoptive immunotherapy." In this model, NK cells and lymphocytes targeted against tumor cells help to kill residual tumor cells. As a result of these clinical and economic advantages, peripheral blood has replaced bone marrow as the source of stem cells in the autologous setting.

Peripheral blood has also become the predominant source of hematopoietic stem cells in adult allogeneic HSCT.[1,24] Approximately 75% of allogeneic HSCTs performed in adults currently come from PBSCs harvested from normal donors, despite early concerns that the increased numbers of T lymphocytes found in peripheral blood could increase the risk of GVHD. Concerns also were raised over the safety and ethics of administering G-CSF to normal individuals volunteering as donors. G-CSF is generally well tolerated. Short-term effects are similar to those seen in cancer patients (e.g., bone pain, headache, fever, arthralgias, malaise). Although there are concerns about increased risk of acute leukemia in healthy subjects given G-CSF, no higher risk has been observed.[25]

Randomized controlled trials and large registry studies show that patients who received allogeneic PBSC transplants from HLA-identical siblings experienced more rapid hematopoietic recovery and required fewer transfusions compared with patients receiving bone marrow.[24,26,27] The difference in the rate of engraftment may be related to the threefold higher numbers of $CD34^+$ cells infused in recipients of PBSC transplants. Although most of these studies did not report an increased risk of acute GVHD or transplant-related mortality in patients receiving allogeneic PBSC transplants, a higher incidence of chronic GVHD has been observed. In a meta-analysis of nine randomized trials evaluating HLA-matched sibling donor transplants in adult patients, the risk of chronic GVHD was nearly twofold higher for patients who received allogeneic PBSC transplants compared with those who received bone marrow transplantation (BMT). However, the risk of relapse was higher in the patients receiving BMT and no significant difference in overall survival was observed. When patients were analyzed based on disease status at the time of transplant, patients with hematologic malignancies at high risk of relapse had a better overall survival when transplanted with PBSC as compared to those who received BMT, which may be related in part to the lower risk of relapse in patients who received PBSC transplants.[27] A randomized comparison of BMT versus PBSC transplants from matched unrelated donors has been completed by the NMDP and data analysis is ongoing.

In addition to bone marrow and peripheral blood, hematopoietic stem cells are found in UCB. UCB is an attractive source for several reasons.[28,29] Because the stem cells are collected from placental blood, there is no risk to the mother or the baby and a very low risk of transmissible infectious diseases, such as cytomegalovirus and Epstein-Barr virus. As most UCB units are banked, the cells are available immediately because the donor does not have to be located and the material harvested. UCB initially was obtained from siblings, but now recipients of transplants from unrelated donors account for almost all patients who receive UCB transplants. More than 450,000 UCB grafts are available in over 100 UCB banks and greater than 20,000 unrelated UCB transplants have been performed worldwide.

Results of uncontrolled studies show that recipients of UCB transplantation have a lower risk of GVHD but a higher risk of graft failure as compared with recipients of BMT.[28] Recipients of UCB transplantation usually receive a $CD34^+$ cell dose more than one log lower than that given to recipients of BMT, and this difference in $CD34^+$ cell dose may explain the delayed engraftment in recipients of UCB transplantation. The number of infused total nucleated and $CD34^+$ cells correlates with outcomes following UCB transplantation. Although no randomized comparisons have been performed, analysis of data from the CIBMTR and the New York Blood Center showed similar survival in children with acute leukemia who underwent either unrelated HLA-mismatched UCB transplantation or unrelated HLA-matched BMT. Children who received an HLA-matched UCB transplant had better outcomes than those who received an HLA-matched BMT. However, higher transplant-related mortality was observed in children transplanted with a low UCB cell dose and a mismatched UCB graft.[30]

A major limitation of UCB transplants is the small volume of blood collected, usually 60 to 150 mL with resultant low numbers of $CD34^+$ cells. Although the relatively low numbers of hematopoietic cells may be adequate for hematopoietic engraftment in children and small adults, it may not be adequate for larger recipients. Efforts to expand the number of hematopoietic stem cells include culturing them ex vivo with combinations of hematopoietic growth factors or "pooling" several units of UCB for one recipient. Retrospective reviews and registry data with unrelated UCB transplants following both myeloablative and reduced-intensity regimens in adult recipients show similar outcomes as compared to BM and PBSC transplants. UCB transplants are now considered an acceptable alternative if an HLA-matched donor is not available.[28,29]

APPROACHES TO ERADICATE MALIGNANT CELLS

CONDITIONING REGIMENS

6 Traditionally, the role of the pretransplant conditioning regimen has been to eradicate malignant cells and thus these regimens contained very high doses of chemotherapy with or without radiation. Due to the severe myelosuppression caused by these regimens, these types of regimens are classified as "myeloablative" conditioning (MAC). All patients undergoing autologous HSCT receive MAC. These regimens are also commonly used in allogeneic transplantation but over the last 15 years, reduced-intensity conditioning (RIC) regimens have emerged in the allogeneic setting. These regimens consist of lower doses of chemotherapy, with or without radiation, or different drugs. The primary goal of RIC is to suppress the recipient's immune system to allow for donor engraftment; malignant cells are primarily eradicated by the graft-versus-malignancy effect.

Myeloablative Regimens

MAC regimens usually include anticancer drugs which have a relatively steep dose-response curve and bone marrow suppression as their dose-limiting toxicity. As part of the conditioning regimen, they are given at very high doses, which would be associated with severe and life-threatening bone marrow suppression if hematopoietic stem cells were not infused. In patients undergoing allogeneic HSCT, another purpose of the conditioning regimen is to suppress the immune system of the recipient so that the graft is not rejected.

Cyclophosphamide, a drug with both immunosuppressive and cytotoxic effects, is commonly used in MAC regimens. Because of the inadequate antitumor activity of cyclophosphamide in some types of cancers, other drugs are often added or substituted. Examples include cytarabine (ara-C), busulfan, thiotepa, etoposide (VP-16), carboplatin, cisplatin, carmustine (BCNU), melphalan, and ifosfamide.

Total-body irradiation (TBI) is sometimes used in pretransplant conditioning regimens. In patients with malignant disease, the rationale of TBI is to eradicate malignant cells located in areas inaccessible to the systemic circulation and thus to the cytotoxic agents. TBI also has significant immunosuppressive activity. Historically, the standard TBI regimen involved administration of a midline tissue dose of approximately 10 Gy (1,000 rad), which is more than twice the lethal dose of radiation for a normal person. Many centers currently give fractionated (split over several days, once or twice a day) rather than single-dose TBI to patients with malignant disease. The rationale for this approach is an improved therapeutic ratio, that is, destruction of more leukemic cells and marrow stem cells while sparing other normal tissues. The acute toxicities of TBI consist of fever, nausea, vomiting, diarrhea, mucositis, and tender swelling of the parotid gland. Long-term complications of TBI-containing regimens include cataract formation, growth retardation, carcinogenesis, permanent reproductive sterility, and secondary malignancies.

Two of the most commonly used MAC regimens (especially for allogeneic HSCT) are cyclophosphamide and TBI (CyTBI) or busulfan and cyclophosphamide (BuCy). When given with TBI, cyclophosphamide is usually given first as two doses of 60 mg/kg/day, followed by TBI. In the original BuCy regimen, busulfan was given orally at a dosage of 1 mg/kg orally every six hours for 16 doses on days −9 to −6 (4 mg/kg/day for four days), followed by four doses of cyclophosphamide given intravenously once daily at a dosage of 50 mg/kg on days −5 to −2. In one widely used modification of the regimen (BuCy2), the total cyclophosphamide dosage is reduced from 200 (50 × 4) to 120 (60 × 2) mg/kg. Plasma busulfan concentrations are monitored at some centers because studies suggest that systemic exposure correlates with outcome, and use of a targeted busulfan and cyclophosphamide preparative regimen may improve patient outcome.[31] A commercially available intravenous form of busulfan (Busulfex®) reduces some of the interpatient variability in systemic exposure and may also reduce the risk of sinusoidal obstruction syndrome. The dose of intravenous busulfan approved for pretransplant conditioning regimens is 0.8 mg/kg every six hours for four days, although once daily dosing regimens have also been developed.

Several prospective randomized studies have compared CyTBI to BuCy in patients with acute or chronic myelogenous leukemia undergoing allogeneic HSCT.[32–34] Results of these studies show that BuCy has similar or greater antileukemic activity than CyTBI in patients with chronic myelogenous leukemia (CML). However, some studies suggest that the CyTBI regimen in patients with acute myelogenous leukemia (AML) was associated with slightly better disease-free survival rates than BuCy. However, none of the patients in these studies who were randomized to BuCy received busulfan doses adjusted on the basis of plasma concentrations, which may explain the differences between CyTBI and BuCy.[31] Long-term toxicities between the two regimens appear to be comparable.

CLINICAL CONTROVERSY

Based on studies showing that busulfan concentrations correlate with outcomes, some centers routinely monitor busulfan concentrations in patients undergoing allogeneic HSCT. However, the busulfan assay is not available at most centers because it is technically difficult to monitor and the number of patients receiving BuCy is low at most centers. Therefore, therapeutic drug monitoring of busulfan usually is inconvenient and expensive because samples must be sent to another center. Some centers have switched to intravenous busulfan to reduce the interpatient variability in pharmacokinetics and avoid the need for monitoring busulfan concentration.

Most preparative regimens used in autologous HSCT include an alkylating agent (either cyclophosphamide or melphalan), with other agents added that may have specific activity against the tumor type being treated. TBI usually is not included in the conditioning regimen in patients who have received prior radiotherapy. One commonly used regimen in autologous HSCT for lymphoma is the CBV regimen, which consists of cyclophosphamide (1.5 g/m^2 on days −6 to −3), carmustine (BCNU; 300 mg/m^2 on day −6), and etoposide (VP-16; 100 mg/m^2 every 12 hours for six doses on days −6 to −4). Other examples of lymphoma conditioning regimens are BEAC (BCNU, etoposide, ara-C, and cyclophosphamide) and BEAM (BCNU, etoposide, ara-C, and melphalan). The availability of anti-CD20–radiolabeled monoclonal antibodies offers the potential to deliver targeted radiation to CD20 positive tumor cells and less to normal organs. ^{131}I-tositumomab has been given, either alone or combined with high-dose cyclophosphamide and etoposide, or with the BEAM regimen followed by autologous HSCT to patients with non-Hodgkin lymphoma.[35,36] With this approach, very high radiation doses could be delivered to sites of disease. Preliminary results with this approach are encouraging and a Blood and Marrow Clinical Trials Network study that randomized patients with non-Hodgkin lymphoma to BEAM conditioning with or without ^{131}I-tositumomab has been completed; analysis of the data is ongoing. No single preparative regimen is clearly superior to other regimens for treatment of lymphoma. Single agent melphalan (200mg/m^2) is the standard conditioning regimen for patients undergoing autologous HSCT for myeloma. Studies are ongoing evaluating the addition of newer agents (e.g., bortezomib).

Reduced-Intensity Conditioning Regimens

❼ Donor T cells contribute to the tumor cell kill and prevention of relapse observed after allogeneic HSCT, an effect referred to as the *graft-versus-malignancy* (GVM) *effect*. Evidence for the GVM effect is based on retrospective studies showing that patients who developed GVHD had a lower risk of leukemic relapse than those who did not develop GVHD. However, the overall survival rate was not different because of the increased nonrelapse mortality associated with GVHD. Other anecdotal evidence supporting a T-cell–mediated GVM effect was the increased risk of relapse found with T-cell–depleted transplants compared with unmodified transplants and the difference in relapse rates between recipients of syngeneic and HLA-identical sibling transplants.

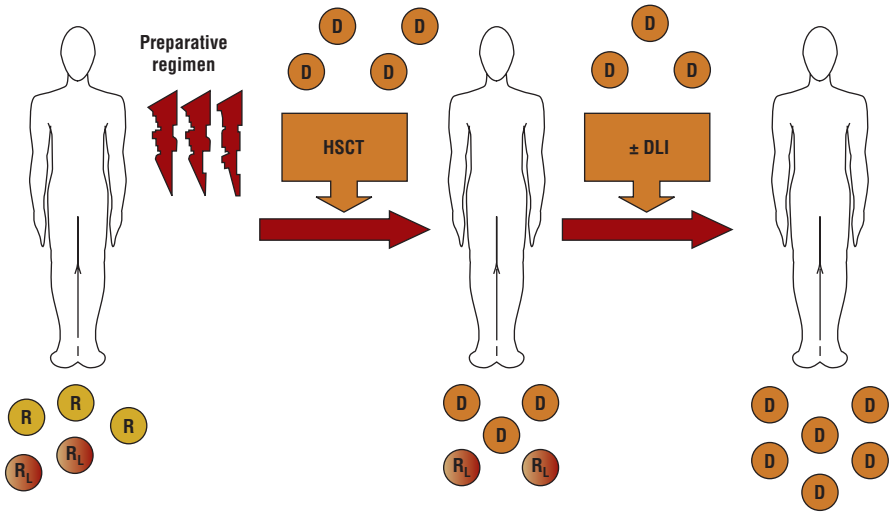

FIGURE 148-3. Schema for nonmyeloablative transplantation for hematologic malignancy. Recipients (R) receive a reduced-intensity conditioning regimen and an allogeneic hematopoietic stem cell transplant (HSCT). Initially, mixed chimerism is present with the coexistence of donor (D) cells and recipient-derived normal and leukemia/lymphoma (R_L) cells. Donor-derived T cells mediate a graft-versus-host hematopoietic effect that eradicates residual recipient-derived normal and malignant hematopoietic cells. Donor lymphocyte infusions (DLI) can be administered to enhance graft-versus-malignancy effects.

In the early 1990s, researchers began to evaluate RIC regimens as a method to take advantage of the GVM effect. The rationale for RIC is based on the assumption that much of the tumor cell kill associated with allogeneic HSCT is the result of the GVM effect and not only an effect of the myeloablative doses of chemotherapy or radiation (Fig. 148–3).[37,38] If this assumption is correct, a major role of the conditioning regimen is to suppress the host immune system, thus allowing engraftment of donor hematopoietic stem cells and donor T-cell cytotoxicity. A major advantage of RIC is that potentially curative transplants are being offered to patients who typically would not be considered for allogeneic HSCT because of their unacceptably high risk of transplant-related complications (e.g., increased age or moderately compromised organ function). More than 60% of patients receiving RIC regimens are older than 50 years compared to less than 20% of those receiving MAC regimens.[1] In addition, because of the lower rate of toxicity, allogeneic HSCT with RIC can be offered to patients who have relapsed after traditional myeloablative autologous or allogeneic transplants. Approximately 30% of allogeneic transplants are now being performed with RIC regimens.[1]

Because RIC regimens may not be completely myeloablative, host hematopoiesis can persist and lead to mixed chimerism (blood cells from both donor and recipient are present; see Fig. 148–3).[37] Several studies have reported significant correlations between donor T-cell chimerism levels and the risk of graft rejection, GVHD, and relapse. For example, a low percentage of donor T and NK cells present on day 14 has been associated with graft rejection, whereas high T-cell donor chimerism on day 28 has been associated with acute GVHD. Achievement of full donor chimerism was associated with better progression-free survival. These data suggest that monitoring donor chimerism posttransplant may allow early interventions to prevent graft rejection or relapse.

A number of RIC regimens that vary in their cytotoxic, myelosuppressive, and immunosuppressive activity have been developed.[37,38] Most regimens include fludarabine (125–240 mg/m^2) because of its potent immunosuppressive activity, combined with either low-dose TBI (at doses up to 8 Gy [800 rad]) or an alkylating agent, such as cyclophosphamide (2–3.6 g/m^2 or 120–200 mg/kg), busulfan (up to 10 mg/kg), or melphalan (up to 180 mg/m^2). Antithymocyte globulin or alemtuzumab is sometimes given for additional immunosuppression, and other purine analogs (e.g., pentostatin or clofarabine) are sometimes used instead of fludarabine. Rituximab has also been included in patients with CD20-positive lymphoid malignancies.[39] Many of these regimens are myeloablative but are defined as RIC because of the reduced doses of chemotherapy used resulting in a lower transplant-related mortality.

Some RIC regimens are considered nonmyeloablative (NMA). These regimens generally result in minimal myelosuppression (not requiring hematopoietic cell support) and very little regimen-related toxicity but, like other RIC regimens, are immunosuppressive enough to result in full engraftment of important donor immune effector cells.[40] Two of the most common NMA regimens are fludarabine (25 mg/m^2/day for 3 to 5 days) combined with cyclophosphamide (60 mg/kg/ day × two days) or with TBI (≤2 Gy [<200 rad]). Although regimen-related toxicity is reduced with RIC and NMA regimens, GVHD remains a significant cause of morbidity and mortality similar to that seen after MAC regimens.[41]

Several clinical studies have reported the results of RIC regimens from HLA-matched related or unrelated donors.[37,38] Two hundred and fifty-three patients received HLA-matched related allogeneic HSCT with an NMA regimen at one of several transplant centers that are part of an international consortium of transplant centers led by the Fred Hutchinson Cancer Research Center. All patients had a hematologic malignancy. The source of hematopoietic stem cells was G-CSF–mobilized PBSCs. The median age was 54 years; the oldest patient was 73 years. The median followup was at 13 months. The first 58 patients were conditioned with TBI alone (2 Gy [200 rad]); 17% of these patients experienced nonfatal graft rejection. Fludarabine was added to the conditioning regimen in the remaining patients and the incidence of graft rejection decreased to less than 5%. A combination of cyclosporine and mycophenolate mofetil was given as GVHD prophylaxis. Most patients did not require platelet transfusions, and only approximately two thirds of patients required RBC transfusions. Most of the transplants were performed entirely in the ambulatory care setting. Typical side effects, such as mucositis, diarrhea, and organ toxicities, were absent.

Although the risk of infection in the first 100 days appeared to be lower than that seen with myeloablative allogeneic HSCT, the risk of late viral and fungal infections persisted.[41] GVHD, although delayed compared to historical controls, still was a significant problem. Transplant-related mortality was only 5% at day 100. Compared with matched controls, patients who received NMA conditioning had significantly lower transplant-related mortality at day 100 and at one year.[42]

Under a similar protocol, the same consortium of transplant centers treated 89 patients with HLA-matched unrelated NMA transplant.[43] Durable engraftment was observed in 85% of patients who received G-CSF–mobilized PBSCs but only in 56% of marrow recipients. Transplant-related mortality was 11% at day 100. Patients who received PBSCs had improved progression-free and overall survival compared with marrow recipients.

CLINICAL CONTROVERSY

Although RIC regimens reduce transplant-related mortality, whether this approach results in improved survival compared with MAC regimens is not clear. Also unclear is whether this approach improves survival compared with conventional chemotherapy. Direct comparison of the results of NMT versus myeloablative transplants is difficult because patients undergoing NMT tend to be older and have more comorbidities. Randomized controlled trials addressing these questions are ongoing, and the results of these studies should better define the role of RIC regimens and NMT.

Progression-free and overall survival varies depending on the specific RIC regimen, disease type and status at the time of transplant, donor type, and patient age and comorbidities. Patients with indolent lymphoid malignancies had the lowest relapse rate after NMA transplants, whereas those with advanced myeloid and lymphoid malignancies had the highest relapse rate.[44] Patients transplanted while in remission had lower relapse rates than those who were not in remission at the time of transplant. Direct comparison of the results of NMA versus myeloablative transplants is difficult because patients receiving NMA regimens tend to be older and have more comorbidities. In two retrospective comparisons of NMA regimens versus standard myeloablative transplants in patients with AML who were older than 50 years, nonrelapse mortality was lower in the NMA-treated patients, but leukemia-free survival was equivalent due to the higher relapse rate seen in the NMA groups.[45,46] Studies evaluating "disease-targeted" therapy (radiolabeled monoclonal antibody, imatinib, or rituximab) combined with NMA transplants to improve outcomes in specific malignancies are ongoing.[37] Antitumor responses have been observed with RIC regimens in patients with renal cell carcinoma, melanoma, breast cancer, and other solid tumors.[37,47] In order to improve the efficacy seen in this setting, some investigators are evaluating novel approaches that enhance allogeneic immune responses against tumor-associated antigens (if available), such as posttransplant vaccination.

PURGING THE STEM CELL PRODUCT

One disadvantage of autologous HSCT is that the stem cell product (graft) may be contaminated with malignant cells. Infusion of these malignant cells may contribute to tumor relapse. Many approaches have been developed to eliminate ("purge") the marrow of these tumor cells. The most common approach is addition of substances, such as chemicals or monoclonal antibodies, to the stem cell product while it is outside of the body (ex vivo; Fig. 148–4). Because the substances are removed before the stem cells are infused, nonhematopoietic tissues are not exposed to the substances and therefore are not damaged. However, these substances can remove or damage hematopoietic stem cells, which are essential for complete and rapid engraftment, and purging has been associated with delayed marrow recovery. Ex vivo marrow purging has also been performed in allogeneic HSCT in an attempt to eliminate T lymphocytes believed to be responsible for acute GVHD (Fig. 148–4). Results with this approach are discussed in the section on Graft-Versus-Host Disease.

One approach is the addition of one or more monoclonal antibodies that are directed against specific antigens present on the tumor cells but are absent on nearly all other cells.[35] Although this approach is theoretically attractive, it is limited because not all cells from patients with the same type of cancer express a specific antigen. Furthermore, for some types of cancers, identifying antigens distinct from those present on normal hematopoietic stem cells is difficult. To date, this strategy has been used most commonly in patients with lymphoid malignancies, such as acute lymphoblastic leukemia (ALL), chronic lymphocytic leukemia, or non-Hodgkin lymphoma.

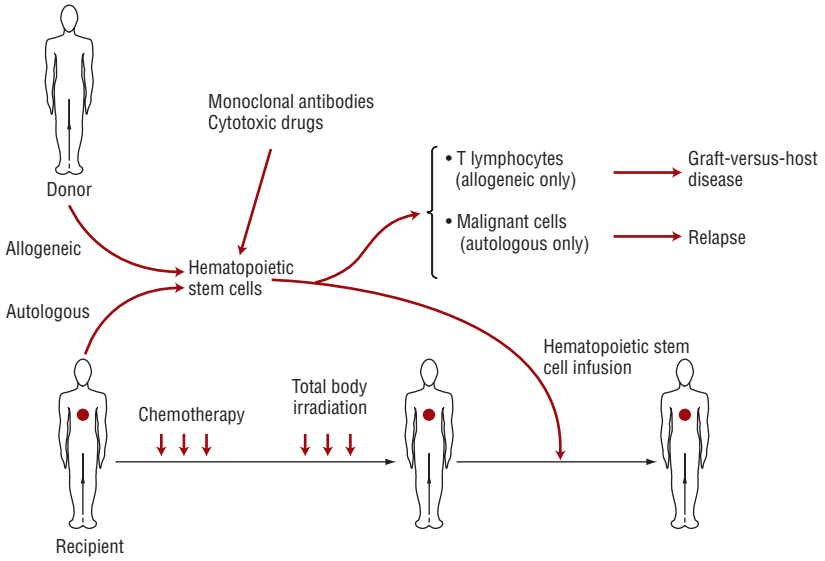

FIGURE 148-4. Use of ex vivo marrow purging to remove or destroy T cells (allogeneic only) or residual malignant cells (autologous only).

Rituximab has been used pretransplant for in vivo purging of the stem cell graft prior to autologous HSCT in patients with non-Hodgkin lymphoma.[35,39] When used for in vivo purging, rituximab usually is given before apheresis. Although use of rituximab was effective in reducing the number of tumor cells in the stem cell graft, whether this approach improves disease-free survival after autologous HSCT is not clear.

POSTTRANSPLANT THERAPY

8 Relapse of primary disease remains the most common cause of death for both allogeneic and autologous transplant patients. Several posttransplant therapies have been evaluated including immunotherapy, conventional chemotherapy, and targeted therapy. Relapse following autologous transplant can often be treated with standard doses of chemotherapy, a second autologous transplant. or even an allogeneic transplant, depending on the diagnosis, disease status, and side effects, response and duration of response to the first transplant. Options for treatment of relapse after an allogeneic transplant, however, are limited by GVHD and regimen-related toxicities caused by the conditioning regimen.

Immunotherapy

Donor Lymphocyte Infusions The rationale for posttransplant immunotherapy after allogeneic HSCT is based on the GVM effect. To take advantage of the GVM effect in patients who relapse after allogeneic HSCT, immunosuppressive therapy being used for GVHD is withdrawn as quickly as possible without inducing a serious GVHD flare. In rare cases, this is enough to reinduce a remission but in the majority of cases, further therapy is required.

Perhaps the most commonly used form of posttransplant immunotherapy is donor lymphocyte infusions (DLI).[48,49] Lymphocytes are collected from the same donor who provided hematopoietic stem cells. Most experiences with DLI have been in patients with CML. More than 80% of patients who are in cytogenetic or molecular relapse respond to DLI. The response rate of patients in more advanced phases is approximately 15% to 30%. Although the time to response is delayed (median 3 to 4 months), patients often have a durable molecular remission to DLI.

Response rates to DLI of patients with other myeloid malignancies, such as AML and myelodysplasia, are generally lower (25% to 30%) than the rates of patients with CML.[48,49] This may be related to the rapid proliferation of acute leukemia within the often prolonged time to response after DLI or to the lack of suitable target antigens on non-CML cells for recognition by donor cytotoxic T cells. Patients with relapsed AML post-HSCT are more likely to achieve a complete response to DLI if they had a longer remission period after transplant and had some GVHD after the DLI; low tumor burden, remission at the time of DLI, and good-risk cytogenetics have also been shown to be favorable characteristics. Administration of induction chemotherapy prior to DLI administration may improve the antitumor activity of DLI in patients with AML, but this method has not been tested in a randomized study. DLI has been shown to have limited benefit in patients with relapsed ALL after transplant.

DLI appears to be effective in patients with multiple myeloma who relapse after allogeneic HSCT, with reported response rates of 40% to 50%. Unfortunately, these responses tend to be transient and associated with the occurrence of GVHD. Anecdotal evidence suggests a graft-versus-lymphoma effect in patients with indolent non-Hodgkin lymphoma and chronic lymphocytic leukemia

DLI is sometimes given posttransplant for treatment of residual or progressive disease in patients with mixed chimerism after NMA conditioning. Preliminary results show that DLI in this setting is effective and is associated with acceptable toxicity (mostly GVHD) in patients with early signs of disease persistence or progression.[50] Prophylactic DLI to eradicate residual disease and reduce the risk of relapse is being investigated.

The most serious complications of DLI are pancytopenia and GVHD, and DLI is not usually given to patients with GVHD. The cytopenias generally are transient and can be treated with hematopoietic growth factors. A small percentage of patients may have a more prolonged course of aplasia with associated risk of infection, bleeding, and anemia. These patients may benefit from another infusion of donor stem cells. Acute GVHD (grade II or greater) occurs in 40% to 60% of patients receiving DLI. Although the severity of GVHD has been correlated with the GVM effect, complete responses have been seen in the absence of GVHD, suggesting that the effects can be separated. DLI is associated with 10% to 15% nonrelapse mortality at one year.

Because of the potential of DLI to cure some patients with certain hematologic malignancies, investigators are evaluating strategies to separate the GVM effect from the GVH effect, which would make DLI more tolerable. Other investigators are developing methods that would expand the efficacy of DLI to other malignancies. Some of these strategies include T-cell depletion from the stem cells, followed by delayed T-cell add-back transplant for patients with evidence of residual disease approximately three months posttransplant; selective depletion of $CD8^+$ cells from the DLI; in vivo or in vitro T-cell activation with interleukin (IL)-2; and infusion of T cells that are selected to recognize tumor-specific antigens.[49]

Immunomodulatory Cytokines Another approach to inducing a GVM effect in patients who relapse after HSCT is posttransplant administration of a cytokine with immunomodulatory activity, such as IL-2.[51] Some benefit in terms of effects on NK cells and other important antitumor immune responses has been observed with the use of IL-2. Toxicities have been tolerable in most patients but can be serious and life-threatening. Studies that will define the role of these cytokines in prolonging relapse-free survival after HSCT are necessary.

Monoclonal Antibodies Rituximab is being evaluated as adjuvant therapy in patients with non-Hodgkin lymphoma treated with autologous HSCT.[35,39] The timing and number of doses of rituximab therapy vary. The Stanford program reported promising results with two four-week courses starting at day 42 and 6 months posttransplant.[52] Neutropenia was observed in approximately 50% of the patients treated.

Chemotherapy or Targeted Therapy

Imatinib has been evaluated for the treatment of posttransplant relapse of CML in several studies.[53] These reports suggest that imatinib may be an effective therapy with up to 70% of patients achieving a complete molecular response, which is maintained in some patients even after discontinuation of imatinib. There was no indication that GVHD was exacerbated and imatinib appeared to be well tolerated posttransplant. Based on these data, imatinib may be considered an alternative to DLI in selected patients. There are less data to support the use of second-generation tyrosine kinase inhibitors but these agents may play a role in this setting because most CML patients who currently undergo allogeneic HSCT have imatinib-resistant disease. Patients may also benefit from combining one of these agents with DLI. Patients with Philadelphia chromosome positive ALL who relapse posttransplant may also respond favorably to tyrosine kinase inhibitors. Ongoing clinical trials are evaluating tyrosine kinase inhibitors as remission maintenance therapy to prevent relapse after transplant.

Based on its activity in AML and MDS, 5-azacitidine is being evaluated in the posttransplant setting to prevent or treat relapse. Investigators at the M.D. Anderson Cancer Center reported their experience with low-dose 5-azacitidine (16 to 40 mg/m^2/day subcutaneously for five days) in 17 patients.[54] That study demonstrated that administration of these lower doses is feasible without extramedullary toxicity or exacerbation of GVHD. Durable remissions were seen in some patients who were treated for posttransplant relapse but those with rapidly progressing disease were less likely to respond. A randomized controlled trial for posttranplant maintenance therapy is underway at that institution.

Finally, posttransplant therapy is being evaluated in multiple myeloma. Previous studies have shown a potential benefit of thalidomide to prevent relapse posttransplant but questions remain regarding which patients would benefit the most from this approach. In addition, the use of thalidomide is limited by its neurotoxicity and other bothersome side effects. Combinations of newer agents such as lenalidomide and bortezomib are now being evaluated in this setting.[55]

TRANSPLANT-RELATED COMPLICATIONS

9 Although many patients with cancer who are treated with high-dose chemotherapy and autologous or allogeneic HSCT experience long-term survival and cure of their disease, this modality is associated with many serious and potentially life-threatening complications. In the early 1970s, posttransplant mortality was extremely high, and most allogeneic HSCT patients did not survive beyond 100 days because of infection, GVHD, organ toxicities, and leukemic relapse. Today, largely because of the availability of improved broad-spectrum antiinfective agents, immunosuppressive drugs, and hematopoietic growth factors, transplant-related mortality after allogeneic HSCT with HLA-matched sibling donors has been reduced to less than 30%. Mortality is even lower with the use of RIC regimens. Causes of death are still related to transplant-related organ toxicity, GVHD, or immunosuppression. Until recently, allogeneic HSCT usually was restricted to patients younger than 50 years with an HLA-identical sibling donor and younger than 40 years with an HLA-matched unrelated donor. With advances in the prevention and treatment of transplant-related complications and the availability of RIC regimens, allogeneic HSCT now is being offered to patients up to the age of 70. The risk of transplant-related mortality after high-dose chemotherapy with autologous HSCT generally is less than 5%, depending on patient population and conditioning regimen. Mortality is lower with autologous transplants because of the lack of GVHD and associated complications of immunosuppression. Transplant-related mortality in autologous HSCT usually is caused by conditioning regimen organ toxicity or infection.

Table 148–1 lists the dose-limiting nonhematologic toxicities for several drugs that are commonly included in MAC regimens. These toxicities may be uncommon or rare with administration of conventional doses of specific drugs. When these agents are given in high doses, the toxicities seen with conventional doses (e.g., mucositis, enteritis, nausea, vomiting, hematuria) can be more frequent and/or severe. Several unusual and severe manifestations of regimen-related toxicities are discussed in this section.

TABLE 148-1 Dose-Limiting Nonhematologic Toxicities for Selected Chemotherapeutic Agents Included in Myeloablative Conditioning Regimens in Hematopoietic Stem Cell Transplantation

Drug	Conventional Dose[a] (mg/m^2)	HSCT Dose (mg/m^2)	Dose-Limiting Toxicity
Busulfan (oral)	2	450	Hepatic
Carboplatin	400	2,000	Hepatic, renal
Carmustine	200	1,200	Pulmonary, hepatic
Cisplatin	100	200	Renal, peripheral neuropathy
Cyclophosphamide	1,000	7,500	Cardiomyopathy
Etoposide	300–600	2,400	Mucositis
Ifosfamide	5,000	18,000	Renal
Melphalan	40	225	Mucositis
Thiotepa	20–50	1125	Mucositis, central nervous system

HSCT, hematopoietic stem cell transplantation.
[a]Doses are approximate and are for drugs used as single agents. When combinations are used, doses may need to be decreased.

SINUSOIDAL OBSTRUCTION SYNDROME

Sinusoidal obstruction syndrome (SOS), formerly known as hepatic venoocclusive disease (VOD), occurs as a result of chemotherapy-induced dilation of hepatic sinusoids, necrosis of perivenular hepatocytes, and collagenization of the hepatic sinusoids and venules. These histologic changes can lead to obstruction of sinusoidal flow, portal hypertension, and hepatic failure.[53] Clinical signs of SOS include fluid retention (resulting in sudden weight gain and ascites), hepatomegaly (sometimes painful), and hyperbilirubinemia/jaundice. SOS usually occurs within the first three weeks after transplant. The incidence of SOS ranges from 5% to 20% in most published series. Severe SOS is fatal in 50% to 75% of cases. Factors that reportedly increase the risk of SOS include use of TBI-containing conditioning regimens (dose-dependent), increased systemic exposure to busulfan, individual variability in cyclophosphamide metabolism, chronic viral hepatitis, and elevated liver function tests pretransplant. Pretransplant exposure to gemtuzumab ozogamicin (Mylotarg®) has been implicated in the development of SOS in patients undergoing allogeneic HSCT, especially when given within a few months of transplant.

The pharmacokinetics of busulfan or cyclophosphamide may correlate with the risk of SOS.[56] Because busulfan concentrations have been correlated with the risk of SOS, many HSCT centers adjust busulfan doses based on plasma concentrations. Exposure to the O-carboxyethyl-phosphoramide mustard metabolite of cyclophosphamide has been reported to correlate with the risk of SOS and nonrelapse mortality. In addition, when busulfan and cyclophosphamide are given in combination, the order in which they are given may contribute to the risk of SOS. Presumably because of the effect of busulfan on cyclophosphamide pharmacokinetics (increased exposure to active and/or toxic metabolites), liver toxicity appears to be worse when busulfan is given first, as traditionally given in the BuCy regimen. This effect appears to be ameliorated by reversing the order or delaying cyclophosphamide administration to 24 to 48 hours after busulfan.

Some studies suggest that prostaglandin E_1, unfractionated low-molecular-weight heparin, or ursodiol may be partially effective in preventing SOS.[56] In a systematic review of three randomized trials comparing prophylactic ursodiol versus no treatment, Tay et al.[57] found a reduced risk of SOS (relative risk 0.34, 95% confidence interval 0.17–0.66) with prophylactic ursodiol. These studies were conducted in patients undergoing myeloablative transplants. Transplant-related mortality was reduced (relative risk 0.58, 95% confidence interval 0.35–0.95). Other outcomes, such as relapse and overall survival, were not affected. Prophylactic defibrotide may also be effective.[56]

Treatment is generally supportive, including fluid and electrolyte management. Mild-to-moderate disease generally resolves without specific therapy. Recombinant tissue plasminogen activator has been given to patients with severe SOS because of the possible role of the coagulation cascade in the pathogenesis of SOS. Responses have been reported, but patients also experienced a higher risk of bleeding.[56] Defibrotide has been evaluated in a randomized phase II study as therapy of severe SOS.[58] Patients received either 25 mg/kg/day or 40 mg/kg/day. Overall response rate and posttransplant day 100 survival rates were 46% and 42%, respectively, with no difference between the two doses. There was also no significant difference in adverse events. Defibrotide 25 mg/kg/day was selected for ongoing phase III trials in patients with SOS.

PULMONARY COMPLICATIONS

Pulmonary complications following HSCT can be categorized as infectious and noninfectious (infectious complications are discussed in Chap. 131). Noninfectious complications can be caused by direct damage to the pulmonary tissue by chemotherapy or radiation used in the conditioning regimen, immune effects of the graft, or other causes not clearly understood. Early complications include diffuse alveolar hemorrhage, engraftment syndrome, and idiopathic interstitial pneumonitis. Diffuse alveolar hemorrhage is characterized by dyspnea, hypoxia, dry cough, and fever; chest x-ray usually shows diffuse infiltrates in an alveolar pattern. Diffuse alveolar hemorrhage is diagnosed by examination of bronchoalveolar lavage fluid via bronchoscopy, which reveals progressively bloodier fluid with each instilled aliquot, and negative findings on microbiologic analysis. Although the condition can be life-threatening or fatal, prompt treatment with high doses of corticosteroids is sometimes beneficial. A few patients have been treated successfully with recombinant human activated factor VIIa, desmopressin, or aminocaproic acid.[59]

Engraftment syndrome is characterized by fever, erythrodermatous skin rash, and noncardiogenic pulmonary edema can occur during neutrophil recovery after HSCT.[60] The incidence of engraftment syndrome is not known because of the lack of uniform diagnostic criteria, although some series report that approximately 10% of patients who receive autologous HSCT develop the syndrome. Engraftment syndrome can progress to life-threatening respiratory failure with or without multiple organ failure. Corticosteroids are effective in some patients.

Idiopathic interstitial pneumonitis (also called idiopathic pneumonia syndrome) is defined as widespread alveolar injury in the absence of active lower respiratory tract infection following HSCT. Patients with idiopathic interstitial pneumonitis are clinically indistinguishable from patients with interstitial pneumonitis related to infection. Idiopathic interstitial pneumonitis is postulated to have a multifactorial etiology, including toxic effects of myeloablative conditioning, immunologic cell-mediated injury, inflammatory cytokine-induced lung damage, and occult pulmonary infections. The risk is similar in recipients of autologous HSCT or allogeneic HSCT but appears to be higher in patients who are conditioned with a TBI-containing regimen or who have acute GVHD. The incidence of idiopathic interstitial pneumonitis may be lower after RIC compared to conventional regimens.[61] Mortality as high as 70% has been reported, and treatment consists of supportive care only. Etanercept has been beneficial in some patients with idiopathic interstitial pneumonitis.[62]

Late pulmonary complications cover a wide spectrum of disorders and include both obstructive and restrictive lung diseases. The most well-described of these disorders is bronchiolitis obliterans with or without organizing pneumonia.[63] While bronchiolitis obliterans is thought to be a result of chronic GVHD affecting the lungs, its pathogenesis has not been completely elucidated. Therapy consists of corticosteroids, which are approximately 50% effective. Patients with mild-to-moderate airflow impairment appear to have the best response. Survival at five years from diagnosis of bronchiolitis obliterans is less than 20%.

GRAFT FAILURE

Initial engraftment after high-dose chemotherapy conditioning regimens usually occurs in the first two to four weeks posttransplant. Engraftment is evidenced by rising peripheral blood counts and the presence of hematopoietic precursor cells in the marrow. In allogeneic HSCT, the presence of donor cells (i.e., chimerism) is confirmed by fluorescent in situ hybridization of sex chromosomes and PCR-based analysis of polymorphic DNA sequences. Full chimerism is defined as greater than 95% of T cells of donor origin. In most patients, engraftment is sustained with complete recovery of hematopoiesis.

Graft failure can occur after autologous, syngeneic, and allogeneic HSCT. It can be the result of an immunologic reaction between donor and host, heavy pretreatment with chemotherapy and/or radiation therapy, infusion of insufficient numbers of hematopoietic stem cells, viral infection, recurrence of primary hematologic malignancy, drug reaction (e.g., to ganciclovir), or development of a secondary myelodysplasia. Two syndromes have been observed. Early graft failure occurs when the rate of hematopoietic recovery is delayed (primary graft failure or delayed engraftment), whereas late graft failure is characterized by a decline in peripheral blood counts after initial engraftment (secondary graft failure). With widespread use of PBSCs and posttransplant growth factors, primary graft failure is rare after autologous and HLA-matched related allogeneic HSCT but is not uncommon after UCB transplant. Graft failure that occurs after allogeneic HSCT, characterized by regrowth of immunocompetent host cells and a simultaneous loss of donor cells, is referred to as *graft rejection*. Graft rejection occurs rarely after HLA-matched related allogeneic HSCT. An increased risk of graft rejection has been observed in recipients of hematopoietic stem cells from HLA-mismatched related or unrelated donors, recipients of T cell–depleted marrow, and patients with severe aplastic anemia. The long-term prognosis of patients with graft failure is poor. Despite supportive care, death may result from infection or bleeding. In some patients with an allogeneic donor, a second infusion of stem cells can be attempted. The most effective therapy for graft failure is G-CSF or GM-CSF.

Hematopoietic growth factors usually are given posttransplant to patients who receive autologous HSCT, although some clinicians believe that posttransplant G-CSF or GM-CSF is unnecessary because of the already rapid engraftment seen after mobilized PBSC transplants.[64,65] The usual dosage of GM-CSF is 250 mcg/m^2/day. Many different dosages and schedules of G-CSF have been used after autologous HSCT. Originally, G-CSF was given at a dose of 5 to 10 mcg/kg/day beginning on the day of or the day after infusion of stem cells and continued until neutrophil recovery to greater than an arbitrary number of neutrophils (500 to 1,000 cells/mm^3 [0.5×10^9 to 1.0×10^9]). In one study of three different G-CSF dosages (5, 10, and 16 mcg/kg/day), no significant difference in the rate of hematopoietic recovery between the different dosages was observed.[66] In another study, delayed initiation of G-CSF at a dosage of 5 mcg/kg/day until day five posttransplant did not impair hematopoietic recovery after autologous HSCT.[67] Pegfilgrastim in the posttransplant setting has been evaluated in several uncontrolled trials and one randomized, controlled trial.[17] Although pegfilgrastim appears to be equally efficacious to filgrastim, more data is needed to justify the added cost of pegfilgrastim in this setting.

Hematopoietic growth factors accelerate the rate of hematopoietic recovery in patients undergoing allogeneic HSCT. However, laboratory studies show that growth factors can modify T-cell and dendritic cell function, and one retrospective study of patients with acute leukemia reported that G-CSF use after allogeneic BMT was associated with significantly increased risk of acute GVHD and death.[68] No detrimental effects of G-CSF were noted in patients receiving allogeneic PBSC transplants. In a meta-analysis of 34 randomized controlled trials, no increased risk of acute GVHD or treatment-related mortality was observed when G-CSF or GM-CSF was used after allogeneic HSCT.[69] In another retrospective analysis of 2,719 patients from the CIBMTR, no association between G-CSF use and acute or chronic GVHD, transplant-related mortality, or survival was observed in recipients of HLA-identical sibling bone marrow, recipients of HLA-identical sibling peripheral blood, and recipients of HLA-matched unrelated donor bone marrow.[70] The use of growth factors after allogeneic HSCT remains controversial, except in patients receiving UCB transplants who are at increased risk for delayed engraftment and graft failure.

Results of studies with platelet growth factors, such as thrombopoietin and IL-11, given posttransplant have been disappointing. Platelet transfusions remain the standard of care in patients with thrombocytopenia below a given threshold (e.g., 10,000 cells/mm^3 [10×10^9]) or in patients with significant bleeding.

Anemia may be problematic in the posttransplant setting, especially in patients receiving allogeneic HSCT. The etiology is unclear and most likely is multifactorial. Although erythropoietin administration may be useful in reducing the need for red blood cell transfusions, its use in cancer patients is associated with an increased risk of adverse events and is limited by FDA warnings and restrictions.

GRAFT-VERSUS-HOST DISEASE (GVHD)

GVHD is caused by immunocompetent allogeneic donor T cells reacting against recipient/host antigens presented by antigen-presenting cells. In that setting, donor T cells recognize unmatched major or minor histocompatibility antigens of the host as genetically foreign, become activated, proliferate, and attack recipient tissue, thereby producing the clinical syndrome of GVHD.

Two different clinical GVHD syndromes (acute and chronic) are recognized, depending on the time of onset and clinical presentation.[71,72] *Acute* GVHD usually presents prior to day 100 posttransplant (*classic* acute GVHD), but it can be *persistent, recurrent*, or *late-onset* with clinical manifestations occurring after day 100. Acute GVHD observed after day 100 usually is the result of immunosuppression withdrawal for relapsed or persistent malignancy or administration of DLI, or occurs in the setting of RIC. *Chronic* GVHD usually occurs after day 100, either with or without concurrent acute GVHD. Chronic GVHD without characteristics of acute GVHD (*classic* chronic GVHD) occurs after resolution of acute GVHD or de novo (no prior acute GVHD). An "overlap syndrome" may occur in which features of both acute and chronic GVHD are present simultaneously, usually when chronic GVHD develops prior to resolution of acute GVHD (progressive onset). Acute GVHD usually is limited to the gastrointestinal tract, skin, and liver, whereas signs and symptoms of chronic GVHD resemble an autoimmune disorder and can affect many organ systems.

A "hyperacute" form of GVHD may occur in patients with multiple HLA mismatches and in patients who receive T-cell–replete transplants without adequate GVHD prophylaxis, especially in myeloablative regimens.[73] Descriptions of hyperacute GVHD vary but usually include fever, generalized erythroderma, desquamation, and edema. More severe forms with accompanying organ failure have been seen in haploidentical donors. Hyperacute GVHD typically occurs approximately one week after transplant before engraftment of neutrophils. The response rate to first-line therapy appears to be lower in patients with hyperacute GVHD compared with patients who develop GVHD later posttransplant, but no difference in survival has been observed.

Acute Graft-Versus-Host Disease

The pathophysiology of acute GVHD has been described as a three-step process.[74] In step 1, the conditioning regimen causes damage to the intestinal mucosa leading to release of lipopolysaccharides into the systemic circulation. This stimulates secretion of inflammatory cytokines such as IL-1 and tumor necrosis factor-α (TNF-α). These cytokines upregulate MHC gene products and host antigen-presenting cells such as dendritic cells, which play a critical role in this immune response. In step 2, donor T cells are activated, and secretion of other cytokines (IL-2 and interferon-γ) by activated T cells results in recruitment of macrophages and alteration of target cells in the gastrointestinal tract and skin so that they are more susceptible to damage. In step 3, multiple cytotoxic effector cells (T cells and macrophages) are generated and contribute to target tissue injury by secreting more inflammatory cytokines that cause target cell apoptosis. The term *cytokine storm* is sometimes used to describe the critical role of inflammatory cytokines in this process.

Based on this three-step model, three general approaches can be used to prevent GVHD in humans. The first is to reduce host tissue damage with the use of RIC regimens. The second and most widely used approach is to modulate donor T cells by reducing T-cell numbers (T-cell depletion), activation (most immunosuppressive agents), or proliferation (antiproliferative agents). The third approach is to block inflammatory stimulation and effectors (e.g. TNF-α inhibition, IL-1 receptor blockade).

The principal target organs in acute GVHD are the skin, liver, and gastrointestinal tract.[74] Acute GVHD is classified into four grades, depending on the number of organs involved and the degree of involvement of each organ (Table 148–2). Grade I disease involves only the skin. Grades II through IV involve the skin and either the liver, gastrointestinal tract, or both. The initial sign of acute skin GVHD usually is a generalized maculopapular rash that initially involves the face, ears, palms, soles, and upper trunk. The skin rash can spread to the rest of the body and, if untreated or refractory to treatment, will progress to bullae formation and desquamation, much like a burn injury. Gastrointestinal GVHD is manifested as diarrhea but may progress to abdominal pain/cramping and ileus. GVHD of the upper intestinal tract has been described presenting as nausea, vomiting, anorexia, and dyspepsia. The diagnosis of gastrointestinal GVHD should be made by biopsy of the intestinal tract (stomach, duodenum, or rectum). Hepatic GVHD usually is asymptomatic, consisting of hyperbilirubinemia and elevated alkaline phosphatase levels; increases in serum transaminases occur less consistently. The diagnosis can be made by biopsy, although many patients cannot provide biopsy samples because of the inherent risk of hemorrhage.

The overall incidence of moderate to severe (grades II to IV) acute GVHD ranges from 10% to more than 80%.[74] Mortality directly attributable to acute GVHD or its treatment occurs in 10% to 20% of patients. The incidence of GVHD is related to the degree of histocompatibility, number of T cells in the graft, donor and recipient age and gender, intensity of the conditioning regimen, source of hematopoietic cells (bone marrow versus peripheral blood), and prophylactic regimen. The risk of acute GVHD is lower in recipients of UCB transplants.[28] The most severe acute GVHD is

TABLE 148-2 Consensus Grading of Acute Graft-Versus-Host Disease

Stage	Skin	Liver	Intestinal Tract
	Organ/Extent of Involvement		
1	Rash on <25% of skin[a]	Bilirubin 2–3 mg/dL (34.2–51.3 μmol/L)[b]	Diarrhea >500 mL/day[c] or persistent nausea[d]
2	Rash on 25–50% of skin	Bilirubin 3–6 mg/dL (51.3-102.6 μmol/L)	Diarrhea >1,000 mL/day
3	Rash on >50% of skin	Bilirubin 6–15 mg/dL (102.6–256.5 μmol/L)	Diarrhea >1,500 mL/day
4	Generalized erythroderma with bulla formation	Bilirubin >15 mg/dL (>256.5 μmol/L)	Severe abdominal pain with or without ileus
Grade			
0	None	None	None
I	Stage 1–2	None	None
II	Stage 3	or Stage 1	or Stage 1
III	–	Stage 2–3	or Stage 2–4
IV[e]	Stage 4	or Stage 4	–

[a]Use the "rule of nines" to determine body surface area involvement.
[b]Range given as total bilirubin. Downgrade one stage if an additional cause of elevated bilirubin has been documented.
[c]Volume of diarrhea applies to adults. For pediatric patients, the volume of diarrhea should be based on body surface area.
[d]Persistent nausea with histologic evidence of graft-versus-host disease in the stomach or duodenum.
[e]Grade IV may include lesser organ involvement but with extreme decrease in performance status.

observed in allogeneic HSCT with non–HLA-identical donors. In these settings, the incidence of grades II to IV acute GVHD exceeds 50% despite aggressive GVHD prophylaxis.

Multiorgan acute GVHD and the drugs given to prevent or treat the disease are associated with delayed immunologic recovery and increased susceptibility to infections. Infection is often the primary cause of death in patients with GVHD. Patients with GVHD treated with an immunosuppressive regimen should receive prophylactic antiviral, antibacterial, and antifungal therapy and be monitored routinely for the occurrence of these infections.

10 Because treatment of established acute GVHD often is unsatisfactory, aggressive preventive measures usually are taken. The most common strategy used to prevent acute GVHD is blocking the activation of T cells by administration of immunosuppressive agents.[74] Several immunosuppressive agents have been used, including methotrexate, cyclosporine, tacrolimus, mycophenolate mofetil, antithymocyte globulin, corticosteroids, and monoclonal antibodies directed at T cells. Most GVHD prophylaxis regimens combine two or more immunosuppressive agents that affect different stages of T-cell activation. Another strategy is removing or depleting most T cells from donor bone marrow ex vivo prior to transplant by physical separation (i.e., lectin agglutination) or by treatment with monoclonal antibodies directed at T cells (Fig. 148–4).[74]

In allogeneic HSCT with HLA-matched donors, the combination of cyclosporine or tacrolimus and either methotrexate or corticosteroids reduces the incidence of grades II to IV acute GVHD to 25% to 40%. Intravenous cyclosporine or tacrolimus usually is started a few days before or on day 0. Cyclosporine is given at an initial dosage of 3 to 5 mg/kg/day and tacrolimus at 0.02 to 0.03 mg/kg/day. Dosages are adjusted based on trough concentrations. Patients are converted to oral formulations when they can be tolerated. Cyclosporine and tacrolimus typically are given at full doses until days 50 to 100, gradually tapered in the absence of GVHD, and discontinued by day 180. Methotrexate is given intravenously on days 1, 3, 6, and 11 posttransplant. The methotrexate dosage is 10 mg/m^2, except for the first dose given on day 1 (15 mg/m^2). Alternatively, some centers use 5 mg/m^2 (same schedule). The day 11 dose is sometimes omitted because of the drug's myelosuppressive effects, severe mucositis or other toxicities, or development of conditions that may prolong methotrexate systemic exposure (e.g., renal failure or third spacing). When corticosteroids are used, methylprednisolone or prednisone usually is started during the first two weeks posttransplant, given at full dosages for several weeks, and gradually tapered in the absence of GVHD. Although the efficacy of methotrexate-based regimens and corticosteroid-based regimens appears to be similar, use of methotrexate may increase the risk of delayed engraftment and is associated with significant mucositis, and corticosteroid administration is associated with a higher incidence of infections. Three-drug regimens composed of cyclosporine, methotrexate, and corticosteroids have been studied but have not been shown to be more efficacious in HLA-matched transplants.

Two large multicenter randomized trials compared cyclosporine and methotrexate with tacrolimus and methotrexate. One study was performed in patients undergoing HLA-identical sibling allogeneic HSCT,[75] and the other study was performed in patients undergoing matched unrelated allogeneic HSCT.[76] Both studies found the tacrolimus combination to be significantly superior to the cyclosporine combination in preventing grades II to IV acute GVHD. The incidence of renal impairment was higher in patients receiving tacrolimus, and more tacrolimus-treated patients in the HLA-identical sibling allogeneic HSCT trial required hemodialysis. The incidence of hypertension was significantly higher in cyclosporine-treated patients in the HLA-matched sibling allogeneic HSCT trial. No difference in the overall or relapse-free survival rate was reported in the two trials. However, in the subgroup of patients with advanced disease in the HLA-identical sibling allogeneic HSCT trial, cyclosporine-treated patients had significantly better overall and disease-free survival rates at two years compared to patients who received tacrolimus. The authors explained that lowering the target blood levels to less than 20 ng/mL (20 mcg/L; 24.8 nmol/L) might reduce the renal toxicity of tacrolimus and most centers currently use target trough tacrolimus levels of 5 to 15 ng/mL (5–15 mcg/L; 6.2–18.6 nmol/L). Based on the results of these two studies, many transplant centers use tacrolimus and methotrexate as first-line acute GVHD prophylaxis.

With alternative donors, the risk of moderate-to-severe (grades II–IV) acute GVHD is 50% or higher with conventional two-drug prophylaxis. Several approaches are used to reduce the risk of acute GVHD in this high-risk group of patients: three-drug GVHD prophylaxis, pretransplant administration of antithymocyte globulin, or ex vivo T-cell depletion of donor bone marrow (Fig. 148–4). Encouraging results have been reported with the addition of novel immunosuppressive agents, such as sirolimus, to two-drug prophylaxis regimens.[77] The addition of antilymphocyte or antithymocyte globulin to the pretransplant conditioning regimen reduced the risk of acute and chronic GVHD but increased the risk of serious infections.[78]

Because of the gastrointestinal and hematologic toxicities of methotrexate, other prophylactic regimens have been evaluated. One of these regimens, developed by investigators at the Dana-Farber Cancer Institute, uses sirolimus in place of methotrexate in combination with tacrolimus. In an uncontrolled study of 53 patients receiving myeloablative allogeneic HSCT, the combination of sirolimus and tacrolimus was associated with rapid engraftment and low incidences of grades II to IV acute GVHD and treatment-related mortality.[79] A randomized trial comparing this regimen to standard methotrexate in combination with tacrolimus is being conducted by the Blood and Marrow Clinical Trials Network. Another drug that has been

substituted for methotrexate is mycophenolate mofetil. The results of two small randomized trials have shown less toxicity with mycophenolate mofetil but little to no improvement in the rate of acute GVHD or overall survival.[80,81] Acute GVHD prophylaxis regimens used with RIC or NMA conditioning regimens generally consist of cyclosporine and mycophenolate mofetil. Single agent cyclophosphamide (50 mg/kg on days 3 and 4 posttransplant) also has been tested in patients undergoing RIC or NMA conditioning.[82]

The role of ex vivo T-cell depletion from donor grafts is controversial (Fig. 148–4).[74] Although use of T-cell–depleted marrow can reduce the incidence and severity of acute GVHD, it is associated with an increased risk of graft failure, delayed immune reconstitution, leukemic relapse, cytomegalovirus reactivation, and Epstein-Barr virus–related lymphoproliferative disorders. As a result, this approach does not improve the survival rate in recipients of HLA-identical sibling donor marrow. These observations suggest that important cell populations are being eliminated in the depletion process. Various approaches that selectively remove the T cells responsible for GVHD while leaving those cells that mediate engraftment, antileukemic effect, and suppression of Epstein-Barr virus–transformed lymphocytes are being investigated. Another approach is infusion of the T cells originally depleted from the graft later in the posttransplant period to prevent leukemic relapse. Because of the higher risk of GVHD in allogeneic HSCT with HLA-mismatched donors, T-cell depletion is sometimes included as part of the GVHD prophylaxis regimen in that setting.

Patients with mild skin-only acute GVHD (grade I) can be treated with topical corticosteroid preparations and counseled on the appropriate use of sunscreen. If a patient develops grades II to IV GVHD, prophylactic agents are continued and high-dose corticosteroids in the form of intravenous methylprednisolone are given.[74] The usual dosage is 1 to 2 mg/kg/day, given in two divided doses; higher dosages have not been shown to be more efficacious. Approximately 25% to 40% of patients with established acute GVHD respond to high-dose corticosteroids. If the patient responds, the corticosteroid dose is tapered gradually over several weeks to months, depending on response. In patients who experience a flare in GVHD during the taper phase, therapy consists of increasing the corticosteroid dose and then tapering more slowly. Oral beclomethasone dipropionate, a topically active corticosteroid, has been shown to reduce the frequency of gastrointestinal GVHD relapses when continued after prednisone taper.[83] Administration of beclomethasone has been associated with a better survival at 200 days and 1 year after transplant. Budesonide, another nonabsorbable corticosteroid, has also been evaluated in uncontrolled studies.[84] GVHD-associated mortality is strongly correlated to response to initial treatment and ranges from approximately 25% in patients who had a complete response to approximately 80% in patients who had no response or progressive disease.

Several randomized trials have evaluated other agents combined with methylprednisolone as initial therapy for acute GVHD.[74] In particular, the addition of anti–T-cell antibodies, such as antithymocyte globulin or monoclonal antibodies (e.g., daclizumab), has not been shown to improve patient outcome.[85] Similarly, the combination of methylprednisolone and the anti–TNF-α monoclonal antibody infliximab has not been shown to increase response rate compared to methylprednisolone alone.[86] The Blood and Marrow Transplant Clinical Trials Network conducted a randomized phase II trial designed to identify the most promising agent for initial therapy of acute GVHD in combination with 2 mg/kg/day of methylprednisolone.[87] One hundred and eighty patients were randomized to etanercept, mycophenolate mofetil, denileukin diftitox, or pentostatin. After 28 days of treatment, complete response rates were 60% for mycophenolate mofetil, 53% for denileukin diftitox, 38% for penotstatin, and 26% for etanercept. Efficacy and toxicity data suggest the use of mycophenolate mofetil plus corticosteroids is the most promising regimen to compare with corticosteroids alone in a definitive phase III trial.

While different centers may have varying criteria for corticosteroid-refractory acute GVHD, in general, if the manifestations of acute GVHD in any organ worsen over three days of treatment or symptoms do not improve by five days, the patient likely will not respond to corticosteroids and secondary therapy should be considered.[88] Most clinicians continue administration of corticosteroids and add another immunosuppressant agent, such as antithymocyte globulin, mycophenolate mofetil, sirolimus, or pentostatin. One approach that has shown benefit as corticosteroid-sparing therapy is extracorporeal photopheresis. During this procedure, the patient's blood is exposed extracorporeally to 8-methoxypsoralen followed by ultraviolet A radiation, and then returned to the patient. This process is thought to result in suppression of T-cell reactivity and induction of regulatory T cells. Clinical results have been positive, especially in patients with skin GVHD.[89] In addition, a variety of humanized monoclonal antibodies or fusion proteins, such as denileukin diftitox (Ontak®), daclizumab (Zenapax®), infliximab (Remicade®), rituximab (Rituxan) and etanercept (Enbrel®), are being evaluated for treatment of corticosteroid-refractory acute GVHD.[88] There is no standard treatment of patients with corticosteroid-refractory acute GVHD and the prognosis is dismal. New agents continue to be evaluated.

CLINICAL CONTROVERSY

Optimal treatment of steroid-refractory GVHD is unclear. Comparative trials are needed to determine a standard approach to this difficult condition.

Chronic Graft-Versus-Host Disease

Chronic GVHD is the major determinant of late transplant-related morbidity and mortality.[71,90] The pathophysiology of chronic GVHD is poorly understood but is generally thought to be a result of pathogenic donor T cells that proliferate unchecked by normal mechanisms. These T cells are responsible for tissue damage through direct cytolytic attack, stimulation of inflammatory cytokines, or B-cell activation and antibody production. Chronic GVHD is often considered an autoimmune disease because of its similarity to other autoimmune disorders.

The incidence of chronic GVHD in patients who survive more than 150 days ranges from 20% to 70%.[90] The risk of chronic GVHD increases with increasing donor and recipient age and is higher in patients who receive transplants from HLA-nonidentical donors and in patients who receive PBSC transplants (especially with higher $CD34^+$ cell doses). The incidence of chronic GVHD is rising because of increasing use of alternative donors, use of PBSCs as the graft source, use of DLI for treatment of recurrence, and older recipient age. Previous acute GVHD increases the risk of chronic GVHD, but approximately 20% to 30% of patients who develop chronic GVHD after HLA-matched allogeneic HSCT have no history of acute GVHD. Unlike acute GVHD, prophylactic immunosuppression does not appear to reduce the incidence or severity of chronic GVHD.

Chronic GVHD resembles autoimmune diseases and can affect any organ or tissue of the body.[91] The most common sites involved are the skin, mouth, liver, and eye but other sites include the gastrointestinal tract, joints, muscles, and lungs. The National Institutes of Health Consensus Development Project developed standardized criteria for the diagnosis of chronic GVHD and proposed a new clinical scoring system for the evaluation of patients with chronic GVHD.[72] The Working Group recommends that the diagnosis of chronic GVHD be made with the presence of at least one *diagnostic*

clinical sign of chronic GVHD (e.g., poikiloderma or esophageal web) or a *distinctive* manifestation (e.g. keratoconjunctivitis sicca) confirmed by biopsy or other test (e.g., Schirmer test).

The most widely used staging system for chronic GVHD prior to the National Institutes of Health Consensus Development Project was the limited/extensive classification proposed by the Seattle HSCT program. In that system, chronic GVHD is classified as limited or extensive, depending on pathologic findings and the extent of systemic involvement. *Limited* chronic GVHD indicates localized skin involvement, mild hepatic dysfunction, or both. Most patients have *extensive* disease, with involvement of the skin, liver, eyes, mouth, esophagus, or other organs. Many patients with extensive chronic GVHD will die of infections or become disabled.

The National Institutes of Health Consensus Working Group recommended a global staging system that categorizes chronic GVHD into mild, moderate, and severe.[72] *Mild* chronic GVHD involves only one or two organs or sites (except the lung) with no clinically significant functional impairment (maximum score of one in all affected organs or sites). *Moderate* chronic GVHD involves at least one organ or site with clinically significant but no major disability (maximum score of two in any affected organ or site), or three or more organs or sites with no clinically significant functional impairment (maximum score of one in all affected organs or sites), or lung score of one. *Severe* chronic GVHD indicates major disability caused by chronic GVHD (score of three in any organ or site) or lung score of two or greater.

11 If no functional impairment is present, patients with mild skin-only disease can be treated with a variety of topical preparations, such as clobetasol, tacrolimus, and pimecrolimus.[92] Initial treatment of patients with more severe or systemic involvement of chronic GVHD consists of prednisone 1 mg/kg/day.[90] Prospective randomized trials evaluating the addition of cyclosporine or mycophenolate mofetil have shown limited to no benefit compared to prednisone alone.[92] If patients are on tapering doses of prednisone for treatment of acute GVHD, the dose is generally increased and/or another immunosuppressive agent is added. Treatment is continued until signs and symptoms of the disease have resolved and then are tapered gradually, usually over a period of several months to years. Approximately 50% of patients will require long-term immunosuppression to control chronic GVHD.

In addition to topical therapy for skin manifestations, other treatments can be applied to lessen the symptoms of chronic GVHD.[93] Patients should be educated on the use of sunscreens (and/or avoidance of sun exposure) to reduce skin injury and exacerbation of GVHD skin lesions. Nonsclerotic skin lesions without erosions or ulcerations may respond well to topical corticosteroids and emollients. Patients should be advised to maintain good oral hygiene with routine dental care. Saliva substitutes can be given for dry mouth symptoms, and topical corticosteroid gels can be used for localized and symptomatic oral lesions. Artificial tears or, if necessary for more severe symptoms, cyclosporine or corticosteroid eye drops are useful for patients with chronic GVHD manifesting as dry eyes or conjunctivitis. Physical therapy is recommended to reduce functional loss as a result of steroid myopathy, joint contractures, and deconditioning.

Patients who do not respond to initial therapy have a very poor prognosis. Noncomparative trials have investigated several therapies with varying degrees of success, including thalidomide, extracorporeal photophoresis, tacrolimus, sirolimus, pentostatin, mycophenolate mofetil, hydroxychloroquine, rituximab, imatinib and others.[90,91,94,95] The Blood and Marrow Clinical Trials Network has initiated a randomized phase II/III trial comparing the following three treatment strategies: sirolimus and prednisone; sirolimus, extracorporeal photophoresis, and prednisone; and sirolimus, a calcineurin inhibitor, and prednisone. Eligible subjects must have chronic GVHD, as diagnosed by National Institutes of Health consensus criteria, and must be either untreated and high risk or not responding to standard therapy. Sirolimus and extracorporeal photophoresis were chosen due to favorable response rates seen in phase II studies and because of laboratory data suggesting a positive effect on regulatory T cells which are thought to mitigate GVHD.

Infection is the primary cause of death in patients with chronic GVHD, and antimicrobial prophylaxis is an important component of the care of patients being treated for chronic GVHD. Patients should receive oral trimethoprim–sulfamethoxazole, penicillin, an antifungal azole agent, and acyclovir to prevent infections commonly seen in immunocompromised patients.[90–92] Routine monitoring for cytomegalovirus reactivation should be performed. Some HSCT centers also administer intravenous immunoglobulin to patients with low serum immunoglobulin G levels.

INFECTION

Patients undergoing high-dose chemotherapy with autologous HSCT or allogeneic HSCT are severely immunocompromised and therefore are at high risk for bacterial, fungal, and viral infection. Management of these infections is discussed in detail in Chap. 131.

LATE COMPLICATIONS

With the success of HSCT, the number of long-term survivors has grown. Many survivors experience delayed complications of transplantation, including restrictive and obstructive pulmonary disease; bone and joint disease (including osteoporosis and avascular necrosis); cataract formation; endocrine dysfunction (including sterility and thyroid dysfunction); impaired growth and development; infections; cardiovascular disease; chronic renal and hepatic dysfunction; and secondary malignancies.[96,97] Physical recovery tends to occur earlier than psychological or work recovery. Full recovery usually takes several years, and approximately two thirds of patients are without major limitations by five years. The Bone Marrow Transplant Survivor Study compared late mortality (two years after HSCT) in allogeneic and autologous patients with that of the general population.[98,99] Both types of transplants were associated with a several-fold increase in risk of premature death; relative mortality decreased with time but remained significantly elevated even ten years posttransplant. The leading cause of death was relapse of primary disease in both allogeneic and autologous patients but allogeneic HSCT patients also continued to die from complications of chronic GVHD while autologous HSCT patients frequently succumbed to secondary malignancies.

ABBREVIATIONS

ALL: acute lymphoblastic leukemia

AML: acute myelogenous leukemia

BMT: bone marrow transplant

BuCy: busulfan and cyclophosphamide

CIBMTR: Center for International Blood and Marrow Transplant Research

CML: chronic myelogenous leukemia

DLI: donor lymphocyte infusion

G-CSF: granulocyte colony-stimulating factor

GM-CSF: granulocyte-macrophage colony-stimulating factor

GVHD: graft-versus-host disease

GVM: graft-versus-malignancy (effect)

HLA: human leukocyte antigen
HSCT: hematopoietic stem cell transplantation
MAC: myeloablative conditioning
MHC: major histocompatibility complex
MLC or MLR: mixed lymphocyte culture or reaction
MMF: mycophenolate mofetil
NK: natural killer (cells)
NMDP: National Marrow Donor Program
NMA: nonmyeloablative
PBSC: peripheral blood stem cell
RIC: reduced-intensity conditioning
SOS: sinusoidal obstruction syndrome
TBI: total-body irradiation
TNF-α: tumor necrosis factor-α
UCB: umbilical cord blood

SECTION 18
NUTRITION DISORDERS

CHAPTER 149

Assessment of Nutrition Status and Nutrition Requirements

KATHERINE HAMMOND CHESSMAN AND VANESSA J. KUMPF

KEY CONCEPTS

1. Classification of nutrition status is often desired as a means to identify those who are nutritionally at risk due to over- or undernutrition.
2. Nutrition screening programs should identify those at risk for poor nutrition-related outcomes as a consequence of either over- or undernutrition.
3. Comprehensive nutrition assessment is the first step in formulating a patient-specific nutrition care plan for a patient who is found to be nutritionally at risk.
4. A nutrition-focused medical, surgical, and dietary history and a nutrition-focused physical examination are key components of nutrition assessment and will reveal risk factors for and the likelihood of malnutrition and nutrient deficiencies or toxicities.
5. Appropriate anthropometric measurements are essential in a complete nutrition assessment and should be evaluated based on published standards.
6. Biochemical (laboratory) tests are essential for nutrition assessment but must be interpreted in the context of the physical findings, medical and surgical history, and clinical status of the patient, as well as specific test limitations.
7. Nutrient deficiencies and toxicities involving micronutrients (e.g., vitamins or trace elements) or macronutrients (e.g., fat, protein, or carbohydrate) are possible, and a comprehensive nutrition assessment will identify the presence of these.
8. When determining patient-specific nutrition requirements, goals should be established based on the patient's clinical condition and the need for maintenance or repletion in adults, as well as for continued growth and development in children.
9. Drug-nutrient interactions can affect an individual's nutrition status as well as the response to and adverse effects seen with drug therapy and must be considered when evaluating a patient's nutrition care plan.
10. An initial nutrition assessment and determination of nutrition requirements only defines an empirical starting point for a nutrition care plan. Close monitoring is required so that timely adjustments to the nutrition care plan can be made based on patient-specific responses to ensure appropriate nutrition-related outcomes.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Nutrition care is a vital component of quality patient care. This chapter reviews the tools most commonly used for nutrition screening and accurate, relevant, and cost-effective nutrition assessment. Determination of patient-specific macro- and micronutrient requirements and potential drug–nutrient interactions are also discussed.

CLASSIFICATION OF NUTRITION DISEASE

1 Undernutrition usually results from starvation (inadequate nutrient intake), impaired absorption of nutrients, or altered metabolism (inappropriate use of ingested nutrients). An alteration in nutrient metabolism exists when the cell has altered substrate demands or use, such as cachexia associated with inflammatory or neoplastic conditions. In such situations, enhancing nutritional intake may not be sufficient to meet the increased demand.[1] Regardless of the cause, undernutrition results in changes in subcellular, cellular, and/or organ function that expose the individual to increased risks of morbidity and mortality. In general, deficiency states can be categorized as those involving protein and calories or single nutrients such as individual vitamins or trace elements. Protein-calorie malnutrition can be classified as marasmus, kwashiorkor, or mixed marasmus/kwashiorkor.

Marasmus is a chronic condition resulting from prolonged inadequate intake or utilization of protein and calories. Somatic protein (skeletal muscle) and adipose tissue (subcutaneous fat) wasting occurs, but visceral protein (e.g., albumin [ALB] and transferrin [TFN]) production is usually preserved. Weight loss typically exceeds 10% of usual body weight (UBW; typical weight). When

severe, cell-mediated immunity, measured by delayed cutaneous hypersensitivity (DCH), and muscle function are impaired. Patients with wasting diseases such as cancer commonly have marasmus and a prototypical starved, wasted appearance.[1,2]

Kwashiorkor develops when there is inadequate protein and antioxidant micronutrient intake and usually develops in geographic areas where there is famine, limited food supply, and low levels of education. This condition has rarely been reported in the United States but can be seen in children who are abused or neglected and has been reported in elderly individuals. While these patients may appear well nourished due to relative adipose tissue preservation, especially with mild undernutrition, there is depletion of visceral (and to some degree somatic) protein stores with severe hypoalbuminemia and edema commonly seen in more advanced cases.[2]

Mixed marasmus/kwashiorkor is a form of severe protein-calorie malnutrition that develops in chronically ill, starved patients during periods of hypermetabolic stress, such as trauma, infection, and burns. There is reduced visceral protein synthesis superimposed on wasting of somatic protein and energy (adipose tissue) stores. Immunocompetence is lowered, increasing the incidence of infection, and wound healing is compromised.

Obesity (overnutrition) is a major healthcare concern in the United States. It is estimated that 66% of American adults are overweight (defined as a body mass index [BMI] ≥25 kg/m^2), while 32.9% of American adults are obese (BMI ≥30 kg/m^2).[3] In 2008, only one state (Colorado) had a prevalence of obesity less than 20%.[4] Additionally, many children and adolescents (age 2–19 years) are obese with approximately 11.3% having a BMI at or above the 97th percentile for age, and 16.3% having a BMI at or above the 95th percentile for age[5] on the gender-appropriate BMI-for-age growth chart published by the Centers for Disease Control National Center for Health Statistics [NCHS]).[6] Many more children (31.9%) are considered to be overweight (BMI at or above the 85th percentile for age).[5] Nutrition assessment allows identification of obese individuals or those at risk of becoming obese. The consequences of obesity are numerous and include type 2 diabetes mellitus, cardiovascular disease, and stroke (see Chap. 154).

NUTRITION SCREENING

2 Because it is neither practical nor warranted to conduct a comprehensive nutrition assessment on every patient, nutrition screening provides a rapid systematic way to identify individuals for whom a more detailed nutrition assessment is needed. A nutrition screen can be used to detect those who are overweight, obese, malnourished, or at risk for malnutrition, predict the probability of their outcome as a result of nutritional factors, and provide an indication as to whether nutritional treatment is likely to influence the patient's outcome.[7–10] The nutrition screen should be a rapid and simple process that can be done in homes by patients, caregivers, or home healthcare professionals, in long-term care facilities, in ambulatory care clinics, or in hospitals. Nutrition screening using simple tools in the community or outpatient setting, especially in young children and the elderly, can identify potential nutrition issues early before they become significant problems. Because the Joint Commission includes nutrition screening and assessment in its performance standards for accredited institutions, each entity must define in writing the process by which a nutrition screen is done and criteria that determine when a more in-depth assessment needs to be performed. For inpatients, these screenings typically must be completed within 24 hours of admission. For outpatients, nutrition screening should occur at the first visit with a provider and thereafter as warranted by the patient's condition.[11] By identifying at-risk individuals, nutrition screening can be a cost-effective way to decrease complications and length of hospital stays.

Appropriate screening is based on risk factor identification. Risk factors for undernutrition include any disease state, complicating condition, treatment, or socioeconomic condition that may result in a decreased nutrient intake, altered metabolism or nutrient utilization, and/or malabsorption. Risk factors for obesity include family history of obesity, certain medical diagnoses, poor dietary habits, lack of exercise, and some drug therapies. Various rating and classification systems have been proposed to assess nutrition risk and guide subsequent interventions.[7,8,12,13] Checklists are used in many clinical settings to quantify a person's food and alcohol consumption habits; ability to buy, prepare, and eat food; weight history; diagnoses; and medical/surgical procedures. Depending on the specific criteria evaluated, the presence of three to four risk factors may increase a person's risk for malnutrition. Pediatric screening programs most often evaluate growth parameters against the NCHS growth charts and medical conditions known to increase nutrition risk. Screening programs must also identify patients receiving specialized nutrition support (enteral or parenteral nutrition). In any setting, patients determined to be at "nutrition risk" should receive a comprehensive nutrition assessment to verify nutrition-related risk and to formulate a nutrition care plan.

ASSESSMENT OF NUTRITION STATUS

3 A comprehensive nutrition assessment is the first step in formulating a patient-specific nutrition care plan. Nutrition assessment has four major goals: (a) identification of the presence of factors associated with an increased risk of developing malnutrition, including disorders resulting from macro- or micronutrient deficiencies (undernutrition), obesity (overnutrition), or impaired metabolism or utilization; (b) determination of risk of malnutrition-associated complications; (c) establishment of estimated nutrition needs; and (d) establishment of baseline nutrition status with parameters against which to measure nutrition therapy outcomes.

Nutrition assessment should include a nutrition-focused medical, surgical, and dietary history, a nutrition-focused physical examination including anthropometrics, and laboratory measurements. A comprehensive nutrition assessment provides a basis for determining the patient's nutrition requirements and the optimal type and timing of nutrition intervention.

CLINICAL EVALUATION

4 Clinical or bedside evaluation of nutrition status correlates well with objective evaluations (e.g., laboratory and anthropometric measurements). The medical, surgical, and dietary history components of the clinical evaluation provide information regarding those factors that predispose to malnutrition (e.g., prematurity, chronic diseases, gastrointestinal [GI] malfunction, and alcohol abuse) and overnutrition (e.g., poor dietary habits, limited exercise, chronic diseases, and family history). The clinician should direct the interview to elicit any history of weight gain or loss, anorexia, vomiting, diarrhea, and decreased or unusual food intake (Table 149–1).

The nutrition-focused health history and physical examination takes a systems approach to assess lean body mass (LBM) and findings of vitamin, trace element, or essential fatty acid deficiencies or excesses. The assessment should include documentation of the presence and degree of muscle wasting, edema, loss of subcutaneous fat, dermatitis, glossitis, cheilosis, jaundice, or other findings suggestive of malnutrition (Table 149–2).

Since the 1980s, the Subjective Global Assessment, a simple, reproducible, cost-effective, bedside approach to nutrition assessment, has been used by many practitioners in a variety of patient populations.[2,8,14,15] Five aspects of the medical and dietary history make up the Subjective Global Assessment: weight changes in the previous

TABLE 149-1 Pertinent Data from Nutrition-Focused Medical, Surgical, and Dietary History

Nutrition intake and dietary habits
Anorexia
Unusual or absent taste
Dietary intake and special diets, including enteral or parenteral nutrition
Supplemental vitamin, mineral, or herbal intake
Food allergies or intolerance
Underlying pathology with nutritional effects
Chronic infections or inflammatory states
Neoplastic diseases
Endocrine disorders
Chronic illness, including pulmonary disease, cirrhosis, and kidney failure
Hypermetabolic states, such as trauma, burns, and sepsis
Digestive or absorptive disease, nausea, vomiting, diarrhea, and constipation
Hyperlipidemia
End-organ effects
Weight changes
Skin or hair changes
Exercise intolerance or fatigue
Gastrointestinal tract symptoms such as diarrhea, vomiting, and constipation
Gastrointestinal surgery
Bariatric surgery
Small bowel and/or colon resection
Gastrectomy
Miscellaneous
Catabolic medications or therapies, including corticosteroids, immunosuppressive agents, radiation, or chemotherapy
Other medications, including diuretics, laxatives, or anabolic steroids
Genetic background, including body habitus of parents, siblings, and family
Alcohol or drug abuse

Data from references 7 to 16.

TABLE 149-2 Physical Findings Suggestive of Malnutrition

General appearance
Edema (especially ankle and sacral)
Cachexia or obesity
Ascites
Signs and symptoms of dehydration, including poor skin turgor, sunken eyes, orthostasis, or dry mucous membranes
Muscle wasting or loss of subcutaneous fat
Skin and mucous membranes
Thin, shiny, dry, or scaly skin
Decubitus ulcers
Ecchymoses or perifollicular petechiae
Poor healing of surgical or traumatic wounds
Pallor or redness of gums or fissures at mouth edge
Glossitis, stomatitis, or cheilosis
Musculoskeletal
Retarded growth/short stature
Bone pain or tenderness or epiphyseal swelling
Muscle mass less than expected for habitus, genetic history, and level of exercise
Neurologic
Ataxia, positive Romberg test[a], or decreased vibratory or position sense
Nystagmus
Seizures or paralysis
Encephalopathy
Failure to meet age-appropriate developmental milestones
Hepatic
Jaundice
Hepatomegaly

[a]The Romberg test is a neurologic test used to detect problems with balance.
Data from references 7 to 16.

6 months, dietary intake changes, GI symptoms, functional capacity of the GI tract, and the presence of disease states known to affect nutrition status. Weight loss of less than 5% of UBW is considered a "small" loss, 5% to 10% loss is "potentially significant," and more than a 10% loss is "definitely significant." Dietary intake is characterized as either normal or abnormal, and the length of time and degree of abnormal intake is noted. The presence of GI symptoms (e.g., anorexia, nausea, vomiting, or diarrhea) on a daily basis for longer than 2 weeks is significant. Functional capacity assesses the patient's energy level and whether the patient is active or bedridden. Finally, disease states present are assessed as to their impact on metabolic demands (i.e., no stress, low, moderate, or high stress). Four physical examination findings are rated as normal, mild, moderate, or severe: loss of subcutaneous fat (triceps and chest), muscle wasting (quadriceps and deltoids), edema (ankle and sacral), and ascites. The clinician then ranks the patient's nutrition status as adequately nourished, moderately malnourished or suspected of being malnourished, or severely malnourished. Critics of the Subjective Global Assessment find it time-consuming and complex.[2] Another tool, the Mini Nutritional Assessment has been used extensively in geriatric patients and found to be useful for community-living elderly, residents in subacute care facilities, and those in nursing homes.[2,16]

ANTHROPOMETRIC MEASUREMENTS

5 Anthropometric measurements, physical measurements of the size, weight, and proportions of the human body, are often used to assess nutrition status. The most common measurements are weight, stature (standing height or recumbent length, depending on age), head circumference (for children younger than 3 years of age), waist circumference, and measurements of limb size, such as skinfold thickness, midarm muscle circumference, and wrist circumference. Bioelectrical impedance analysis (BIA) is also an anthropometric assessment tool. These parameters are used to compare an individual with normative standards for a population and as repeated measurements in an individual to monitor response to a nutrition care plan. In adults, nutrition-related changes in anthropometric measurements occur slowly; several weeks or more are usually required before detectable changes are noted. In infants and young children, however, changes may occur more quickly. Acute changes in weight and skinfold thickness usually reflect changes in hydration status, which must be considered when interpreting these parameters, particularly in hospitalized patients.

WEIGHT, STATURE, AND HEAD CIRCUMFERENCE

Body weight is a nonspecific measure of body cell mass, representing skeletal mass, body fat, and the energy-using component referred to as LBM. Change in weight over time, particularly in the absence of edema, ascites, and voluntary losses, is an important indicator of altered LBM. Interpretation of actual body weight (ABW) should take into consideration ideal weight-for-height, also referred to as the ideal body weight (IBW), UBW, fluid status, and age (Table 149–3). The UBW is intended to describe an individual's typical weight and is generally more useful when assessing weight loss or gain than comparing the current weight to the estimated IBW. Dehydration will result in decreased ABW but not a loss in LBM. Once the patient is rehydrated, rechecking the weight is important to establish the baseline weight to use for nutrition evaluation. The presence of edema or ascites increases total body water (TBW), thus increasing ABW. Weights of patients with severe edema and ascites should not be used for nutrition assessment without taking the extra water weight into consideration. Thus, acute and chronic changes in fluid status can affect the ABW; these changes often can be detected by monitoring the patient's daily fluid intake and output.

TABLE 149-3 Evaluation of Body Weight

ABW compared to IBW	
ABW <69% IBW	Severe malnutrition
ABW 70%–79% IBW	Moderate malnutrition
ABW 80%–89% IBW	Mild malnutrition
ABW 90%–120% IBW	Normal
ABW >120% IBW	Overweight
ABW ≥150% IBW	Obese
ABW ≥200% IBW	Morbidly obese
ABW compared to UBW	
ABW 85%–95% UBW	Mild malnutrition
ABW 75%–84% UBW	Moderate malnutrition
ABW <75% UBW	Severe malnutrition
BMI (kg/m²) or (lb/in²)	**Interpretation**
Adults	
<16	Severe malnutrition
16–16.9	Moderate malnutrition
17–18.9	Mild malnutrition
19–24.9	Healthy
25–29.9	Overweight
30–40	Moderate obesity
>40	Severe or morbid obesity
Children	
BMI-for-age <5th percentile	Underweight
BMI-for-age 5th–84th percentile	Healthy
BMI-for-age 85th-94th percentile	Overweight
BMI-for-age ≥95th percentile	Obese

ABW, actual body weight; BMI, body mass index; IBW, ideal body weight; UBW, usual body weight.
Data from references 5, 6, and 8.

TABLE 149-4 Expected Growth Velocities in Term Infants and Children

Age	Weight (g/day)	Height (cm/month)[a]
0–3 months	24–35	2.8–3.4
4–6 months	15–21	1.7–2.4
7–12 months	10–13	1.3–1.6
1–3 years	5–9	0.6–1
4–6 years	5–6	0.5–0.6
7–10 years	7–11	0.4–0.5

Example of growth assessment:
Age: 2 months; weight: 3.9 kg; weight at 1 month of age, 3.1 kg; days since last wt: 30
Growth velocity = [(3.9 kg–3.1 kg) × 1,000 g/kg]/30 days = 26.7 g/day
Interpretation: normal growth

[a]Growth velocity of 1 cm/month is equivalent to 0.4 inches/month.
Data from reference 6.

The IBW provides one population reference standard against which the ABW can be compared to detect both over- and undernutrition states. Numerous IBW-for-height reference tables have been generated based on various populations. In clinical practice, mathematical equations based on gender and height (Hamwi method) are used commonly. IBW is calculated as 48 kg + [2.7 × (inches over 5 feet)] for adult men, and for adult women as 45 kg + [2.3 × (inches over 5 feet)]. For both equations, a range of ± 4.5 kg for large or small frame size is used for interpretation purposes.[8] For obese adults, use of an adjusted IBW has been recommended for nutrition-related calculations: adjusted IBW = [(ABW – IBW) × 0.25] + IBW. However, there is no evidence that supports the use of adjusted body weight, and its use can result in overfeeding; thus this practice has largely been abandoned. The IBW of children can be calculated as {[(height in cm)² × 1.65]/1,000}. Alternatively, IBW-for-height in children can be determined by identifying the weight corresponding to the same growth percentile as the child's measured stature on the appropriate NCHS growth chart.

Change in weight over time can be calculated as the percentage of UBW, where percent change = [(ABW/UBW) × 100] (see Table 149–3). Use of the UBW as a reference point provides a more accurate reflection of clinically and nutritionally significant weight changes. Determining a patient's UBW, however, depends on patient or family recall, which may be inaccurate. The use of UBW avoids the problems of normative tables and documents comparative changes in body weight. Any change in weight also should be interpreted relative to time. Unintentional weight loss, especially rapid weight loss (e.g., 5% of UBW in 1 month or 10% of UBW in 6 months), may increase the risk of poor clinical outcomes.[8]

Stature is determined by both genetics and nutrition intake. In infants, recumbent length is measured, while in older children and adults, a standing height is preferred. If a standing height cannot be measured, the measurement of demispan can be used to project height. Demispan is determined by measuring the distance from the sternal notch to the web between the middle and ring fingers along a horizontally outstretched arm with the wrist in neutral rotation and zero extension or flexion while the patient is seated. Demispan may more accurately assess height in the elderly, especially those with kyphosis and/or vertebral collapse. Once the demispan is measured, height can be estimated using the following equations: women: height (cm) = 1.35 × demispan (cm) + 60.1; men: height (cm) = 1.4 × demispan (cm) + 57.8.[17] Knee height may also be used to estimate stature and is especially helpful in patients with limb contractures, such as patients with cerebral palsy.[17–20] In one method, the knee height is measured from just under the heel to the anterior surface of the thigh just proximal to the patella. Using the average of two measurements rounded to the nearest 0.1 cm, height is estimated using the following equations: women: height (cm) = 84.88 (0.24 × age [years]) + (1.83 × knee height [cm]); men: height (cm) = 64.19 (0.04 × age [years]) + (2.02 × knee height [cm]).[19]

The best indicator of adequate nutrition in a child is an appropriate rate of growth. At each medical encounter, weight, stature, and head circumference should be plotted on the appropriate NCHS gender- and age-specific growth curve. These charts were developed in 1977 from a large population of healthy, primarily white children and revised in 2002 to better reflect the ethnic mix of the United States' population. Special growth charts are available for assessment of short- and long-term growth of premature infants,[21,22] children with Down syndrome,[23] and other specific conditions. For premature infants with corrected postnatal age of 40 weeks or more, the NCHS growth charts can be used; however, weight-for-age and length-for-age should be plotted according to corrected postnatal age until 2 years and 3.5 years of age, respectively.

Recommended intervals between measurements are weight, 7 days; length, 4 weeks; height, 8 weeks; and head circumference, 7 days in infants and 4 weeks in children up to 3 years of age. Growth velocity can be used to assess growth at intervals too close to plot accurately on a growth chart (Table 149–4). In newborns, average weight gain is 10 to 20 g/kg/day (24–35 g/day in term infants and 10–25 g/day in preterm infants). Weight gain declines considerably after 2 to 3 months of age. Head growth (measured by head circumference), which is usually 0.5 cm/week (0.2 inches/week) during the first year of life, can be compromised during periods of critical illness or malnutrition. Sustained head growth during these periods, especially at a rate above expected, suggests hydrocephalus.

Growth failure or failure-to-thrive is defined as weight-for-age or weight-for-height (or length) below the 5th percentile or a falloff of two or more major percentiles (major percentiles are defined as 97th, 95th, 90th, 75th, 50th, 25th, 10th, 5th, and 3rd). Weight-for-height evaluation is age-independent and helps differentiate the stunted child (chronic malnutrition) from the wasted child (acute malnutrition). Short stature, which is associated with many chronic diseases, is a manifestation of chronic undernutrition. Short stature

in the absence of malnutrition suggests an endocrinopathy, such as growth hormone deficiency, but may also be a normal variant (e.g., constitutional growth delay).

BODY MASS INDEX

In general, a healthy weight is one associated with a reduction in disease risk. BMI, which is most commonly defined as body weight in kilograms divided by the square of the patient's height in meters (kg/m^2), is another index of the appropriateness of weight-for-height. Using pounds and inches, BMI (lb/in^2) can also be estimated as (weight [pounds] × 703/height^2 [inches^2]). A BMI of 25 kg/m^2 or higher is considered a risk factor for premature death and disability as a consequence of being overweight or obese (see Chap. 154). These health risks increase as the BMI increases. Although BMI correlates strongly with total body fat, individual variation, especially in very muscular persons, may lead to erroneous classification of either obesity or malnutrition when BMI alone is used to assess nutrition status. BMI should be interpreted based on an individual's characteristics, including gender, frame size, and age. For example, at the same BMI, a woman tends to have more body fat than a man, and an older subject would have more body fat than a younger individual.

Various tables listing BMI stratified by height and weight are available for quick reference. In general, an adult with a BMI between 25 and 29.9 kg/m^2 is overweight, and one with a BMI of 30 kg/m^2 or higher is considered to be obese.[8,24] These numbers may not be appropriate for older subjects, especially those older than 60 years, where a BMI between 27 kg/m^2 and 30 kg/m^2 has not been associated with the same increased nutrition-related risks as seen in younger individuals.[25] BMI has also been used to assess undernutrition with a BMI less than 18.5 kg/m^2 indicating undernutrition (see Table 149–3).[8,24] Children 2 years of age and older are considered overweight if their BMI is at or above the 85th percentile on the age- and gender-specific NCHS BMI chart and obese if the BMI is at or above the 95th percentile.[5,6] Use of these charts helps to heighten parental and healthcare provider awareness of children whose BMI and family history put them at risk for adult obesity and its associated risks.

CLINICAL CONTROVERSY

Clinicians disagree whether an individual's nutrition status is best evaluated using IBW, ABW, adjusted IBW, or BMI. Frame size and muscle mass, as well as gender and height, can influence both IBW and BMI, leading to misclassification of nutrition status in some individuals. Use of adjusted IBW in obese individuals may lead to under- or overestimation of nutrition needs.

SKINFOLD THICKNESS AND MIDARM MUSCLE CIRCUMFERENCE

More than 50% of the body's fat is subcutaneous, thus changes in subcutaneous fat usually reflect changes in total body fat. Skinfold thickness measurement provides an estimate of subcutaneous fat, whereas midarm muscle circumference, which is calculated using the skinfold thickness, estimates skeletal muscle mass. Although simple and noninvasive, these anthropometric measurements are not used commonly in clinical practice but can be used for both population analysis and long-term monitoring of individuals. Triceps skinfold thickness is the most commonly used skinfold measurement, although reference standards also exist for subscapular and iliac sites. Careful technique in the use of pressure-regulated calipers is essential for reproducibility and reliability in measuring triceps skinfold thickness. Midarm muscle circumference is a calculated value based on the measurement of the midarm circumference and triceps skinfold thickness.

These measurements in individuals should be interpreted cautiously because standards do not account for individual variations in bone size, muscle mass, hydration status, or skin compressibility; reference standards do not account for obesity, ethnicity, illness, and increased age; and technique is critical (interobserver error can be significant). Furthermore, these parameters are slow to change in adults, often requiring weeks before significant alterations from baseline can be detected.

WAIST CIRCUMFERENCE

Waist circumference is a simple measurement used to assess abdominal (visceral) fat. Excess abdominal fat, rather than excess peripheral (subcutaneous) fat, is an independent predictor of risk for obesity-related complications, especially diabetes mellitus and cardiovascular disease.[26,27] Waist circumference is determined by measuring the distance around the smallest area below the rib cage and the top of the iliac crest. Interpretation varies with gender. Men are considered at increased risk (beyond the BMI-related risk) if the waist circumference is greater than 40 inches (102 cm); women are at increased risk if the waist circumference is greater than 35 inches (89 cm), and children are at risk if the waist circumference is at the 90th percentile or greater according to age- and gender-specific standards.

WAIST-TO-HIP AND WAIST-TO-HEIGHT RATIO

For most people, extra weight around the waist confers more of a health risk than extra weight around the hips and thighs. The waist-to-hip ratio is determined by dividing the waist circumference by the hip circumference (maximal posterior extension of the buttocks). In adults, a waist-to-hip ratio of greater than 0.9 in men and 0.85 in women is considered an independent risk factor for adverse health consequences.[26] Waist-to-height ratio (both measured in centimeters) has been used to evaluate children at risk for the metabolic syndrome because, unlike waist circumference, it is age and gender independent. A child with a waist-to-height ratio of 0.5 or less is generally not considered to be at metabolic risk.[28]

BIOELECTRICAL IMPEDANCE

BIA is a simple, noninvasive, and relatively inexpensive technique used to measure LBM.[29,30] The technology is based on the fact that lean tissue has a higher electrical conductivity (less resistance) than fat, which is a poor current conductor because of its lower water and electrolyte content. By applying a very small electric current to appendages (wrist and ankle or both feet), impedance (resistance) to flow can be measured. Assessment of LBM, TBW, and water's distribution into compartments can be determined with BIA. Increased TBW decreases impedance; therefore, it is important to evaluate fluid status along with BIA measurements. Other potential limitations of BIA include variability with electrolyte imbalance, interference by large fat masses (obesity), and the lack of reference standards that reflect variations in individual body size and clinical condition. Although BIA equations have high validity when used in the population in which they were developed (mostly young healthy adults), BIA calculations are subject to considerable errors if applied to other populations. BIA is not superior to BMI as a predictor of overall adiposity in the general population and is therefore used primarily as a research tool.

TABLE 149-5 Visceral Proteins Used for Assessment of Lean Body Mass

Serum Protein	Half-Life (Days)	Function	Factors Resulting in Increased Values	Factors Resulting in Decreased Values
Albumin	18–20	Maintains plasma oncotic pressure; transports small molecules	Dehydration, anabolic steroids, insulin, infection	Overhydration, edema, kidney dysfunction, nephrotic syndrome, poor dietary intake, impaired digestion, burns, congestive heart failure, cirrhosis, thyroid/adrenal/pituitary hormones, trauma, sepsis
Transferrin	8–9	Binds Fe in plasma; transports Fe to bone	Fe deficiency, pregnancy, hypoxia, chronic blood loss, estrogens	Chronic infection, cirrhosis, burns, enteropathies, nephrotic syndrome, cortisone, testosterone
Prealbumin (transthyretin)	2–3	Binds T_3 and to a lesser extent T_4; carrier for retinol-binding protein	Kidney dysfunction	Cirrhosis, hepatitis, stress, surgery, inflammation, hyperthyroidism, cystic fibrosis, burns, kidney dysfunction, zinc deficiency

Fe, iron; T_3, triiodothyronine; T_4, thyroxine.
Data from references 8, 10, and 31.

BIOCHEMICAL ASSESSMENT OF LBM

6 LBM includes skeletal muscle, somatic protein, and functional proteins such as the circulating and visceral proteins. Biochemically, LBM can be assessed by measuring the serum visceral proteins, ALB, TFN, and prealbumin (thyroxine-binding prealbumin or transthyretin). Retinol-binding protein, fibronectin (an opsonic protein), and somatomedin-C (insulin-like growth factor-1), proteins with a very short half-life (less than 12 to 24 hours), have also been evaluated as indicators of nutrition status. However, the clinical availability of these alternative tests is limited, and their relevance to nutrition status and patient outcome has not been established. Creatinine-height index has historically been used to assess LBM but is seldom used today because of the lack of evidence to support its usefulness in assessing muscle mass.

Visceral Proteins

Measurement of serum concentrations of the transport proteins synthesized by hepatocytes can be used to assess the visceral protein compartment. It is assumed that a low serum protein concentration in states of undernutrition reflects the hepatic protein synthetic mass, and therefore indirectly reflects the functional protein mass of other organs such as the heart, lung, kidney, and intestines. The visceral proteins with the greatest relevance for nutrition assessment are serum ALB, TFN, and prealbumin. Many factors other than nutrition may affect the serum concentration of these proteins, including age, abnormal kidney (nephrotic syndrome), GI tract (protein-losing enteropathy), or skin (burns) losses, hydration status (dehydration results in hemoconcentration, overhydration in hemodilution), liver function (because this is the primary synthesis site), and metabolic stress (sepsis, trauma, surgery, and infection). Visceral protein concentrations must be interpreted relative to the individual's overall clinical condition (Table 149–5). Serum visceral proteins are of greatest value in assessing the presence of uncomplicated semi-starvation and recovery. During severe acute stress (trauma, burns, or sepsis), these proteins are relatively poor markers of nutrition status because their synthesis is downregulated as the liver increases the production of acute-phase reactants such as C-reactive protein, α_1-acid glycoprotein, and α_1-antitrypsin.[31]

Albumin is the most abundant plasma protein and is involved in maintenance of colloid oncotic pressure and binding and transport of numerous hormones, anions, drugs, and fatty acids. It is one of the most widely used biochemical markers of malnutrition in population studies and in individuals. It is, however, a relatively insensitive index of early protein malnutrition because there is a large amount normally found in the body (4–5 g/kg of body weight), it is highly distributed in the extravascular compartment (60%), and it has a long half-life (18–20 days). However, chronic protein deficiency in the setting of adequate nonprotein calorie intake leads to marked hypoalbuminemia because of a net ALB loss from the intravascular and extravascular compartments. Serum ALB concentrations also are affected by moderate-to-severe calorie deficiency and liver, kidney, and GI disease. Because it is a negative acute phase reactant, serum concentrations will decrease with infection, trauma, stress, and burns. A positive correlation between decreased serum ALB concentrations and poor clinical outcome has been demonstrated in most of the above mentioned settings. Additionally, serum ALB concentrations less than 2.5 g/dL (25 g/L) can be expected to exacerbate ascites and peripheral, pulmonary, and GI mucosal edema as a result of decreased colloid oncotic pressure, Hypoalbuminemia will also affect the interpretation of serum calcium concentrations as well as serum concentrations of highly protein bound drugs.[8,10,31]

TFN is a glycoprotein that binds and transports ferric iron to the liver and reticuloendothelial system for storage. As a surrogate marker of nutrition status, TFN will decrease in response to protein depletion before the serum ALB concentration decreases because it has a shorter half-life (8–9 days), and there is less of it in the body (less than 100 mg/kg of body weight). Serum TFN concentrations may be determined by direct measurement or can be estimated indirectly from measurement of total iron-binding capacity (in μg/dL), where TFN (in mg/dL) = (total iron binding capacity × 0.8) − 43. Critical illness, hydration status, and iron stores affect the serum TFN concentration. In iron deficiency, hepatic TFN synthesis is increased, resulting in increased serum TFN concentrations unrelated to protein status.[8,10]

Prealbumin is the transport protein for thyroxine and a carrier for retinol-binding protein. The body's content of prealbumin is low (10 mg/kg of body weight), and it has a very short half-life (2–3 days). The serum prealbumin concentration may be reduced in as few as 3 days after calorie and protein intake is significantly decreased or when hypercatabolism or severe metabolic stress (trauma or burns) is present. Because of its short half-life, it is most useful in monitoring the short-term, acute effects of nutrition support or deficits, as it responds very quickly in both situations. As with ALB and TFN, serum prealbumin concentrations are depressed in those with liver disease as a consequence of decreased synthesis. Increased serum prealbumin concentrations have been noted in patients with kidney disease as a result of impaired excretion.[8,10]

IMMUNE FUNCTION TESTS

The frequency of impaired immunocompetence and an increased incidence of infection in malnourished patients suggest that certain immune function tests can be used as nutrition status markers. Nutrition affects immune status either directly, affecting primarily the lymphoid system, or indirectly by affecting cellular metabolism or organ systems that are involved with immune system regulation. Immune function tests used in nutrition assessment are the total lymphocyte count and DCH reactions. Both tests are simple, readily available, and inexpensive.

Total lymphocyte count reflects the number of circulating T and B lymphocytes. Tissues that generate T cells are very sensitive to malnutrition and undergo involution resulting in decreased T cell production and eventually lymphocytopenia. Total lymphocyte count is calculated from a complete blood count with differential: total lymphocyte count = (% lymphocytes × total number of white blood cells). Values less than 1,500 cells/mm^3 (1.5 × 10^9 cells/L) have been associated with nutrition depletion.[2] DCH is commonly assessed using antigens to which the patient was likely previously sensitized. The recall antigens used most frequently in nutrition assessment are mumps, *Candida albicans*, and *Trichophyton*. Anergy is associated with severe malnutrition, and immune response may be restored with nutrition repletion. Other more sophisticated immune function tests have been used to evaluate nutrition status in research settings, including lymphocyte surface antigens (CD4 and CD8 counts, CD4:CD8 ratio), T lymphocyte responsiveness, and serum interleukin concentrations.

Other factors besides nutrition can affect immune status. Nonnutrition factors that affect total lymphocyte count include infection (e.g., human immunodeficiency virus [HIV], viruses, and tuberculosis), immunosuppressive drugs (e.g., corticosteroids, cyclosporine, tacrolimus, sirolimus, chemotherapy, and anti-lymphocyte globulin), leukemia, and lymphoma. DCH can be affected by a number of factors, including fever, viral illness, recent live virus vaccination, critical illness, irradiation, immunosuppressive drugs, diabetes mellitus, HIV, cancer, and surgery. This lack of specificity currently limits the usefulness of these tests as nutrition status markers. Nutrients such as arginine, omega-3 fatty acids, and nucleic acids given in pharmacologic doses have been shown to improve immune function. Monitoring the efficacy of a nutrition care plan that includes these potentially immunomodulating nutrients may need to include immune function assessment with these or other immune function indicators.[32,33]

SPECIFIC NUTRIENT DEFICIENCIES AND TOXICITIES

7 A comprehensive nutrition assessment must include an evaluation for possible trace element, vitamin, and essential fatty acid deficiencies. Because of their key role in metabolic processes (as coenzymes and cofactors), a deficiency of any of these nutrients may result in altered metabolism and cell dysfunction and may interfere with metabolic processes necessary for nutritional repletion. The evaluation of a single nutrient deficiency or toxicity state includes an accurate history to identify symptoms and risk factors that may indicate deficiency or toxicity or a predisposition of the patient to developing a deficiency or toxicity state. A nutrition-focused physical examination for signs of deficiencies and biochemical assessment to confirm a suspected diagnosis should be done. Ideally, biochemical assessment would be based on the nutrient's function (e.g., metalloenzyme activity) rather than simply measuring the nutrient's serum concentration. Unfortunately, few practical methods to assess micronutrient function are available, and most assays measure the serum concentration of an individual nutrient.

TRACE ELEMENTS

Clinical syndromes are associated with deficiency states of the essential trace elements zinc, copper, manganese, selenium, chromium, iodine, fluoride, molybdenum, and iron in children and adults.[34–37] Each element is involved in a variety of biologic functions and is necessary for normal metabolism, serving as a coenzyme and/or playing a role in hormonal metabolism or erythropoiesis. Other essential trace elements for which deficiency states have not been recognized include tin, nickel, vanadium, cobalt, gallium, aluminum, arsenic, boron, bromine, cadmium, germanium, and silicon. Toxicities can occur with excess intake of some trace elements. With the current public interest in alternative and complementary medicine, clinicians must ask patients about their use of dietary supplements and assess for signs and symptoms of toxicities (overdose) as well as deficiencies (Table 149–6).

Zinc is a component of many enzymes and proteins and is involved in the regulation of gene expression. Excess zinc intake is usually eliminated by the kidneys and GI tract. Zinc deficiency is characterized by several signs and symptoms, including a moist eczematous dermatitis that is most apparent in the nasolabial folds and around orifices (see Table 149–6). Recovery is rapid with oral zinc supplementation; severe dermatitis can remit in as little as 4 to 5 days.[37] Acrodermatitis enteropathica is an autosomal recessive genetic disorder of zinc metabolism, and zinc deficiency may also occur with abnormal GI losses, such as in Crohn's disease, malabsorptive states (e.g., cystic fibrosis, short bowel syndrome), and extensive ostomy or fistula losses, or from prolonged inadequate intake, such as with zinc-free or inadequately zinc-supplemented parenteral nutrition. Low zinc stores have also been reported in premature infants and in children with sickle cell disease. Zinc deficiency can be documented by the presence of low plasma zinc concentrations.[38] However, plasma zinc concentrations decrease during acute stress states, such as trauma, surgery, burns, or sepsis, and generally remain depressed until the stress resolves. Also, because zinc is a normal contaminant of most blood collection tubes, special zinc-free collection tubes must be used for plasma assays. Hair zinc analysis and urinary zinc excretion are also biomarkers of zinc status.[38]

Copper is a component of ceruloplasmin and key metalloenzymes involved in iron metabolism (ceruloplasmin), electron transport and energy metabolism (cytochrome oxidase), connective tissue and collagen cross-linking (lysyl oxidase, elastase, and monamine oxidase), and free radical scavenging (superoxide dismutase). Copper intake in excess of metabolic requirements is excreted through the bile. The signs and symptoms of copper deficiency include hypochromic anemia, neutropenia, neurologic dysfunction, skeletal demineralization, and hypercholesterolemia (see Table 149–6). In severe cases, such as in Menkes syndrome, copper deficiency is further manifested as hypothermia, hair and skin depigmentation, progressive mental deterioration, and growth retardation. Factors predisposing to copper deficiency include malabsorption states, protein-losing enteropathy, nephrotic syndrome, and copper-free parenteral nutrition.[39] The chronic ingestion of too much copper or inadequate elimination can result in cirrhosis as seen in Wilson disease, an autosomal-recessive genetic disorder. Copper deficiency is best assessed using serum copper concentrations which appear to reflect changes in copper status in both copper-depleted and copper-replete individuals.[40] As with zinc, serum copper concentrations may not accurately reflect total body copper status because serum concentrations may be altered by a variety of conditions (see Table 149–6). Copper function also may be assessed by measuring ceruloplasmin total protein; however this test appears to be more copper status dependent, reflecting copper status changes only in highly depleted individuals.[40]

Trivalent chromium is an important cofactor, along with insulin, in the maintenance of normal blood glucose concentrations. Recent data indicate that a low-molecular-weight chromium binding substance, sometimes referred to as the glucose tolerance factor, may enhance the response of the insulin receptor to insulin.[41] Chromium deficiency is characterized by glucose intolerance, impaired protein utilization, and increased insulin requirements. Patients with chromium deficiency also may have increased free fatty acid concentrations and a low respiratory quotient (RQ) (see Table 149–6). Chromium deficiency has only been identified in patients receiving long-term parenteral nutrition with inadequate chromium intake.

TABLE 149-6 Assessment of Trace Element Status

Trace Element	Signs of Deficiency	Signs of Toxicity	Factors Associated with Altered Plasma Concentrations
Chromium	Impaired glucose/protein utilization, peripheral neuropathy, low RQ, weight loss, increased LDL-C, increased free fatty acid concentrations	Industrial exposure: skin/nasal septum lesions, allergic dermatitis, increased incidence of lung cancer	Decreased: long-term inadequate intake Increased: kidney failure
Copper	Menkes syndrome, progressive mental deterioration, vomiting, diarrhea, protein-losing enteropathy, hypopigmentation, bone and hair changes Deficiency: neutropenia, hypochromic anemia, pallor, dermatitis, neurologic dysfunction	Wilson disease: cirrhosis, Kayser-Fleischer ring;[a] kidney dysfunction, neurologic/psychiatric symptoms (tremors, slow speech, inappropriate behavior, personality changes) Mild chronic toxicity: fatigue, anemia, thrombocytopenia Acute toxicity: nausea, vomiting, diarrhea	Decreased: high zinc, iron or vitamin C intake, corticosteroid use Increased: infection, rheumatoid arthritis, pregnancy, oral contraceptives, decreased biliary excretion
Iodine	Hypothyroid goiter, neuromuscular impairment, deafmutism, increased embryonic and postnatal mortality, cognitive impairment, impaired fertility, cretinism (severe cases)	Thyrotoxicosis: nodular goiter, weight loss, tachycardia, muscle weakness, warm skin	Decreased: long-term inadequate intake
Iron	Microcytic, hypochromic anemia (weakness, pallor, fatigue), glossitis, headache, dysphagia, nail changes, gastric atrophy, paresthesia, decreased cognitive function	Cirrhosis, cardiomyopathy, pancreatic damage, skin pigmentation changes	Increased: blood transfusion Decreased: blood loss
Manganese	Nausea, vomiting, dermatitis, hair color changes, hypocholesterolemia, growth retardation, defective carbohydrate, lipid, and protein metabolism	Parkinsonian-like symptoms, hyperirritability, hallucinations, libido disturbances, ataxia, mental confusion, lack of attention, memory loss	Increased: decreased biliary excretion, high iron or vitamin C intake
Molybdenum	Tachycardia, tachypnea, altered mental status, visual changes, headache, nausea, vomiting	Gout-like syndrome, increased urinary copper	Decreased: low birth weight, excessive GI losses
Selenium	Muscle weakness/pain, cardiomyopathy, skin and hair pigmentation changes	Nausea, vomiting, hair/nail loss, tooth decay, skin lesions, irritability, fatigue, peripheral neuropathy	Decreased: malignancy, liver failure, pregnancy Increased: reticuloendothelial neoplasia
Zinc	Dermatitis (scaly, hyperpigmented lesions of elbows/knees), altered taste and smell, alopecia, diarrhea, apathy, depression, growth retardation, impaired wound healing, anorexia, immunosuppression, delayed sexual maturation	Acute: diarrhea, vomiting, nausea, dizziness, garlic-smelling breath; death with large intravenous doses Chronic: immunosuppression, decreased HDL-C, copper deficiency	Decreased: infection, burns, stress, hypoalbuminemia, corticosteroids, pregnancy, inflammation Increased: tissue injury, hemolysis, contaminated collection tube

GI, gastrointestinal; HDL-C, high-density-lipoprotein cholesterol; LDL-C, low-density-lipoprotein cholesterol; RQ, respiratory quotient.
[a]Kayser-Fleischer rings are dark rings that appear to encircle the iris of the eye.
Data from references 8 and 34 to 37.

Plasma chromium concentrations do not accurately reflect total body chromium status, presumably because the biologically active form of chromium is the low-molecular-weight chromium binding substance. Toxicity from trivalent chromium is not a common clinical concern, and chromium toxicity has been reported only with contaminated drinking water or industrial exposure. Chromium supplementation as an adjunct for weight loss has not been proven effective.

Manganese is important in the function of many enzymes, including arginase (amino acid metabolism via the urea cycle), pyruvate carboxylase and phosphoenolpyruvate carboxykinase (carbohydrate and cholesterol metabolism), superoxide dismutase (mitochondrial antioxidant), glycosyltransferases (bone formation via proteoglycans), and prolidase (wound healing).[35,37,42] Excess manganese is eliminated via the bile. Manganese deficiency has only been reported in association with the ingestion of chemically defined manganese-deficient oral diets. Table 149–6 lists common symptoms associated with manganese deficiency. Manganese toxicity is more concerning and has been described in industrial exposures via inhaled manganese and in several patients receiving long-term parenteral nutrition supplemented with manganese (standard trace element preparation), especially in the setting of chronic cholestasis.[35,37,42–44] Manganese can accumulate in brain tissue and the newborn brain may be more susceptible to the effects of manganese toxicity.[37,43] Clinical toxicity is evidenced primarily by extrapyramidal symptoms mimicking Parkinson's disease, such as tremors, ataxia, and fascial muscle spasms. These symptoms may be preceded by psychiatric symptoms, including irritability, aggressiveness, and hallucinations. In most reported cases, discontinuation of manganese from the parenteral nutrition solution resulted in resolution of neurologic symptoms in 6 months with partial or total normalization of the magnetic resonance image after 1 to 2 years. Whole-blood manganese concentrations can be obtained to ascertain manganese status. Magnetic resonance imaging with intensity and T1 values in the globus pallidus may be useful for assessing manganese toxicity.[44,45]

Selenium is incorporated into at least 25 enzymes known as selenoproteins, about half of which have a defined metabolic function. Important selenoproteins include: five glutathione peroxidases (antioxidant activity), iodothyronine deiodinase (thyroid hormone regulation), thioredoxin reductase (vitamin C), selenoprotein P (antioxidant activity), selenoprotein V (spermatogenesis), and selenoprotein S (inflammation and immune response).[35,37] Prematurity, acute illness, chronic GI losses, and long-term selenium-free parenteral nutrition are associated with low serum selenium concentrations and decreased glutathione peroxidase activity.[35,37,46] The clinical significance of reduced serum selenium concentrations is unclear, but low selenium concentrations may make individuals more susceptible to physiologic stressors. Selenium deficiency has been described in patients receiving long-term selenium-free parenteral nutrition. Muscle pain, wasting, and weakness were the most frequently observed signs and symptoms (see Table 149–6), but severe biochemical deficiency is not always accompanied by these symptoms. Fatal cardiomyopathy has been reported in several cases. Selenium toxicity or selenosis generally only occurs in those with long-term exposure to foods grown in selenium-rich soil (e.g., Great Plains area of the United States) and may occur when intake exceeds 400 mcg/day for prolonged periods. Selenium toxicity results in hair and nail brittleness and loss, GI disturbance, skin rash, garlic breath odor, fatigue, irritability, and nervous system abnormalities. Plasma, erythrocyte, and whole-blood selenium, plasma selenoprotein P, and

plasma, platelet, and whole-blood glutathione peroxidase activity respond to changes in selenium intake, but the response is heterogeneous.[47] Decreased plasma selenium concentrations may indicate selenium deficiency, but reductions have been observed in patients with malignancies, liver failure, and pregnancy.

Molybdenum is a cofactor for enzymes involved in catabolism of sulfur amino acids, purines, and pyrimidines (i.e., xanthine, aldehyde, and sulfite oxidases).[35,37] Molybdenum deficiency is rare, but an inborn error of metabolism resulting in molybdenum deficiency has been identified. One case of molybdenum deficiency has been reported in a patient receiving long-term parenteral nutrition who presented with symptoms that included tachycardia, tachypnea, headache, night blindness, nausea, vomiting, central scotomas, lethargy, disorientation, and ultimately coma (see Table 149–6). Symptoms were reversed when molybdenum was added to the parenteral nutrition solution.[48] Factors predisposing to molybdenum deficiency appear to be low birth weight,[49] excessive loss via the GI tract, and long-term inadequate intake, such as with molybdenum-free parenteral nutrition. Biochemical abnormalities expected in molybdenum deficiency include very low serum and urine uric acid concentrations (low xanthine oxidase activity) and low urine inorganic sulfate concentrations with high urine inorganic sulfite concentrations (low sulfate oxidase activity).[35,37] Molybdenum toxicity has not been described.

Deficiency of iodine, a component of thyroid hormones, may result in goiter formation (see Chap. 84). However, not everyone with an iodine-deficient diet will develop a goiter. Thyroxine (T_4) and triiodothyronine (T_3) can be used to assess iodine status (see Table 149–6). Intravenous iodine supplementation is not necessary except during long-term parenteral nutrition with minimal enteral intake. Iodine needs may be met by cutaneous absorption of iodine from germicides (e.g., povidone-iodine) used in catheter care or consumption of iodized salt.[35,37] Use of povidone-iodine as a topical antiseptic has decreased with the increased use of chlorhexidine for catheter care; thus the need for iodine supplementation must be individualized. Iodine excess is rarely a clinical concern when thyroid and kidney function are normal.

Iron is an important component of hemoglobin, myoglobin, and cytochrome enzymes; it is important in oxygen transport, muscle iron storage, and cellular energy production. Patients with iron-deficiency anemia generally present with fatigue, weakness, and pallor, but they may have other symptoms (see Chap. 109).[35,37] Inadequate iron intake, malabsorption, and blood loss are the principal causes of iron-deficiency anemia. Iron toxicity (overload) with possible organ damage can occur when chronic iron intake exceeds requirements, such as in patients receiving chronic blood transfusions. Iron deficiency or overload is confirmed by assessment of body iron stores, as reflected indirectly by measurement of hemoglobin, serum iron, total iron binding capacity, and serum ferritin, or directly by marrow staining and liver biopsy. Although the direct methods are the most accurate, they are invasive, and indirect measurements are used more commonly. Because indirect parameters may be altered by chronic illness independent of iron stores, concomitant illness must be considered in their interpretation.

VITAMINS

Vitamins act as both catalysts (cofactors) and substrates in essential metabolic reactions. A comprehensive nutrition-focused history and physical examination is the most valuable means of assessing patients for vitamin deficiency or toxicity (Table 149–7). A thorough review of all the complex interrelationships of vitamins and their effects on nutrition and metabolism is beyond the scope of this chapter.[34–36,50–52] Multiple vitamin deficiencies are most often associated with generalized malnutrition; however, single vitamin deficiencies may be noted. Thiamine deficiency results in lactic acidosis and encephalopathy.[53] Pernicious anemia caused by vitamin B_{12} (cyanocobalamin) deficiency has been reported with increasing frequency, especially in the elderly, as a consequence of decreased gastric acidity.[54] The increasing prevalence of vitamin D deficiency is a growing concern, especially in children and the elderly.[55–57] Laboratory assessment may be useful to confirm the clinical suspicion of a deficiency or toxicity state. The first indication of a deficiency is usually a fall in circulating serum concentrations of the vitamin or its coenzyme. Subsequently, there is a decrease in urinary excretion of the vitamin, which is followed by diminished tissue concentrations. The most common measurements of vitamin status are assays of circulating amounts in plasma or serum. Assays of biochemical or metabolic function of the vitamin are more likely to reflect body stores than are serum concentrations. Most of these functional assays use erythrocyte or leukocyte extracts to determine apoenzyme activity, which is dependent on the vitamin coenzyme (Table 149–7).

Vitamin toxicity can occur, especially with the fat-soluble vitamins (A, D, E, and K), which are stored in the body. Excessive dietary intake of vitamin A (hypervitaminosis A) is linked to an increased risk of hip fractures in both men and women.[58,59] With the exception of cyanocobalamin, which is stored in the liver, water-soluble vitamins are not stored in the body; consequently, the risk of toxicity is considered minimal unless ingested in very high doses. Recent evidence, however, suggests that even water-soluble vitamins may be associated with adverse events when taken chronically in high doses. Although administration of folic acid is definitively associated with a reduction in neural tube defects, its ability to improve some cardiac outcomes (a result of its effect on homocysteine concentrations) is not established.[60] The administration of folic acid, vitamin B_6 (pyridoxine), and vitamin B_{12} after coronary artery stenting has been associated with an increase in the risk of in-stent restenosis.[61] With the current use of nutrition supplements by Americans, the clinician should be alert for the signs of hypervitaminosis (Table 149–7).

ESSENTIAL FATTY ACIDS

The human body can synthesize all fatty acids except linoleic acid (an omega-6 fatty acid) and α-linolenic acid (an omega-3 fatty acid). If approximately 5% of total calories are ingested as these fatty acids, development of a deficiency state can be prevented.[62] Essential fatty acid deficiency is rare in adults and children but can occur with prolonged use of lipid-free parenteral nutrition, with severe fat malabsorption, with very-low-fat enteral feeding formulations or diets, and with severe malnutrition, especially in stressed patients.[63,64] In critically ill adults and older children with increased metabolic demands, biochemical evidence of essential fatty acid deficiency can occur within 1 week of starting lipid-free parenteral nutrition.[63,64] Because newborns, especially those born prematurely, have limited fat stores, they may develop essential fatty acid deficiency more rapidly than adults. Biochemical essential fatty acid deficiency has been noted within 72 hours after birth in preterm infants receiving fat-free intravenous solutions.[65] Symptoms of essential fatty acid deficiency include dermatitis (dry, cracked, scaly skin), alopecia, impaired wound healing, growth failure, thrombocytopenia, and anemia.

Linoleic acid normally is converted to arachidonic acid (a tetraene fatty acid). If linoleic acid is unavailable, oleic acid will be substituted, which results in production of eicosatrienoic acid (a triene fatty acid) as the metabolic end product, enabling an essential fatty acid deficiency to be detected on the basis of decreased tetraene production and increased triene production. Normally, the ratio of trienes to tetraenes is less than 0.4; when this ratio becomes greater than 0.4, the diagnosis of essential fatty acid deficiency is established. However, because analysis of plasma fatty acids is

TABLE 149-7 Assessment of Vitamin Status

Vitamin	Signs of Deficiency	Laboratory Assay	Comments
Water-soluble vitamins			
Thiamine (B_1)	Early: anorexia, fatigue, depression, impaired memory/concentration Late: paresthesia, nystagmus, GI beriberi (nausea, vomiting, abdominal pain, lactic acidosis), beriberi (congestive heart failure, edema), Wernicke encephalopathy, Korsakoff's psychosis, peripheral neuropathy	Whole blood or erythrocyte transketolase activation test Blood thiamine pyrophosphate Erythrocyte glutathione reductase activity coefficient	Increased need with hemo- and peritoneal dialysis, alcoholism, malabsorption, hypermetabolism
Riboflavin (B_2)	Mucositis, dermatitis, cheilosis, glossitis, photophobia, corneal vascularization, lacrimation, decreased vision, impaired wound healing and growth, normocytic anemia	Urinary riboflavin	
Pantothenic acid	Fatigue, malaise, headache, insomnia, vomiting, abdominal cramps	Serum pantothenic acid	
Niacin	Pellagra: dermatitis, dementia, glossitis, diarrhea, memory loss, headaches	Urinary niacin and N_1-methylnicotinamide Erythrocyte NAD and NADP concentrations to determine "niacin number"	Flushing, nausea, and vomiting seen with hyperlipidemia treatment; increased need with hemo- and peritoneal dialysis
Pyridoxine (B_6)	Pellagra, dermatitis, glossitis, cheilosis, distal limb numbness/paresthesia, convulsions, microcytic anemia	Plasma pyridoxal 5-phosphate Urinary 4-pyridoxic acid	Sensory neuropathy and seizures with very high doses (more than 2 g/day)
Folic acid	Macrocytic anemia, diarrhea, glossitis, cheilosis, angular stomatitis, fatigue, difficulty concentrating, irritability, headache, palpitations, shortness of breath, heart failure, tachycardia, postural hypotension, lactic acidosis, neural tube defects, impaired cellular immunity, paranoid behavior	Serum or plasma folate (acute) Red blood cell folate (chronic) Serum homocysteine	Decreased with increased cellular/tissue turnover (pregnancy, malignancy, hemolytic anemia); masks diagnosis of vitamin B_{12} deficiency; decreases risks of neural tube defects
Cyanocobalamin (B_{12})	Pernicious anemia, glossitis, spinal cord degeneration, peripheral neuropathy	Serum cobalamin Plasma homocysteine Urinary methylmalonic acid	Decreased absorption in the elderly, distal ileal resection, loss of gastric intrinsic factor by gastrectomy or long-term gastric acid suppression
Biotin	Dermatitis, depression, lassitude, somnolence	Urinary biotin	
Ascorbic acid (C)	Enlargement/keratosis of hair follicles, impaired wound healing, anemia, lethargy, depression, bleeding, ecchymosis, scurvy	Plasma ascorbic acid Leukocyte ascorbate	GI disturbances, hyperoxaluria and kidney stones, excess iron absorption with excess intake; smokers need 35 mg/day more than nonsmokers; rebound scurvy with abrupt discontinuation after long-term high doses
Fat-soluble vitamins			
Vitamin A (includes retinol, retinal, retinoic acid, and retinyl esters)	Dermatitis, night blindness, xerophthalmia, Bitot spots,[a] pruritus, follicular hyperkeratosis, excessive deposition of periosteal bone, hair changes, poor growth and wound healing, impaired resistance to infection Irreversible: punctate keratopathy, keratomalacia, corneal perforation	Serum retinol Serum retinol-binding protein Serum retinyl esters (toxicity)	Teratogenic, liver toxicity with excessive intake; alcohol intake, liver disease, hyperlipidemia, and severe protein malnutrition increase susceptibility to adverse effects of high intake; β-carotene supplements recommended only for those at risk of deficiency (fat malabsorption); can reverse corticosteroid-induced poor wound healing
D	Rickets, osteomalacia and osteoporosis, muscle weakness, poor growth, hypocalcemia, immune dysfunction, cardiomyopathy	Serum 25-hydroxy vitamin D	Elevated intake causes hypercalcemia, nephrocalcinosis, azotemia, poor growth; decreased in uremia, elderly (especially in winter), fat malabsorption
α-Tocopherol (E)	Hemolysis	Serum α-tocopherol Ratios of serum α-tocopherol to total lipids	Excess intake: hemorrhagic toxicity; increased risk of bleeding with anticoagulants; impaired leukocyte function
K	Bleeding (ecchymosis, petechiae, hematomas)	Prothrombin time INR	Anticoagulant therapy can be affected by supplements or diet

GI, gastrointestinal; INR, international normalized ratio; NAD, nicotinamide adenine dinucleotide; NADP, nicotinamide adenine dinucleotide phosphate.
[a]Bitot spots are spots located superficially in the conjunctiva, which are oval, triangular, or irregular in shape.
Data from references 8, 34 to 36, 50, and 51.

expensive and not widely available, diagnosis is generally made based on clinical findings and risk assessment.

CARNITINE

Carnitine is a quaternary amine required for transport of long-chain fatty acids into the mitochondria for β-oxidation and energy production. Carnitine also binds acyl residues and helps in their elimination (detoxification), thereby decreasing the number conjugated with coenzyme A and increasing the ratio of free to acetylated coenzyme A. Carnitine is available from a wide variety of dietary sources (especially meats) and can be synthesized by the liver and kidneys from lysine and methionine. Hepatic synthesis is decreased in premature infants, and low plasma carnitine concentrations and/or overt

carnitine deficiency have been documented in premature infants receiving parenteral nutrition or carnitine-free diets, as well as in those with inborn errors of metabolism.[66,67] Other predisposing factors for carnitine deficiency include chronic kidney[68] or liver disease, chronic use of valproic acid and zidovudine,[69] and a vegetarian diet. The clinical presentation of carnitine deficiency includes generalized skeletal muscle weakness, fatty liver, and fasting hypoglycemia.[66,67]

In clinical practice, carnitine status is most often assessed by measurement of plasma total and free carnitine concentrations and acylcarnitine; although tissue concentrations, especially muscle, are higher than plasma concentrations.[66,67] Plasma and urine carnitine concentrations are most helpful in primary carnitine deficiency (an inborn error of metabolism); acylcarnitine concentrations are more helpful in secondary causes of carnitine deficiency. When only total and free concentrations are available, the free is subtracted from the total to give the acylcarnitine concentration.

MUSCLE FUNCTION TESTS

Diminished skeletal muscle function can be a useful indicator of malnutrition as muscle function is an end-organ response. Muscle function also recovers more rapidly in response to initiation of nutrition support than anthropometric measurements. Hand-grip strength (forearm muscle dynamometry), respiratory muscle strength, and muscle response to electrical stimulation have been used. Measuring hand-grip strength is a relatively simple, noninvasive, and inexpensive (most hand-grip dynamometers cost less than $400) procedure that correlates with patient outcome.[70–72] Ulnar nerve stimulation causes measurable muscle contraction and is currently used in the intensive care unit to monitor the adequacy of neuromuscular blockade. In the setting of malnutrition, increased fatigue and a slowed muscle relaxation rate have been noted; these indices return to normal after refeeding. Both these parameters have the advantage of being indicators of tissue function rather than composition. Their usefulness in clinical practice is currently hampered by a lack of appropriate reference standards and limited data confirming their sensitivity and specificity for nutrition assessment.

OTHER NUTRITION ASSESSMENT TOOLS

Various methods to determine body composition have been used in the research setting. These methods generally are complex, require expensive technology, and at present are limited to research centers. One of the most promising for routine clinical practice is dual-energy x-ray absorptiometry (DXA). DXA is best known for its use in measuring bone density for the evaluation of osteoporosis, but DXA can be used to quantify the mineral, fat, and LBM compartments of the body.[73–76] DXA is available in most hospitals and many outpatient clinics. Equipment for a central DXA scan requires a fair amount of space and is expensive; that is, $40,000 to $160,000 depending on complexity of the scanner. Portable (or peripheral) DXA devices that use ultrasound and infrared interactance can be used to measure bone density in peripheral bones, such as the wrist, fingers, or heel, and have also been used to assess subcutaneous fat. These portable DXA scanners are much less expensive ($10,000–$20,000 or less) and are amenable for use in community screenings in malls, health fairs, and pharmacies. Further research is needed to determine if DXA will be useful clinically in nutrition assessment.

Magnetic resonance imaging and computed tomography can measure subcutaneous, intraabdominal, and regional fat distribution. Neutron activation is a means of measuring body nitrogen, calcium, sodium, chloride, and phosphorus. These measurements can then be used to calculate total body fat, bone, and protein. Isotope dilution methods determine TBW, and underwater weighing determines density. In addition, these methods can be used to estimate LBM and body fat because fat tissue is less dense than muscle and bone. LBM also can be estimated using total body electrical conductivity and by measuring the naturally occurring isotope ^{40}K. These techniques are used primarily in research and seldom in clinical practice.

ASSESSMENT OF NUTRIENT REQUIREMENTS

8 Nutrition requirements depend on an individual's clinical condition and the need for continued maintenance of adequate nutrition or whether starvation or ongoing metabolic stress dictates a need for repletion. For obese patients, usual nutrition requirements may be altered because of the need for weight loss. In children, there is the added consideration of sustaining or reestablishing normal growth and development. Organ function (e.g., intestine, kidney, liver, and pancreas) may affect nutrient utilization.

Nutrient requirements vary with age, gender, size, disease state, clinical condition, nutrition status, and physical activity. An estimate of nutrient requirements must be made using guidelines interpreted in the context of these patient-specific factors. The Recommended Dietary Allowances (RDAs) were initially established in 1941. In the early 1990s, the Food and Nutrition Board began a significant revision of the RDAs and introduced a new family of nutrition reference values, the Dietary Reference Intakes (DRIs), in 1997.[77]

The four categories of the DRIs are Estimated Average Requirements (EARs), RDAs, Adequate Intakes (AIs), and Tolerable Upper Intake Levels (ULs). EARs can be used for planning nutrient intakes for groups, as they are defined as the amount of the nutrient that meets the needs of 50% of persons in a given group or population. The RDA is designated as the nutrient intake that meets the needs of almost all persons in the designated group. The RDA is approximately 2 standard deviations above the EAR for nutrients for which the requirement is well defined, and 1.2 times the EAR for other nutrients. To evaluate an individual's daily intake, the RDA is the most appropriate comparator. AIs are defined as the average intake for the designated group that appears to sustain a particular nutrition state, growth, or other functional indication of health. This category is reserved for nutrients for which no EAR or RDA has been determined. Finally, the UL is the maximum nutrient intake that is unlikely to pose adverse effects in almost all persons in a designated group.[77]

DRIs have been established for six of the seven established nutrient groups: calcium, phosphorus, magnesium, vitamin D, and fluoride; folate and other B vitamins; antioxidants (e.g., selenium and vitamins C and E); trace elements; macronutrients (e.g., protein, fat, carbohydrates, and fiber); and electrolytes and water.[77] Recommendations for group seven, which includes other food components (e.g., phytoestrogens), are still in development. Due to the increased prevalence of vitamin D deficiency, the calcium and vitamin D recommendations are being reassessed. The United States Department of Agriculture's Website includes an Interactive DRI for Healthcare Professionals which easily calculates a generally healthy individual's nutrition needs based on the DRIs.[78]

ENERGY

According to the DRIs, adults should consume 45% to 65% of their total calories as carbohydrates, 20% to 35% as fat, and 10% to 35% as protein.[62] The recommendations for children are similar: carbohydrate, 45% to 65%; fat, 30% to 40%; and, protein, 10% to 30%. Infants, especially premature infants, need a higher proportion of fat (approximately 40%–50% of total calories) in their diets to ensure normal neurologic development. The RDA for total daily carbohydrates for adults and children is 130 g.[62]

TABLE 149-8 Dietary Reference Intakes for Energy and Protein in Healthy Children

Age (Reference Age/Weight)	Estimated Energy Requirement (kcal/day)[a]		Protein RDA (g/kg/day)[b]
	Boy	*Girl*	
0–6 months (3 months/6 kg)	570	520	1.52[c]
7–12 months (9 months/9 kg)	743	676	1.5
1–2 years (24 months/12 kg)	1,046	992	
1–3 years (24 months/12 kg)			1.1
3–8 years (6 years/20 kg)	1,742	1,642	
4–8 years (6 years/20 kg)			0.95
9–13 years (11 years/M: 36 kg; W: 37 kg)	2,279	2,071	0.95
14–18 years (16 years/M: 61 kg; W: 54 kg)	3,152	2,368	0.85

M, men; RDA, recommended dietary allowance; W, women.
[a]One kcal/day is approximately 4.19 kJ/day.
[b]Protein requirements in metabolically stressed children increase by 50% or more.
[c]Adequate Intake (AI).

TABLE 149-9 Equations to Estimate Energy Expenditure in Adults and Children[a]

Adults

Harris-Benedict[b] (kcal/day)[c]

Men: BEE = 66 + [(13.7W(kg)] + [5H(cm)] – (6.8A)
Women: BEE = 655 + [(9.6W(kg)] + [1.8H(cm)] – (4.7A)

DRI equations (kcal/day)[c]

Men: EER = 662 – 9.53A + (PA × 15.91W) + 539.6H(m)
Women: EER = 354 – 6.91A + (PA × 9.36W) + 726H(m)
PA = 1 if sedentary; 1.12 if low active; 1.27 if active; and 1.45 if very active.

Children

FAO/WHO/UNU (kcal/day)[c]

0–3 years of age
Boys: BMR = 60.9W – 54
Girls: BMR = 61W – 51
4–10 years of age
Boys: BMR = 22.7W + 495
Girls: BMR = 22.5W + 499
11–18 years of age
Boys: BMR = 17.5W + 651
Girls: BMR = 12.2W + 746

DRI equations (kcal/day)

Birth through 2 years of age
EER = (89W – 100) + GF
GF = 175 kcal if 0–3 months; 56 kcal if 4–6 months; 22 kcal if 7–12 months; 20 kcal if 13–35 months
3–18 years of age
Boys: EER = 88.5 - (61.9A) + PA [26.7W + 903H(m)] + GF
Girls: EER = 135.3 - (30.8A) + PA [10W + 934H(m)] + GF
GF = 20 kcal if 3–8 years; 25 kcal if 9–18 years.
PA = 1 if sedentary; 1.13–1.16 if low activity; 1.26–1.31 if normal activity; and 1.42–1.56 if very active

A, age in years; BEE, basal energy expenditure; BMR, basal metabolic rate; DRI, Dietary Reference Intakes; EER, estimated energy requirement; FAO/WHO/UNU, Food and Agriculture Organization/World Health Organization/United Nations University; GF, growth factor, H, height in centimeters (cm) or meters (m), as indicated; PA, physical activity factor; W, weight in kilograms.
[a]No real consensus exists as to which formula is best in all situations. Many clinicians use more than one equation and calculate a range of acceptable intakes.
[b]The common practice of using an adjusted body weight for obesity in these calculations is not supported by the original data which used actual body weight in all cases up to a BMI of 56 kg/m^2 in men and 40 kg/m^2 in women.[64]
[c]One kcal/day is equivalent to 4.19 kJ/day.
Data from references 2, 62, 64, 79, and 81.

Estimating Energy Expenditure

An individual's total daily energy expenditure depends on the basal energy expenditure (BEE), the energy used for substrate metabolism, and energy used for physical activity. More than 200 methods for determining an individual's total energy or calorie (kcal) requirement have been published. The most commonly used methods to determine energy requirements use population estimates of calories per kilogram of body weight (kcal/kg), equations that estimate an individual's energy expenditure, or indirect calorimetry. The corresponding SI unit is kilojoule per kilogram of body weight (kJ/kg) where 1 kcal/kg is equivalent to 4.186 kJ/kg. The simplest method to assess energy requirements is to use population estimates of calories required per kilogram of body weight. This method assumes standard values for the energy requirements associated with various disease states or clinical conditions, as well as the additional requirements for repletion of a malnourished individual. It does not take into consideration age- or gender-related differences in energy needs. Daily adult requirements determined by this method are accepted to be[2,79]:

Healthy/normal nutrition status/minimal illness severity: 20 to 25 kcal ABW/kg/day (84–105 kJ ABW/kg/day)

Illness, metabolic stress (BMI <30 kg/m^2): 25 to 30 kcal ABW/kg/day (105–126 kJ ABW/kg/day)

Illness, metabolic stress (BMI ≥30 kg/m^2): 11 to 14 kcal ABW/kg/day or 22 to 25 kcal IBW/kg/day (92–105 kJ ABW/kg/day)

Major burn injury (≥50% total body surface area) or repletion: ≥30 kcal ABW/kg/day (≥126 kJ ABW/kg/day)[80]

Table 149–8 shows suggested calorie intakes for maintenance and normal growth of healthy infants and children.[62] For children, these maintenance energy requirements are approximately 150% of basal metabolic rate, with the additional calories needed to support activity and growth. Caloric requirements increase with fever, sepsis, major surgery, trauma, burns, and long-term growth failure, and in the presence of chronic conditions such as bronchopulmonary dysplasia, congenital heart disease, and cystic fibrosis. Energy needs may decrease with obesity and neurologic disability (e.g., cerebral palsy).[20] Close monitoring and appropriate clinical decisions are essential to ensure that the desired nutrition therapy outcomes are attained.

Various equations are used to estimate energy needs of adults and children (see Table 149–9). The Harris-Benedict equations which were derived in 1919 based on a study of 239 individuals are still a popular means for assessing energy requirements in adults. They have the advantage of taking into consideration the patient's age, height, weight, gender, and clinical condition. These equations were derived from oxygen (O_2) consumption measurements made on normally nourished healthy individuals who were in a fasting and resting state. Although these equations are commonly referred to as the "BEE equations," they actually estimate resting energy expenditure (REE), the amount of energy expended at rest by a fasting, awake individual in a temperature-controlled environment performing only basal functions such as breathing, circulation, and metabolic processes.

Because these equations approximate REE, their results must be modified by a factor that is most representative of the individual's clinical condition. For example, an individual who is confined to bed may require a calorie intake that is only 20% to 30% above the REE; whereas a person who is suffering from a severe burn injury may require 150% to 200% of the calculated REE. Some clinicians multiply the calculated REE by both a stress factor and an activity factor. Because validation studies in healthy subjects have shown that these equations overestimate REE by 6% to 15%, the calculated REE should be multiplied by either a stress factor or an activity factor to avoid further overestimation of the individual's energy needs.[2] It should also be noted that ABW (up to a BMI of 57 kg/m^2 in men and 40 kg/m^2 in women), not IBW or adjusted IBW, was

TABLE 149-10 Stress Factors for Use in Children and Adults

Condition	Factor
No stress	
Confined to bed	1.2
Out of bed: normal activity	1.3
Catch-up growth	1.5
Mild stress[a]	
Postoperative recovery: uncomplicated surgery	1–1.15
Trauma: mild (e.g., long-bone fracture)	1.2
Moderate stress[a]	
Sepsis (moderate)	1.2–1.4
Trauma: central nervous system (sedated)	1.3
Trauma: moderate to severe	Children: 1.5 Adults: 1.3–1.4
Severe stress[a]	
Sepsis (severe)	Children: 1.6 Adults: 1.3
Trauma: central nervous system (severe)	Children: up to 2.0 Adults: up to 1.3
Burns (proportionate to burned area)[b]	Up to 2.0

[a]Implies decreased activity during period of stress.
[b]Formulas specifically for estimating energy needs in burned children and adults have been published and are likely more accurate. See reference 80.
Data from references 2 and 82

used to generate the original data with these equations.[64] The metabolic response to stress in children appears to be similar to that seen in critically ill adults, and the "stress factors" used in adults, shown in Table 149–10, can be used in children once the REE has been determined using one of the equations shown in Table 149–9. Controversy exists over the accuracy and reliability of predicting energy expenditure based on these equations because clinical judgments of stress or activity level will vary between clinicians and the variability of the Harris-Benedict equations in predicting BEE is well documented.[64,81]

CLINICAL CONTROVERSY

Numerous equations and "stress" factors have been published for estimating energy requirements, but none has been shown to be superior in all situations. Measuring energy expenditure with indirect calorimetry is more accurate, especially for the obese, stressed, and mechanically ventilated patient, but it is neither appropriate nor available for all patients. Regardless of the method chosen, recognition that it is only an estimate and careful monitoring of the response to nutrition intervention are imperative.

Measuring Energy Expenditure

The most accurate method to determine energy expenditure, especially in acutely ill or obese patients, is to measure it using indirect calorimetry, also referred to as metabolic gas monitoring. Indirect calorimetry methodology is based on the fact that when substrates (carbohydrates, fat, and protein) are oxidized, O_2 is consumed and carbon dioxide (CO_2) is produced in varying amounts depending on the substrate being oxidized. Indirect calorimetry is a noninvasive procedure where oxygen consumption (VO_2, mL/min) and carbon dioxide production (VCO_2, mL/min) are measured, and the measured resting energy expenditure (MREE; kcal/day) is calculated using the abbreviated Weir equation as MREE = [(3.94 VO_2 + 1.11 VCO_2) + (2.17 uN_2] × 1.44.[82–85] The urinary nitrogen component (uN_2) is often excluded when calculating energy expenditure because it accounts for less than 4% of the energy expenditure in critically ill patients and thus results in only a 1% to 2% error in calculation. Excluding the nitrogen component obviates the need for a 24-hour urine collection which can be problematic in many patients.[82,83]

MREE represents the total energy expended by the patient during the time period over which the measurements were taken. It is often extrapolated to a 24-hour period to approximate daily energy requirements. MREE reflects alterations in energy requirements as a result of disease or clinical condition, but it does not include energy required for nutritional repletion of a malnourished individual or growth in a child. The energy intake required for these functions is accounted for by multiplying MREE by a metabolic or activity factor: mechanically ventilated, critically ill, 1; critically ill, no mechanical ventilation, 1 to 1.1; adult acute noncritically ill, 1.1 to 1.4, depending on activity; adult needing repletion or a child, 1.3 to 2; adult outpatient, 1.1 to 2, depending on activity; and adult depletion (weight loss), less than 1.[85]

The data obtained from indirect calorimetry also can be used to determine the RQ, which reflects substrate oxidation, characterizes substrate use, and is calculated as VCO_2/VO_2. RQ values for nutrient substrates are fat, 0.7; carbohydrate, 1; protein, 0.8; and mixed substrate (fat, carbohydrate, and protein), 0.85. RQ values of greater than 1 represent either lipogenesis or hyperventilation; less than 0.7 may indicate a ketogenic diet, fat gluconeogenesis, or ethanol oxidation. Values outside the physiologic range of 0.67 to 1.3 should raise doubts as to the test's validity. Clinically, the RQ is used to determine if a patient is being overfed, which is likely if the RQ value is greater than 1.

There are limitations to the use of indirect calorimetry.[64,82–85] Not all institutions have metabolic carts available or personnel trained to use them. Calibration errors are common, and indirect calorimetry overestimates REE for patients with hyperventilation, metabolic acidosis, overfeeding, and air leaks anywhere in the system. Underestimation of REE is likely with hypoventilation, metabolic alkalosis, underfeeding, and gluconeogenesis. Mechanically ventilated patients are technically easier to study because the indirect calorimeter circuit can be integrated into the ventilator circuit. The patient must be at complete rest for 1 hour, must not receive bolus feedings either by feeding tube or orally for 4 hours, should have no changes in substrate delivery for 12 hours, must be on a fraction of inspired O_2 of less than 0.6, and the positive end-expiratory pressure must be less than 5 cm H_2O to ensure a steady-state reading. Unfortunately, many of the patients in whom indirect calorimetry would be most useful will not meet these requirements. Indirect calorimetry should be considered in obese patients (BMI >30 kg/m^2); patients who are metabolically stressed; patients receiving mechanical ventilation, continuous sedatives or paralytics, or dialysis; and patients with HIV infection.[79,83] In the outpatient setting, less expensive, portable devices have allowed an increase in the use of indirect calorimetry for weight management, including both weight loss and weight gain.[86]

CLINICAL CONTROVERSY

Clinicians continue to debate whether an individual's energy requirements should be expressed as total or nonprotein calories. Proponents of nonprotein calories argue that sufficient energy must be provided from nonprotein sources (dextrose and fat) to spare protein from conversion to energy to be used for wound healing and LBM maintenance. Supporters of total calories state that the nonprotein calorie approach overestimates energy needs because 15% of daily energy expenditure is derived from protein breakdown. Regardless of the method chosen, the practitioner should consistently document which method was used.

PROTEIN

Daily protein requirements are based on age, gender, nutrition status, disease state, and clinical condition. Table 149–8 lists the RDA for protein for children; for individuals older than 18 years of age, the RDA is 0.8 g/kg/day, which is significantly less than most Americans typically consume.[62] In adults older than 60 years of age, protein needs are increased to 1 to 1.5 g/kg/day to help reduce loss of LBM that occurs with aging, and 1.5 to 2 g/kg/day may be needed in states of metabolic stress, such as infection, trauma, and surgery, to prevent loss of LBM.[62,79,87] Protein requirements are also higher in pregnant and lactating women (1.1 g/kg/day or 6–10 g protein per day above the usual RDA).[62,88]

Protein metabolism depends on both kidney and liver function; thus protein requirements are altered with kidney or liver dysfunction (see Chap. 153). Critical illness (e.g., sepsis, burns, or trauma) results in a hypercatabolic state in which there is increased protein synthesis and degradation. Consequently, protein requirements are increased to 1.2 to 2 g/kg/day. For critically ill obese patients, protein needs are 2 g/kg IBW or more if the BMI is 30 to 40 kg/m^2 and 2.5 g/kg IBW or more if the BMI is greater than 40 kg/m^2.[79] In burned patients, protein requirements may be 2.5 to 3 g/kg/day or more or 20% to 25% of total calories in children.[80] Liver failure typically results in the need for protein restriction (0.5 g/kg/day) except if a hypercatabolic state is also present, in which case the requirement may be increased to 1.5 g/kg/day. Protein needs in kidney failure are variable and affected by the various kidney replacement therapies available. The application of these guidelines requires both clinical judgment and frequent monitoring of kidney and liver function, serum chemistries, clinical condition, and nutrition outcomes.

Nitrogen is found only in protein and at a relatively constant ratio of 1 g nitrogen per 6.25 g protein. This ratio may vary somewhat for enteral and parenteral feeding formulations, depending on the biologic value of the protein source. Adequacy of protein intake can be assessed clinically by a nitrogen balance study—measuring urinary nitrogen excretion and comparing it with nitrogen intake. Nitrogen balance indirectly reflects an individual's protein use or protein catabolic rate, which increases with hypercatabolism. As the stress level increases, a concomitant increase in protein catabolism results in an increase in urinary nitrogen excretion. Usually the amount of urea nitrogen is measured in a 24-hour urine urea collection. In healthy individuals, urine urea nitrogen accounts for 80% to 90% of the total urine nitrogen excreted. Nitrogen output (g/day) can be approximated as 24-hour urine urea nitrogen + 4, where 4 is a factor representing usual skin, fecal, and respiratory nitrogen losses. Alternatively, if available, total urine nitrogen can be measured and may be more accurate, especially in critically ill patients. If total urine nitrogen is used, then the best estimate of nitrogen output is total urine nitrogen × 1.05.[89] In patients with kidney failure, in which case neither urine urea nitrogen nor total urine nitrogen accurately represents net protein degradation, nitrogen balance can be approximated with equations based on urea nitrogen appearance.[90]

FAT

The daily adequate intake (AI) for men and women for α-linolenic acid is 1.6 and 1.1 g, respectively; for linoleic acid, it is 14 to 17 g/day for men and 11 to 12 g/day for women.[62] Overall, for adults, fat should represent no more than 10% to 35% of total calories, with the recommendation that saturated fatty acids, *trans* fatty acids, and dietary cholesterol intake be kept as low as possible while consuming a nutritionally adequate diet. Fat should constitute 30% to 40% of energy in children 1 to 3 years of age and 25% to 35% of energy in children 4 to 18 years of age. Fat intake in children younger than 3 years of age is critical for proper central nervous system growth and development; generally, fat-restricted diets (e.g., skim milk) should not be imposed until after the age of 2 to 3 years except under strict medical supervision. A lower limit of 15% of total energy intake has been suggested as the minimum fat intake in children, when fat restriction is warranted.[91]

FIBER

Maintenance of normal bowel habits, lower blood pressure, and lower serum cholesterol concentrations has been attributed to dietary fiber intake. Fiber intake may also have a role in the prevention of colon cancer and may promote weight control through its effect on satiety. Men and women 50 years of age and younger should ingest 38 g/day and 25 to 26 g/day, respectively, of total fiber. For men and women older than 50 years of age, the recommended intakes are 30 g/day and 21 g/day, respectively.[62,92] An adequate intake for fiber has not been set for children younger than 1 year of age. For other children, the recommended fiber intake is 19 g/day for children 1 to 3 years of age, 24 g/day for children 4 to 8 g/day, and 26 to 31 g/day for children 9 to 13 years of age.[62] Another method to determine fiber need in children is the "age + 5" rule. The recommended daily intake of fiber is calculated by adding 5 g to the child's age in years.[93] Using this rule, a 6-year-old child should ingest 11 g/day of dietary fiber.

FLUID

The daily fluid requirement for an adult depends on many factors but is generally estimated to be 30 to 35 mL/kg, 1 mL for each kcal (or per every 4.19 kJ) ingested, or 1,500 mL/m^2. Fluid requirements per kilogram of body weight are higher for children and even higher for preterm infants because of their higher percentage of TBW and basal energy needs. Additionally, premature neonates have increased fluid requirements because of greater insensible losses and the kidney's inefficiency in concentrating urine. The Holliday-Segar method is a commonly employed, quick, and simple method for estimating minimum daily fluid needs of children that also can be applied to adults. Children who weigh less than 10 kg should receive at least 100 mL/kg per day. An additional 50 mL/kg/day should be provided for each kilogram of body weight between 11 kg and 20 kg, and 20 mL/kg/day for each kilogram above 20 kg. Thus daily fluid needs for a child weighing 8 kg would be at least 800 mL/day, whereas at least 1,350 mL/day would be needed for a 17-kg child.

Table 149–11 lists factors that alter fluid needs for both adults and children. All sources of fluid intake should be assessed (e.g., fluid vehicles for intravenous medications and intravenous or feeding tube

TABLE 149-11 Factors That Alter Fluid Requirements

Increased Requirements	Decreased Requirements
Fever	Fluid overload
Radiant warmers	Cardiac failure
Diuretics	Decreased urinary output
Vomiting	Heat shields
Nasogastric suction	Relatively high humidity
Ostomy/fistula drainage	Humidified air via endotracheal tube
Diarrhea	Kidney failure
Glycosuria	Hypoalbuminemia with starvation
Phototherapy	Syndrome of inappropriate secretion of antidiuretic hormone (SIADH)
Diabetes insipidus	
Increased ambient temperatures	
Hyperventilation	
Prematurity	
Excessive sweating	
Increased metabolism (e.g., hyperthyroidism)	

TABLE 149-12 Recommended Daily Electrolytes, Trace Elements, and Vitamins Intakes[a]

	Adult (≥19 years of age)		Pediatric	
Nutrient	***Enteral***	***Parenteral***	***Enteral***	***Parenteral***
Electrolytes and minerals				
Acetate[b]	–	–	–	–
Calcium	1,000–1,200 mg	0–15 mEq (0-7.5 mmol)	0–12 months: 210–270 mg 1–3 years: 500 mg 4–8 years: 800 mg 9–18 years: 1,300 mg	Premature: 2–4 mEq/kg (1–2 mmol/kg) Other: 1–2.5 mEq/kg (0.5–1.25 mmol/kg)
Chloride[b]		–	–	2–6 mEq/kg (1–3 mmol/kg)
Magnesium	M: 400–420 mg W: 310–320 mg	10–20 mEq (5–10 mmol)	0–6 months: 30 mg 7–12 months: 75 mg 1–3 years: 80 mg 4–8 years: 130 mg 9–18 years: 240–410 mg	0.25–1 mEq/kg (0.12–0.5 mmol/kg)
Phosphorus	700 mg	20–45 mmol	0–6 months: 100 mg 7–12 months: 275 mg 1–8 years: 460–500 mg 9–18 years: 1,250 mg	Premature: 1–2 mmol/kg Others: 0.5–1 mmol/kg
Potassium[c,d]	4,700 mg	60–100 mEq (60-100 mmol) (1–2 mEq/kg [1-2 mmol/kg])	0–6 months: 400 mg 7–12 months: 700 mg 1–8 years: 3,000–3,800 mg 9–18 years: 4,500–4,700 mg	2–5 mEq/kg (2–5 mmol/kg)
Sodium[c,d]	1,200–1,500 mg	60–100 mEq (60-100 mmol) (1–2 mEq/kg [1-2 mmol/kg])	0–6 months: 120 mg 7–12 months: 370 mg 1–8 years: 1,000–1,200 mg 9–18 years: 1,500 mg	2–6 mEq/kg (2–6 mmol/kg)

(continued)

TABLE 149-12 Recommended Daily Electrolytes, Trace Elements, and Vitamins Intakes[a] (continued)

	Adult (≥19 years of age)		Pediatric	
Nutrient	***Enteral***	***Parenteral***	***Enteral***	***Parenteral***
Cobalamin (mcg) (Vitamin B_{12})	2.4	5	0–12 months: 0.4–0.5 1–8 years: 0.9–1.2 9–18 years: 1.8–2.4	1
Folic acid (mcg)	400	400	0–12 months: 65–80 1–8 years: 150–200 9–18 years: 300–400	140
Niacin (mg NE)	14–16	40	0–12 months: 2–4 1–8 years: 6–8 9–18 years: 12–16	17
Pantothenic acid (mg)	5	15	0–12 months: 1.7–1.8 1–8 years: 2–3 9–18 years: 4–5	5
Pyridoxine (mg) (Vitamin B_6)	1.3–1.7	4	0–12 months: 0.1–0.3 1–8 years: 0.5–0.6 9–18 years: 1–1.3	1
Riboflavin (mg)	1.1–1.3	3.6	0–12 months: 0.3–0.4 1–8 years: 0.5–0.6 9–18 years: 0.9–1.3	1.4
Thiamin (mg)	1.1–1.2	3	0–12 months: 0.2–0.3 1–8 years: 0.5–0.6 9–18 years: 0.9–1.2	1.2
Vitamin A (mcg RE) (Retinol)	700–900	600–1,000 (3,300–5,500 international units)	0–12 months: 400–500 1–8 years: 300–400 9–18 years: 600–900	700 (2,300 international units)
Vitamin D[i] (mcg)	≤50 years: 5 (200 IU) 51–70 years: 10 (400 international units) >70 years: 15 (600 international units)	5 (200 international units)	All ages: 5 (200 international units)	5–10 (200–400 international units)
Vitamin E (mg TE) (α-tocopherol)	15 (15 international units)	10 (10 international units)	0–12 months: 4–5 (4–5 international units) 1–8 years: 6–7 9–18 years: 11–15	7 (7 international units)
Vitamin K (mcg)	90–120	0.7–2.5 mg	0–12 months: 2–2.5 1–8 years: 30–55 9–18 years: 60–75	200

M, men; NE, niacin equivalents; RE, retinol equivalents; TE, tocopherol equivalent; W, women.

[a]Data represent either the recommended dietary allowance (RDA) or the adequate intake (AI) for each nutrient where established.

[b]Not established; as needed to maintain acid–base balance.

[c]Newborns and low-birth-weight or very-low-birth-weight infants or with concomitant disease (e.g., necrotizing enterocolitis) may have higher requirements. Intake in nonhealthy children must be individualized.

[d]No recommended dietary allowance or adequate intake has been established.

[e]An additional 20 mcg/day is recommended in patients with significant intestinal losses.

[f]May accumulate in cholestasis

[g]Long-term parenteral nutrition only if no topical preparations containing iodide or iodized table salt are used.

[h]Additional intake needed with small bowel losses which can be 12.2 mg zinc/L or 17.1 mg zinc/kg of stool or ileostomy output; an additional 2 mg/day needed for acute catabolic stress.

[i]Data suggest that intakes should be higher; currently being reviewed.

Data from references 34, 35, 37, 50, 51, and 94.

flushes) when determining fluid requirements. Monitoring of urine output and specific gravity as well as serum electrolytes and weight changes can be used to assess fluid status. A urine output of at least 1 mL/kg/hour (in children) and approximately 40 to 50 mL/hour (in adults) is considered adequate to ensure tissue perfusion. Urine output should be higher if large fluid volumes or high renal solute loads (e.g., parenteral nutrition or concentrated enteral feeding formulations) are being administered. Urine specific gravity depends on the kidney's concentrating and diluting capabilities. Concomitant diuretic therapy, as a result of increased solute excretion, limits the usefulness of urine specific gravity as an index of fluid status.

MICRONUTRIENTS

Requirements for micronutrients (e.g., electrolytes, trace elements, and vitamins) vary with age, gender, and the route by which the nutrient is ingested (Table 149–12; see Chaps. 58 to 60).[34–37,50,51,94] The variability between oral and parenteral requirements is a result of bioavailability considerations. Micronutrients poorly absorbed via the GI tract usually are required in greater doses enterally than parenterally. However, many water-soluble micronutrients are excreted more rapidly via the kidneys when administered intravenously. In these situations, the intravenous dose is greater than the oral dose. Other factors that affect micronutrient requirements include GI losses through diarrhea, vomiting, or high-output fistula; wound healing; and hyper-metabolism/catabolism. Cutaneous micronutrient losses (e.g., zinc, copper, and selenium) also may be significant after major burn injury. Sodium, potassium, magnesium, and phosphorus excretion are particularly dependent on kidney function, and in the setting of kidney failure, intake will likely need to be restricted. Calcium needs, on the other hand, may be increased in these patients. (See Chaps. 51 and 53.) Patients who are severely malnourished will have increased electrolyte requirements during early refeeding owing to preexisting deficiencies and/

or rapid intracellular uptake with anabolism. Failure to provide adequate electrolytes during refeeding has resulted in death from the refeeding syndrome.[95]

DRUG–NUTRIENT INTERACTIONS

9 Drug-induced nutrient deficiency, poor therapeutic response, enhanced drug toxicity, and failure to achieve desired nutrition outcomes can occur if either nutrition support or drug therapy is stopped as a consequence of adverse effects.[96–100] Patient outcomes may be enhanced when an effective screening method to identify significant drug–nutrient interactions is coupled with a patient-counseling program. An important part of the screening process is to recognize risk factors that influence drug–nutrient interactions. The potential for drug–nutrient interactions is greatest in pediatric and elderly individuals, those with poor nutrition status (obesity and marasmus), those receiving multiple drug therapies, and those receiving tube feedings.

Mineral and electrolyte serum concentrations may change because of drug therapy. For example, with loop diuretics, urine sodium, potassium, calcium, and magnesium wasting may occur, causing a reduction in their respective serum concentrations (see Chaps. 58 to 60). Alternatively, calcium excretion is reduced with thiazide diuretics. Serum electrolyte concentrations also may increase as a direct result of the drug's mechanism (e.g., potassium-sparing diuretics) or because of the drug's salt form. Corticosteroids and cyclosporine are known to cause hyperglycemia, whereas other drugs are prescribed to pharmacologically lower blood glucose concentrations, for example, insulin and oral hypoglycemics (see Chap. 83).

Vitamin status also may be affected by drugs (Table 149–13). For example, sulfasalazine therapy causes a decrease in folic acid, isoniazid therapy causes pyridoxine deficiency, and furosemide therapy may result in decreased thiamin concentrations. Drug therapy outcomes also may be affected by vitamin intake. The ingestion of high doses of folic acid may decrease methotrexate's therapeutic effect, whereas changes in an individual's usual vitamin K or vitamin E intake may cause variability in warfarin's anticoagulant effects.

Drug-delivery vehicles also may contain nutrients. Most intravenous therapies (maintenance intravenous fluids, drugs, and electrolyte replacements) are delivered using either dextrose (e.g., dextrose 5% or 10% in water) or sodium (e.g., 0.9% normal saline) in the admixture. Lipid emulsion (10%) is used as the vehicle for the anesthetic agent propofol and the intravenous calcium channel blocker clevidipine and will contribute fat calories when continuous infusions are used. In these instances, nutrition support regimens must be adjusted to accommodate the calories and other nutrients delivered through these therapies.

TABLE 149-13 Drug and Vitamin Interactions

Drug	Effect
Antacids	Thiamin deficiency
Antibiotics	Vitamin K deficiency
Aspirin	Folic acid and deficiency; increased vitamin C excretion
Cathartics	Increased requirements for vitamins D, C, and B_6
Cathartics	Increased requirements for vitamins D, C, and B_6
Cholestyramine	Vitamins A, D, E, and K, β-carotene malabsorption
Colestipol	Vitamins A, D, E, and K, β-carotene malabsorption
Corticosteroids	Decreased vitamins A, D, and C
Diuretics (loop)	Thiamin deficiency
Histamine$_2$ antagonists	Vitamin B_{12} deficiency
Isoniazid	Vitamin B_6 and niacin deficiency
Isotretinoin	Vitamin A increases toxicity
Mercaptopurine	Niacin deficiency
Methotrexate	Folic acid inhibits effect
Orlistat	Vitamins A, D, E, and K malabsorption
Pentamidine	Folic acid deficiency
Phenobarbital	Vitamin D malabsorption; vitamin C affects protein binding
Phenytoin	Vitamin D malabsorption; altered vitamin C binding; effect reversed by folic acid
Primidone	Folic acid deficiency
Proton pump inhibitors	Vitamin B_{12} deficiency
Sulfasalazine	Folic acid malabsorption
Trimethoprim	Folic acid depletion
Warfarin	Vitamin K inhibits effect; vitamins A, C, and E may affect prothrombin time
Zidovudine	Folic acid and B_{12} deficiencies increase myelosuppression

PRACTICAL GUIDELINES FOR NUTRITION ASSESSMENT

10 The value of any given marker used for nutrition assessment is only as great as its ability to accurately identify the patient with malnutrition and to correlate with malnutrition-associated complications. Most of the currently available markers of nutrition status were first used in epidemiologic studies to define large populations suffering from malnutrition caused by famine. The response of the various nutrition status markers to nutrition therapy and the correlation between improvement in these markers and decreased morbidity and mortality further support their validity. However, when applied to an individual, most of these markers lack specificity and sensitivity, which makes the development of a clinically useful, cost-effective approach to individual patient nutrition assessment challenging.

The importance of the nutrition-focused history and physical examination in both nutrition screening and nutrition assessment cannot be overemphasized. The least amount of objective data that can further substantiate the clinical impression and provide a baseline for subsequent monitoring are those markers that show the best correlation with outcome: weight and serum albumin concentration. The cost-effectiveness of the addition of further biochemical parameters is yet to be determined. The assessment of other anthropometric measures is most useful in the setting of anticipated long-term nutrition support in which these measurements will serve as a longitudinal marker of an individual's response to the nutrition care plan.

Initially, nutrition requirements are determined on the basis of assumptions made about the patient's clinical condition and the nutrition needs associated with repletion or growth, if needed. Once a nutrition intervention has been initiated, periodic reassessment of nutrition status is critical to determine the accuracy of the initial estimate of nutrition requirements. Also, nutrition requirements are dynamic in the setting of acute or critical illness—as the patient's clinical status changes, so will protein and energy requirements, further emphasizing the need for continued reassessment.

Better markers of nutrition status and methods for determining patient-specific nutrition requirements are needed to allow further refinement of estimates of an individual's nutrition needs. Functional tests and simple, noninvasive tests for body composition analysis hold promise for the future. However, until better methods of assessment become available clinically and are demonstrated to be cost-effective, the currently available battery of tests will continue to be the mainstay of nutrition assessment.

Information in this chapter can be used to establish empiric goals for a nutrition care plan. However, as with other forms of therapy, continuous monitoring and reassessment are required to determine if these goals are appropriate for an individual patient.

ABBREVIATIONS

ABW: actual body weight

AI: Adequate Intake

ALB: albumin

BEE: basal energy expenditure

BIA: bioelectrical impedance analysis

BMI: body mass index

DCH: delayed cutaneous hypersensitivity

DRI: Dietary Reference Intake

DXA: dual-energy x-ray absorptiometry

EAR: Estimated Average Requirement

GI: gastrointestinal

HIV: human immunodeficiency virus

IBW: ideal body weight

LBM: lean body mass

MREE: measured resting energy expenditure

NCHS: National Center for Health Statistics

RDA: Recommended Dietary Allowance

REE: resting energy expenditure

RQ: respiratory quotient

TBW: total body water

TFN: transferrin

UBW: usual body weight

UL: Tolerable Upper Intake Level

VCO_2: carbon dioxide production

VO_2: oxygen consumption

CHAPTER 150

Medication Administration Considerations with Specialized Nutrition Support

ROLAND N. DICKERSON AND GORDON S. SACKS

KEY CONCEPTS

1. Enteral feeding access site and tube characteristics influence which drug administration and enteral feeding techniques will be used to optimize pharmacotherapy.
2. The drug formulation often guides the medication administration protocol for patients receiving enteral nutrition (EN).
3. Potential physical incompatibilities of liquid, elixir, and suspension medication formulations with enteral feeding necessitate the use of alternative dosage forms, changes in the route of administration, changes in the medication administration protocol, or selection of a different medication.
4. Many medication formulations, particularly delayed-release and enteric-coated products, should not be crushed.
5. Gastrointestinal (GI) intolerance to liquid and suspended medication forms are usually related to either the hypertonicity or the sorbitol content of the drug product.
6. It is important that the clinician closely evaluate every enterally administered medication for efficacy as well as toxicity for those patients receiving EN, given the particular characteristics of drug absorption, the location of the feeding tube within the GI tract, and the potential adsorption to the feeding.
7. A critical part of evaluating parenteral nutrition (PN) medication admixtures is understanding the difference between stability and compatibility.
8. It is important to determine if the PN is either a two-in-one or three-in-one admixture when considering adding a medication, as the presence of an intravenous (IV) lipid emulsion can markedly change the stability characteristics of the PN.
9. IV Y-site administration of calcium, potassium phosphate, sodium phosphate, and magnesium with PN admixtures must be avoided.

The use of parenteral and enteral nutrition requires a high level of clinical expertise and careful attention to ensure that patient outcomes are optimized and that untoward events are minimized. This chapter provides a foundational framework for the identification and management of drug–nutrient interactions associated with enteral nutrition (EN) and parenteral nutrition (PN). Issues related to EN include feeding tube access site factors, medication administration techniques, dosage form–associated physical incompatibilities, and prevention of enteral tube occlusions. The key factors associated with PN formulation and drug interactions include physiochemical issues affecting compatibility and stability, adverse events associated with trace element contamination, treatments for vascular access device occlusions, and IV lipid emulsion (IVLE)–associated risks and adverse events.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

MEDICATION ADMINISTRATION CONSIDERATIONS WITH ENTERAL NUTRITION

It is usually preferable for patients who require EN that medications also be given via their feeding tube when possible. When administering medications via a feeding tube, only syringes manufactured and intended for oral or enteral use should be used to measure and administer medications. In addition, the tips of the oral syringes should be too wide to fit IV Luer ports in an effort to prevent inadvertent IV delivery of oral medications. The administration of oral medications for patients receiving continuous enteral tube feeding is problematic, as mixing enteral feeding with medications may lead to reduced drug bioavailability, tube clogging, or adverse GI effects, such as cramping and diarrhea. Parenteral administration of medications obviates the potentiality of any physical interaction with the enteral regimen; however, IV medications are usually more expensive and may be associated with venous access problems, such as infection. Alternative routes, such as buccal, sublingual, and transdermal, are available for only a limited number of medications and may not be practical for critically ill patients. Therefore, enteral administration of drugs is preferred.

ENTERAL FEEDING TUBE ACCESS SITE, TUBE CHARACTERISTICS, AND METHODS OF MEDICATION ADMINISTRATION

1 The characteristics of the feeding tube may dictate the selection of the appropriate medication administration technique for the patient. Medications should not be administered via a needle catheter jejunostomy due to the small internal diameter and the high risk for tube clogging. Conversely, larger bore feeding tubes (e.g., 20 and 28 Fr), such as a gastrostomy or nasogastric tube, can be easily used for medication administration with minimal risk for tube clogging.

2 Although some medications are available in ready-to-administer liquid forms, suspensions, or elixirs, the majority are not. It is necessary to consider the type of available dosage form (e.g., tablets,

TABLE 150-1 Medication Administration Guidelines for Patients Receiving Enteral Nutrition[1–5]

1. Oral administration is preferred.
2. Medications should not be added directly to the feeding formulation.
3. Immediate-release tablets should be crushed to a fine powder, or capsules should be opened and mixed with water to form a slurry.
4. Soft gelatin immediate-release capsules can be dissolved in 15 to 30 mL of warm water.
5. Flush the feeding tube with at least 15 mL of water before and after medication administration.
6. When multiple medications are to be administered at the same time, they should be given separately, with water flushes done between each medication.
7. A liquid/suspension/elixir should be diluted when administered directly into the small bowel if the medication is substantially hypertonic.
8. Sustained-release products should be replaced with a therapeutically equivalent lower dose and increased frequency of administration.
9. Alternative pharmacotherapy or a different dosage form should be considered for enteric-coated tablets.
10. When providing medications in which the absorption of the medication is significantly impaired in the presence of continuous enteral feeding, the feeding should be held for at least 1 to 2 hours before and after the dose.

capsules, suspensions, or liquids) when determining an appropriate method for medication delivery. When suitable formulations are not available, tablets may need to be crushed or pulverized to a fine powder, then mixed with water to make a slurry mixture, or powder-containing capsules must be opened and the contents administered in the same manner as with crushed tablets. Gelatinous liquid capsules may be cut in half or dissolved in warm water, then administered as a solution. Care should be taken not to administer the undissolved gelatin remnants, as they may clog the feeding tube. Suspensions tend to have a higher viscosity than solutions; some are granular and contain modified-release particles. The resistance to flow through the enteral feeding tube is greater for suspensions than liquids and may be reduced by dilution of the suspension. It is recommended that the feeding tube be irrigated with 15 to 30 mL of water before and after each medication is administered. General recommendations for administration of medications via an enteral feeding tube are given in Table 150–1.[1–5]

CONSIDERATION OF THE LOCATION OF THE TIP OF THE FEEDING TUBE FOR DRUG DELIVERY

Although the absorption of some drugs occurs throughout the GI tract, the location of the distal tip of the feeding tube may alter the bioavailability of drugs. Administration of a drug into the jejunum whose primary site of absorption is in the duodenum/early jejunum can result in a significant reduction in bioavailability (e.g., 27% to 67% decrease for ciprofloxacin[6]). Drugs that require an acidic environment for maximum absorption (e.g., ketoconazole[7] and itraconazole[8]) can have a reduced absorption when administered directly into the small bowel, bypassing the stomach. Some drugs, such as digoxin, undergo considerable metabolism within the GI tract.[9] Because postpyloric administration would avoid acid hydrolysis of digoxin, increased drug concentrations delivered to the small bowel result in improved absorption and likely explain why an increased dosage is not necessary for patients with short bowel syndrome, unlike other drugs, such as warfarin.[9–11] Finally, it would be inappropriate to administer a drug via the small bowel whose intended action is through direct administration into the stomach (e.g., antacids and sucralfate).

MEDICATION BINDING TO THE FEEDING TUBE

Some medications, such as phenytoin[12] and carbamazepine,[13] have been shown to adsorb to enteral feeding tubes in vitro, with a loss ranging from ~10% to 25% of the drug dose. Because the degree of adsorption is not linear, less drug loss would occur with higher doses. The potential effect of drug adsorption to the tubing is easily attenuated by the dilution of the liquid medication (with an equal part of water) and with adequate flushing of the tube after drug administration.[12,13]

PHYSICAL INCOMPATIBILITY OF LIQUID, ELIXIR, AND SUSPENSION MEDICATION FORMULATIONS WITH ENTERAL FEEDING

3 Many liquid medications are physically incompatible with EN formulas, and their coadministration may lead to tube clogging.[1–5] The clogging of the enteral feeding tube is due in part to the viscosity of the medication carrier solution itself or the acidic pH of the syrup, which may result in the formation of viscous flocculent precipitates, gelatinous adhesive material, or particulate granulation. Elixirs, which contain varying amounts of alcohol, have been reported to cause tube clogging when coadministered with enteral feedings. The higher the alcohol content, the more likely the elixir is to cause precipitation of inorganic salts present in the EN product.[14] Common liquid forms of medications known to be incompatible with enteral feeding are brompheniramine elixir, calcium glubionate syrup, cimetidine oral solution, ferrous sulfate elixir, potassium chloride liquid and syrup, and pseudoephedrine syrup.[1–3] Ferrous sulfate elixir is the most frequent EN-incompatible medication encountered in clinical practice.[2] Because of the potential incompatibilities, enteral feedings and liquid medications, regardless of their formulation, should not be mixed together.[14]

CONSIDERATIONS FOR SUSTAINED-RELEASE, PH-ACTIVATED, AND ENTERIC-COATED PRODUCTS

4 Most medications are initially marketed as immediate-release tablets; however, the number of medications that are formulated to enhance drug delivery or to improve patient compliance has increased in recent years. Some medications can be immediately identified by their suffix as pharmaceutically modified products. It is important to ascertain whether the medication is formulated as a sustained- or delayed-release, pH-activated, or enteric-coated product, as crushing destroys the properties of the medication. For sustained- and extended-release products, this can result in higher peak serum concentrations and potentially clinical toxicity as the result of the rapid release of a much larger dose. Thus, one should avoid the use of this type of formulation whenever possible in the EN patient. Switching from an extended-release product to an immediate-release (preferably liquid or suspension) formula requires that the clinician appropriately lower the dose and increase the frequency of dosing. Disregard for this pharmacotherapeutic intervention has resulted in significant adverse effects and even death.[15–17]

Enteric- and film-coated medications when crushed and administered into the stomach often yield decreased clinical effectiveness because of acid degradation. This approach has also been known to result in increased gastric mucosa irritation for some medications. Enteric- and film-coated medications in general do not crush well and tend to aggregate in clumps when wet, which increases the risk of tube clogging.[5] Results from a national survey indicated that drug-related feeding tube obstruction occurred in 11% and 16% of

patients when enteric-coated or modified-release drug products, respectively, were routinely crushed.[18]

Some modified-release, microencapsulated drug products can be safely administered via large-bore feeding tubes (e.g., percutaneous endoscopic gastrostomy and nasogastric tubes). The pellets or "beads" in these formulations can be poured down the feeding tube provided that they are not crushed. Medications that have been given in this manner include diltiazem, ferrous gluconate, nizatidine, pancreatic enzymes, theophylline, and verapamil.[1] Antineoplastic drugs such as methotrexate and capecitabine should not be crushed because exposure to the dispersed aerosolized particles may be harmful to the healthcare professional.[1,19] Many medication formulations should not be crushed, and an up-to-date listing can be obtained from the Institute of Safe Medication Practices at *http://www.ismp.org/tools/donotcrush.pdf*.

PROBLEMS WITH THE USE OF LIQUID AND SUSPENDED MEDICATIONS

5 GI intolerance to liquid and suspended medication forms is usually related to either the hypertonicity or the sorbitol content of the drug product. The osmolality of GI tract secretions ranges from 280 to 360 mOsm/kg (280 to 360 mmol/kg).[2] One of the major functions of the colon is to reabsorb excess water prior to passage of the excrement from the body. When this process is impaired, diarrhea occurs. Osmotic diarrhea is the result of excessive unabsorbed substances in the GI that results in retention of water. An analytical method that may help ascertain whether diarrhea is being induced by the administration of osmotically active nonabsorbable substances from the medication is to measure and calculate the stool osmotic gap. This technique involves obtaining a liquid stool sample for sodium (Na) concentration, potassium (K) concentration, and osmolality. The stool osmotic gap is then calculated using the following formula:

$$\text{Osmotic gap (mOsm/kg or mmol/kg)} = \text{Stool osmolality (mOsm/kg or mmol/kg)} - 2 \times (\text{stool Na [mEq/L or mmol/L]} + \text{stool K [mEq/L or mmol/l]})$$

For patients with secretory diarrhea (intestinal secretion of fluid and electrolytes), the osmotic gap should be <50 mOsm/kg (50 mmol/kg), and measured stool osmolality should be roughly equivalent to serum osmolality. A larger gap (>100 mOsm/kg [>100 mmol/kg]) often indicates the presence of an unabsorbed osmotic substance in the stool.[20]

Administration of a hypertonic medication may cause GI intolerance depending on the drug solution itself, the method of administration, and/or the location of the enteral feeding tube.[21] If a hypertonic medication solution is enterally given to a patient, an influx of water is secreted into the GI lumen. Administration of these hypertonic medications are better tolerated when administered intragastrically, as one of the functions of the stomach is to act as a reservoir and dilute hypertonic substances with gastric secretions as it prepares nutrients to be transferred to the small bowel.[1–3] However, very rapid administration of a hyperosmolar solution into the stomach can lead to dumping of large volumes of hyperosmolar solutions into the small intestine, with resultant diarrhea. Additionally, gastric emptying may be slowed by hypertonic solutions because of the regulatory effects of osmoreceptors in the duodenum. This delayed gastric emptying may lead to bloating and nausea. Osmotic diarrhea can be more readily induced by administration of hyperosmolar medications, without dilution, directly into the small bowel, as the physiologic diluting function and the volume reservoir to accommodate additional luminal secretions of the stomach are averted.

When assessing whether the osmolality of a drug solution or suspension may be problematic, it is necessary that the volume of the drug solution and the total osmotic load of the medication be considered. For example, potassium chloride liquid (10%), with an osmolality of ~3,500 mOsm/kg (3,500 mmol/kg), often requires a volume (e.g., 30 mL) for the desired dose (e.g., 40 mEq [40 mmol]), which may cause adverse effects, particularly when given directly into the small bowel. Osmotic loads from common liquid medications are given in Table 150–2.

CLINICAL CONTROVERSY

Hypertonic medication solutions can also be diluted with water prior to administration; however, this practice is limited by the amount of volume that can be practically delivered, as large volumes can also cause GI intolerance. Large water bolus volumes (e.g., >300 mL) administered directly into the small bowel in an effort to reduce osmotic load is not recommended, as this technique has been associated with bowel necrosis[22] and is thus considered to be contraindicated for some patients.

TABLE 150-2 Maximum Reported Osmolalities of Common Drug Solutions and Suspensions[2]

Medication	Osmolality (mOsm/kg or mmol/kg)	Dosage Volume (mL)	Osmotic Load (mOsm or mmol)
Acetominophen elixir, 65 mg/mL solution, 60 mg/mL	5,400	10–15	54–81
Cimetidine	5,550	5	58
Digoxin elixir, 50 mcg/mL	4,420	5	28
Docusate sodium syrup, 3.3 mg/mL	4,700	30	147
Furosemide solution, 10 mg/mL	3,938	4–8	16–32
Haloperidol concentrate, 2 mg/mL	500	5	3
Hydroxyzine syrup, 2 mg/mL	4,450	25	111
Metoclopramide HCl syrup, 1 mg/mL	8,350	10–20	84–167
Multivitamin liquid	5,700	5	29
Phenobarbital elixir, 4 mg/mL	11,630	15	174
Potassium chloride liquid, 10%	3,500	30	105
Potassium iodide saturated solution, 1 g/mL	10,950	0.05–0.25	1–3
Promethazine HCl syrup, 1.25 mg/mL	3,500	20–40	70–140
Sodium citrate liquid, 0.5 g/mL	2,050	10–30	20–60
Theophylline solution, 5.33 mg/mL	4,980	30	147
Trimethoprim/sulfamethoxazole 40/200 per 5 mL	4,560	20	91

Some liquid and elixir medication formulations contain sorbitol as a sweetening or solubilizing agent. Sorbitol is an inert sweetening agent that can induce osmotic diarrhea.[23] The usual minimal laxative dosage for sorbitol is ~20 g; however, some patients may be sensitive to smaller doses, such as 10 g. The most common culprits of high sorbitol-containing liquid medication formulations are acetaminophen, ibuprofen, potassium gluconate, pseudoephedrine, and theophylline.[24,25] Unfortunately, some manufacturers do not list the sorbitol content of their preparations, whereas others change the sorbitol content without notification. It is recommended that the manufacturer be contacted for the sorbitol content for any medication solution in question if the patient is experiencing unexplained diarrhea or if the medication cannot be stopped or changed to an alternative dosage form. For enterally fed patients with diarrhea, consider an alternative dosage form, or substitute a therapeutically equivalent drug. For example, if frequent acetaminophen administration is required, tablets can be crushed to a fine powder and mixed with water to form a slurry mixture.

Lesser known nonabsorbable osmotically active ingredients in some drug solutions that can also induce osmotic diarrhea are polyethylene glycol and propylene glycol.[26] Lorazepam liquid (2 mg/mL) contains 60 g of polyethylene glycol per 100 mL of solution and has been reported to induce diarrhea in an adult patient receiving 240 mg/day of lorazepam (72 g/day of polyethylene glycol). The diarrhea resolved when the dosage form was changed from liquid to crushed tablets.[26]

RELEVANT DRUG–LIQUID ENTERAL NUTRITION INTERACTIONS

Changes in bioavailability of certain medications can result in an impaired or failed therapeutic response, as the drug may not be adequately absorbed into the systemic circulation. Some clinicians have advocated holding the EN for 1 or 2 hours prior to and after each dose of a medication whose absorption is impaired when taken with food. Because the majority of hospitalized patients receive continuous enteral feeding, the feeding rate will need to be increased to account for the time period when feeding is not being given. For a patient receiving drug therapy twice or three times daily, this could result in a significant increase in feeding rate for which the patient may not be able to tolerate the feeding due to adverse GI symptoms, such as abdominal distention, diarrhea, and emesis. In addition, because many critically ill patients are given insulin therapy for effective glycemic control, withholding the feedings for 2 to 4 hours could place the patient at significant risk of hypoglycemia. Therefore, it is extremely important that the clinical relevancy of the drug–nutrient interaction be rigorously scrutinized before withholding the feeding and that the pharmacotherapy be closely monitored to ensure the appropriate therapeutic response. Data regarding many potential drug–liquid EN interactions are limited and often require further study. For drugs with no such data, it is recommended that the package insert for the medication be consulted regarding its administration with food and that its recommendation be applied to the patient receiving continuous EN when possible.

6 It is important that the clinician closely evaluate every enterally administered drug therapy for efficacy as well as toxicity for those patients receiving EN.

Amiodarone

Although the manufacturer's data indicate improved absorption when taken with meals,[4] it has been reported that a nearly threefold increase in amiodarone dosage was required to achieve therapeutic drug concentrations for 8 patients receiving the medication nasoduodenally compared with 85 patients given the medication by the oral route.[27] Unfortunately, details regarding the nutritional regimen and the method of medication administration relative to the enteral feeding were not noted in this study. It is unclear whether this interaction was partially due to the loss of the drug in the dosage process (tablet crushing, etc.), adherence to the enteral feeding formula, or the medication's delivery directly into the duodenum/jejunum. It is advised that amiodarone be given consistently with regard to timing of the enteral feeding and that the patient be monitored closely.

Atovaquone

The bioavailability of a single dose of atovaquone oral suspension is more than doubled when administered with meals compared with fasting.[28] Bioavailability of atovaquone is equivocal with an oral liquid supplement containing 28 g of fat compared with a meal containing 21 g of fat.[28] Atovaquone may be given to patients receiving concurrent EN.

Azole Antifungal Agents: Fluconazole

Three studies[29–31] compared the pharmacokinetics of IV administration to enterally administered fluconazole during continuous enteral feeding for critically ill intensive care units (ICU) patients with invasive mycoses. Doses ranged from 100 mg[29] to 400 mg[31] between studies. The mean bioavailability for the enteral fluconazole for each study was determined to be 80%,[29] 97%,[30] and 100%.[31] Fluconazole may be given intragastrically or via a duodenostomy to patients receiving concurrent EN.

Itraconazole

Itraconazole has been plagued by erratic bioavailability, which has been improved with the development of an oral solution that is given in the fasted state.[32] Steady-state nadir plasma concentrations of IV itraconazole were compared with equidosage enteral itraconazole solution in critically ill, tube-fed patients.[8] The oral solution was administered via the feeding tube with a minimum interval of 2 hours from the enteral feeding or oral food intake. Despite holding the enteral tube feeding, plasma concentrations of itraconazole observed during enteral administration were about two-thirds of plasma concentrations achieved after IV administration. Doubling the enteral dosage to 200 mg twice daily achieved similar plasma concentrations to 100 mg of IV itraconazole; however, increased GI adverse effects (diarrhea) occurred.[8] Itraconazole should not be administered with concurrent EN.

Posaconazole

Concomitant administration of the liquid nutritional supplement with posaconazole resulted in a marked increase in bioavailability compared with the fasted state in healthy volunteers.[33,34] Posaconazole bioavailability increased linearly with coadministration of increasing amounts of liquid supplementation from 35% with fasting, to 60% with 60 mL, to 77% with 120 mL when compared with the area under the curve plasma concentrations achieved with concurrent ingestion of 240 mL of liquid supplement.[33] Posaconazole may be given to patients receiving concurrent EN.

Voriconazole

One small case series in critically ill patients examined peak and nadir plasma concentrations of voriconazole after 3 days of nasogastric administration with concurrent EN.[35] The voriconazole tablets were crushed and suspended in water for medication delivery, and the enteral feeding was interrupted only for the dosage administration and resumed immediately afterward. The investigators concluded that administration of the voriconazole by nasogastric tube was associated with adequate plasma concentra-

tions for seven of the eight studied patients. No clear explanation could be provided for the single patient without acceptable plasma concentrations, and the study's authors questioned whether this variability could be due to polymorphic expression of CYP2C19, the major isozyme implicated in the metabolism of voriconazole.[35] Voriconazole may be given to patients receiving concurrent EN; patients should be monitored closely.

Carbamazepine

It has been shown that carbamazepine can significantly adsorb to the enteral feeding tube.[13] This interaction was easily alleviated by dilution of the suspension with an equal part of water followed by a water flush after medication administration.[13] In a randomized, crossover design in normal volunteers, continuous nasogastric enteral feeding has been shown to reduce carbamazepine absorption only by ~10%.[36] Carbamazepine may be given to patients receiving concurrent EN; patients should be monitored closely.

Digoxin

Although the detrimental effect of a high-fiber diet on digoxin absorption is well established,[37] it is unknown to what extent fiber-containing enteral formulas affect digoxin absorption. It is advised that the medication be given consistently with regard to timing of the enteral feeding and the patient be monitored closely.

Fluoroquinolone Antibiotics

The concentration of fluoroquinolones (ciprofloxacin, levofloxacin, and oflaxacin) is markedly reduced when they are admixed with enteral feedings in vitro.[38] This loss was originally thought to be due to chelation of the antibiotic with cationic minerals,[39] but other evidence indicates that chelation by cations cannot fully explain the magnitude of this drug–nutrient interaction.[14,38] It is possible that protein content of the liquid formulation may also have a significant effect on fluoroquinolone availability[14] analogous to the warfarin–enteral feeding interaction.[40]

CLINICAL CONTROVERSY

The appropriate timing and dosage for changing from IV to enterally administered ciprofloxacin for a patient receiving continuous gastric feeding is controversial. Factors to consider are the severity and location of the infection, sensitivity of the infecting organism, and whether withholding of the feeding before and after medication administration is a viable, safe option.

Ciprofloxacin

Ciprofloxacin is the most widely studied fluoroquinolone for an enteral feeding interaction, and its absorption is detrimentally influenced, more than the other fluoroquinolones, by the presence of enteral feeding. Studies in hospitalized and critically ill patients indicate an overall 33% to 73% bioavailability of ciprofloxacin when coadministered with continuous enteral feeding compared with IV ciprofloxacin.[6,41,42] The bioavailability of ciprofloxacin is also improved by ~28% when administered intragastrically versus intrajejunostomy during continuous enteral feeding.[6] Despite decreased GI absorption of ciprofloxacin in critically ill, enterally fed patients, use of a higher dose (750 mg every 12 hours) given via a nasogastric tube resulted in plasma concentrations similar to IV administration of 400 mg every 12 hours and were well above the minimum inhibitory concentration values for many pathogenic bacteria.[43] Ciprofloxacin may be given to patients receiving concurrent EN, with close clinical monitoring and dosage adjustment.

Levofloxacin

In vitro data demonstrate that levofloxacin binds to liquid nutrition formulas less than ciprofloxacin but more than moxifloxacin.[38] Unfortunately, in vivo data regarding coadministration with enteral feeding is lacking. Levofloxacin may be given to patients receiving concurrent EN, with close clinical monitoring and dosage adjustment.

Moxifloxacin

Because of its good absorption characteristics, moxifloxacin has the best bioavailability of the fluoroquinolones when coadministered with enteral feedings. In a crossover design, healthy volunteers were given equal doses of moxifloxacin as an intact tablet, a crushed tablet as a suspension through a nasogastric tube with 200 mL of water, or a crushed tablet as a suspension through a nasogastric tube with a polymeric enteral feeding solution at 100 mL/hour starting 30 minutes before moxifloxacin administration and continued for another 2 hours after drug administration.[44] The relative bioavailability for the latter two regimens compared with intact tablet control was 91%. These preliminary data indicate that moxifloxacin may be administered to patients receiving concurrent EN.

Ofloxacin

In healthy volunteers, the coadministration of a liquid enteral supplement reduced the relative bioavailability of ofloxacin to only 90% (in contrast to ciprofloxacin, at 72%).[45] These preliminary data indicate that ofloxacin may be given to patients receiving concurrent EN.

Histamine$_2$ Receptor Antagonists

In vitro evaluation of ranitidine and cimetidine binding to enteral feeding demonstrates >90% recovery when admixed with an array of EN formulations; however, in vivo bioavailability studies are lacking.[46,47] These medications likely can be given to patients receiving concurrent EN.

Levetiracetam

In a crossover study of 10 healthy subjects, the absorption of a single dose of levetiracetam was not significantly altered when administered as an intact tablet, crushed powder mixed in applesauce, or crushed powder mixed with 120 mL of liquid EN.[48] Levetiracetam may be given to patients receiving concurrent EN.

Levothyroxine

Bioavailability studies indicate that levothyroxine is better absorbed when ingested in the fasting state (~79% vs 64%, respectively). Additionally, coadministration of levothyroxine with calcium carbonate,[49] magnesium-containing antacids,[50] iron preparations,[51] soy protein,[52] and fiber supplements[53] resulted in significantly decreased absorption of levothyroxine. Some clinicians have suggested that enteral feedings should be held 1 to 2 hours prior to and after levothyroxine administration despite the lack of data on continuous enteral feedings. A recent study examined 15 patients who received levothyroxine therapy during continuous EN.[54] All patients were euthyrotic prior to the initiation of concurrent levothyroxine–enteral feeding. About half of the patients developed a significant increase in serum thyrotopin concentration reflective of subclinical or clinical hypothyroidism. In a small subpopulation, holding the

feedings for 1 hour before and after levothyroxine administration was inadequate for restoring euthyroidism. A modest increase in levothyroxine dosage by 25 mcg/day appeared effective in restoring euthyroidism for those who developed hypothyroidism during continuous enteral feeding. When levothyroxine is administered to patients receiving concurrent EN, routine periodic monitoring of thyroid function tests and a dosage adjustment may be necessary.

Linezolid

In a single-dose, crossover study, 11 elderly hospitalized patients receiving enteral feeding were given equal doses of IV or intragastric linezolid.[55] The intragastrically administered linezolid was given as a suspension. A separate control group of six patients who did not receive continuous liquid enteral feeding were also given IV or an oral suspension of linezolid. The absolute bioavailability (85% to 90% of the IV dose) of linezolid was unaltered by the presence of enteral feeding. Linezolid may be given to patients receiving concurrent EN.

Phenytoin

One of the most well documented drug–enteral feeding interactions is with the antiepileptic drug phenytoin. Since the first report of this interaction in 1982, more than 30 studies, case series, case reports, and reviews have been published.[14,56] Despite this abundance of literature, controversy exists whether dramatic decreases in bioavailability occur when given to individuals receiving continuous EN. Part of the controversy stems from four prospective, randomized, controlled trials in normal volunteers that refute the existence of this interaction.[56] However, there are numerous case series and reports that demonstrate dramatic decreases in serum phenytoin concentrations requiring a dosage adjustment when the medication is coadministered with continuous intragastric enteral feeding with different types of formulas.[14,56] The exact mechanism underlying this interaction is still unknown; however, some in vitro studies demonstrate significant complexation of phenytoin to various liquid enteral formulations.[56] Significant improvement in serum phenytoin concentrations has been observed for patients when the intragastric feeding was held for either 1 or 2 hours before and after phenytoin suspension administration compared with continuous administration. A common clinical practice, in addition to withholding the EN before and after phenytoin administration, is to modify the phenytoin dosing interval to twice daily to minimize the time of interrupted feeding.[2,57] Another strategy is to open the contents of an extended-release capsule, mix with water to make a slurry, and administer via the feeding tube. This method involves giving the total daily dose once daily and holding the feedings for 2 hours before and after phenytoin administration.[57] Unfortunately, the latter method has not been studied and cannot be recommended until confirmatory research confirms its effectiveness. Close monitoring of serum phenytoin concentrations during concurrent phenytoin and enteral feeding is warranted. If a dose escalation is required during EN, a reduction in dosage may be necessary when the feeding is discontinued or if the mode of feeding (continuous vs. bolus) is changed.

Proton-Pump Inhibitors

Omeprazole, esomeprazole, lansoprazole, pantoprazole, and rabeprazole are all acid-labile medications, so they are especially formulated to maintain their integrity until delivery to the alkaline pH of the duodenum, where absorption occurs. The medication forms designated for oral use are manufactured as delayed-release enteric-coated tablets, delayed-release capsules containing enteric-coated granules, or powdered packets for reconstitution. Previously, it was necessary to open the capsules and mix the granules/beads into a solution, then administer via the enteral feeding tube. Depending on the location of the tip of the feeding tube, either an acidic solution for administering the medication into the stomach or an alkalemic solution when the drug was administered into the small bowel was used as the liquid vehicle of choice. However, recent studies have demonstrated the efficacy of using an alkalemic solution when the drug was administered into either the stomach or the small bowel, simplifying the process.[58,59] Some commercially available proton-pump inhibitors (e.g., esomeprazole, lansoprazole, and omeprazole) can be reconstituted with water from a powder packet to make a suspension and administered via an intragastric feeding tube. Pantoprazole is less desirable for administration via a feeding tube. The manufacturer recommends that pantoprazole powder be diluted with apple juice (not water) for administration via an intragastric feeding tube. However, acidic fluids, such as apple juice, can denature proteins, cause enteral formula clumping, and potentially clog the small-bore feeding tube. Care should be taken to flush the enteral feeding tube well when esomeprazole and omeprazole suspensions reconstituted from powders are used, as they contain xanthan gum. This inert ingredient causes the suspension to expand, increasing the suspension's viscosity and thus the potential for clogging the small-bore enteral feeding tube.[60] Immediate-release omeprazole/sodium bicarbonate powder for oral suspension can be given either intragastrically or intraduodenally because it is immediately activated by its mixture with bicarbonate in the suspension.

Sevelamer

The manufacturer recommends against administering sevelamer via a feeding tube because of its viscosity and risk of tube clogging. Sevelamer should be used cautiously in tube-fed patients. The capsule contents must be dissolved and diluted with water and the feeding tube flushed extremely well before and after administration to prevent tube clogging.

Sucralfate

It has been noted that sucralfate complexes with protein sources in the enteral formulation may lead to tube clogging[4] and should not be administered via a small-bore feeding tube. Rare reports of esophageal bezoar formation have also occurred due to the prosthetic device (nasogastric suction tube), allowing regurgitation of gastric contents, particularly in those with esophageal reflux or gastric motility disorders.[61] For high-risk patients, use of sucralfate administration via a large-bore feeding tube warrants vigilant adherence to prevent reflux and gastric pooling.

Tacrolimus

A crossover evaluation of tacrolimus absorption was performed in 10 transplant patients receiving continuous nasoduodenal feeding.[62] One treatment arm consisted of coadministration of tacrolimus with the enteral feeding; in the other treatment arm, the feeding was held for 1 hour prior to and 8 hours after drug administration. No significant differences were noted in pharmacokinetic parameters between administration techniques. Tacrolimus may be given to patients receiving concurrent EN.

CLINICAL CONTROVERSY

Some clinicians still consider warfarin resistance to be attributed to vitamin K content of the liquid enteral formulation. However, more recent data indicate that binding of the warfarin to the enteral feeding during continuous feeding may be a more significant contributor to warfarin resistance.

Warfarin

Warfarin resistance associated with continuous enteral tube feedings was first reported in the early 1980s. This resistance was attributable to the large amounts of vitamin K in the feedings at that time.[63] The nutritional industries subsequently responded to this adverse effect by significantly reducing the vitamin K content of liquid EN formulations. Most current liquid formulations now contain <80 mcg/L of vitamin K. A vitamin K intake of 150 mcg/day significantly decreases International Normalized Ratio (INR) by 0.4 during acenocoumarol anticoagulation.[64] With conservative caloric intakes to avoid overfeeding, it was uncommon for patients to receive more than 160 mcg of vitamin K daily from the liquid enteral formula, yet warfarin resistance was still being encountered in clinical practice. Warfarin, a highly protein-bound drug, has been shown to bind to EN formula in vitro, with 35% to 50% of the warfarin dose being bound to the EN formula.[63] Clinical evidence for this warfarin–enteral feeding binding phenomenon stems from a crossover study of six adult patients who required combined enteral tube feeding and warfarin therapy for at least 10 days.[40] Each patient had at least 3 consecutive days during which the feedings were withheld for 1 hour before and after warfarin administration and at least 3 days when the feedings were not withheld. A significant difference in INR response over each 3-day observation period was noted: a mean rise in INR by 0.74 when feedings were held versus a mean fall in INR by 0.13 when the feedings were given concurrently with the warfarin therapy. These divergent changes in INR occurred despite similar mean warfarin doses (5.6 vs. 5.7 mg/day) and clinically irrelevant differences in mean vitamin K intake (77 vs. 102 mcg/day).[40] It is recommended that enteral feedings be withheld for 1 hour before and after warfarin administration. Close monitoring of the INR is essential.

MEDICATION CONSIDERATIONS WITH PARENTERAL NUTRITION

PN formulations are complex admixtures containing as many as 40 base components (e.g., amino acids, dextrose, and lipid emulsions) and additives (e.g., water, lipids, electrolytes, vitamins, trace elements, and insulin). Two types of PN are used in clinical practice: two-in-one and three-in-one formulations. A two-in-one formulation is a combination of dextrose and amino acids without IVLE. It has a yellow appearance due to the presence of the multivitamins. A three-in-one formulation (also referred to as total nutrient admixture [TNA]) includes the IVLE in the same container with dextrose and amino acids, so it has a milky white appearance.

STABILITY AND COMPATIBILITY

7 A critical part in evaluating PN–medication admixtures is understanding the difference between stability and compatibility. Although often used interchangeably, a distinction exists between these two terms in reference to parenteral admixtures. The inability of PN additives, including medications, to maintain their chemical integrity and pharmacologic activity would suggest instability. Compatibility issues with PN formulations generally involve the formation of precipitates. These precipitates may be solid, such as crystalline matter, or liquid, such as phase separation of oil and water in a TNA. The distinction between stability and compatibility with IVLE can be difficult to discern, as all emulsions are inherently unstable systems that will return to their oils and water components over time, yet there are clearly compatibility issues that result in phase separation of the IVLE components. As a result, compatibility of medications in PN admixtures is often determined by the presence or absence of IVLE.

PARENTERAL NUTRITION AS A DRUG DELIVERY VEHICLE

Adding medications to PN admixtures has been reviewed in the literature.[65–67] The rationale for adding medications to the PN solution may be necessary (e.g., to restrict fluid intake), or due to a limitation of available access for medication administration, or for ease of medication administration, particularly for the home PN patient. Because of the potential for numerous physiochemical drug–PN component interactions, this method of drug delivery is usually not the preferred route.

8 The presence of IVLE in a three-in-one admixture can markedly change the stability characteristics of the PN. Stability of IVLE is maintained by the addition of an emulsifying agent, egg yolk phosphatide. The emulsifier is anionic and renders a negative charge to the surface, which creates repulsive forces between individual lipid droplets. Certain medications or high concentrations of divalent or trivalent cations, such as magnesium, calcium, and iron, can neutralize the negative surface charge and promote attraction among the lipid particles. Ultimately, lipid droplets begin to join or aggregate into large lipid globules (i.e., >1 micron in diameter), and the emulsion becomes destabilized. Animal studies have suggested adverse effects on lung and liver function when unstable lipid emulsions are infused.[68,69] Under those conditions when no other reasonable alternative exists, the following criteria should be used for determining whether PN can be used as a drug administration vehicle:[67]

- The stability and compatibility of the drug with the PN admixture and the PN admixture with the drug have been determined.
- The medication must be clinically effective during continuous infusion.
- The drug dosage is constant during the previous 24-hour period.
- The PN infusion rate is stable during the previous 24-hour period.

In addition, the clinician must be cognizant of when the drug therapy needs to be continued when the PN is discontinued. Given these constraints, there are only a limited number of drugs with which this therapy may be considered. Of these medications, only histamine$_2$ antagonists and regular human insulin (RHI) are considered safe and effective with both two-in-one and TNA solutions; however, other medications have been employed in two-in-one PN solutions. Medications that have been added to the PN formulation for a continuous infusion are given in the following sections.

Albumin

Albumin historically has been added to lipid-free PN solutions as a way to provide a continuous source of colloid for those patients with edema associated with severe hypoalbuminemia.[70] Indications for the use of albumin and the best method for its administration (continuous vs short-term infusion vs. bolus) are still subject to considerable debate among clinical practitioners. Recent data indicate that albumin, when exposed to high concentrations of dextrose, results in glycosylation of a portion of the albumin, which alters its physiologic properties.[70] When added to a two-in-one admixture at a concentration of 25 g/L, albumin has clogged 0.2 micron filters.[70] Addition of albumin to an IVLE-containing PN admixture results in creaming by 4 hours.[71] As a result of these detrimental effects, the addition of albumin to PN formulations is not recommended.

Heparin

Heparin has been added to PN solutions to prevent catheter thrombosis in lipid-free PN admixtures and is clinically effective at concentrations of 3,000 units/L.[67] When undiluted heparin solution (100 units/mL) was admixed in a 1:1 volume mixture with a lipid-containing PN formulation (final heparin concentration of 50,000 units/L), the IVLE portion of the PN was not stable.[72] This instability was believed to be due to heparin's ability to form a bridge between lipid particles, keeping them in close proximity and leading to lipid globule aggregation.[67] It is possible that this adverse effect on IVLE stability is dose-related, as a heparin concentration of 2,158 units/L does not adversely influence IVLE stability over a 24-hour observation period.[65] Therefore, low heparin concentrations used for catheter thrombosis prophylaxis can be added to lipid-containing PN admixtures. Although high concentrations (35,000 units/L) of heparin are stable in lipid-free PN solutions,[65] this approach is not recommended, as titration of the heparin rate to the targeted activated partial thromboplastin time warrants infusion rate adjustments that may cause PN-associated electrolyte and macronutrient metabolic disturbances.

Histamine$_2$ Receptor Antagonists

Stress ulcer prophylaxis with either histamine$_2$ antagonists or proton-pump inhibitors is routine therapy for most patients in ICUs. Also, patients with hypergastrinemia during the early course of their short bowel syndrome are often given histamine$_2$ antagonists for several months with their home PN regimen. Ranitidine, famotidine, and cimetidine are efficacious and stable when admixed with either two-in-one or three-in-one PN admixtures.[65,67,73]

Hydrochloric Acid and Sodium Bicarbonate

Disturbance in acid–base homeostasis due to various etiologies is prevalent among patients receiving PN. In addition to treatment of the primary etiology for the acid–base disorder, sometimes the provision of HCl or $NaHCO_3$ is warranted. The stability of HCl when added to a lipid-free PN solution at a final HCl concentration of 100 mEq/L (100 mmol/L; 0.1 N) has been documented.[65] With consideration of the addition of HCl to a TNA admixture, it is pertinent to note that an extremely low pH <5 can effectively overcome the negative surface charge imparted by the emulsifier and irreversibly destabilize or "crack" the emulsion. This leads to separation of oil from the water phase and appears as an amber oil layer at the top of the PN bag or as yellow-brown streaks of oil throughout the formulation (referred to as "marbling" or "oiling out"). As a result, HCl cannot be added to IVLE-containing PN. Sodium bicarbonate must not be admixed with lipid-free or lipid-containing PN. When added to a PN formulation, it combines with calcium included in the PN to form a calcium carbonate precipitate, also known as chalk.[67]

Iron

Iron dextran has been used safely when added to a two-in-one PN formulation at a concentration of 100 mg/L.[74] The addition of iron dextran at a concentration of 10 mg/L to lipid-free pediatric PN solutions was compatible when the final amino acid concentration was ≥2%.[74] However, the trivalent cation from iron (dextran) disrupts the IVLE component of the TNA when added to IVLE-containing PN, even when given in doses as little as 2 mg/L.[75] Therefore, the addition of iron dextran to IVLE-containing PN is not recommended. The compatibility and stability of sodium ferric gluconate or iron sucrose when added to PN have not been evaluated, and their addition to a two-in-one or TNA solution is not recommended.

Octreotide

Although octreotide is listed as physically compatible when admixed with PN formulations,[72] glycosylation of the octreotide results in formation of pharmacologically inactive metabolites (thus the lack of stability of the medication) due to the availability of dextrose in the PN.[76] Decreased clinical efficacy has also been noted.[76] Therefore, octreotide should not be added to lipid-containing or lipid-free PN admixtures.

Regular Human Insulin

The addition of RHI to two-in-one or three-in-one PN admixtures has been shown to be compatible and effective. Only RHI is compatible with PN formulations; all other insulin formulations, such as neutral protamine Hagedorn (NPH), insulin glargine, lispro, and aspart, are not compatible and should never be added to the PN.[66] It is recommended to add the RHI to the PN formulation to control hyperglycemia after patient stability is achieved or to control mild hyperglycemia. For critically ill patients, an RHI infusion or sliding scale insulin coverage with only modest amounts of RHI provided in the PN is recommended.

COMPATIBILITY OF MEDICATION WHEN COADMINISTERED WITH PARENTERAL NUTRITION FORMULATIONS

Another method of medication administration is by coinfusion through the same IV tubing as the PN. In general, this method should be avoided unless the physical and chemical compatibility of the medication with the PN formulation is assured.[66] Even with the use of double and triple lumen catheters, there are situations encountered in clinical practice in which there are insufficient ports/lumens to provide for the patient's complicated IV therapy, and various medications/PN may need to be coinfused.[77] This is done using a Y-site, where two IV tubes are joined as a single tube. As a result, the two separate infusions are briefly mixed together as one infusion prior to delivery to the patient.

Unfortunately, these data are limited as, typically, only physical compatibility has been evaluated in the majority of studies assessing additive and Y-site compatibility with PN formulations;[72,77] very few consider stability. Unstable substances should not be added to or coinfused with PN regardless of physical compatibility. Another limitation is that the majority of studies examine only a single concentration of the medication with the PN admixture. Morphine is one example; its concentration may affect PN stability. For a two-in-one PN solution, morphine is compatible at both 1 mg/mL and 15 mg/mL concentrations. However, in one study, only morphine 1 mg/mL was compatible with TNA solutions, and "oiling out" of the IVLE-containing PN occurred with the 15 mg/mL concentration.[72] The clinician should consult resources such as *Trissel's Handbook on Injectable Drugs*[78] and the *King Guide to Parenteral Admixtures*[79] for comprehensive current information concerning the compatibility and stability of PN solutions when admixed with medications prior to coadministration of any medication with PN. Common examples of medications known to be incompatible or not recommended to be given concurrently via a Y-site with either a two-in-one or a three-in-one PN formulation are acyclovir, amphotericin B, cyclosporine, doxorubicin, fluorouracil, ganciclovir, immune globulin, midazolam, phenytoin, and sodium bicarbonate. Common drugs known to be compatible with two-in-one PN solutions but not TNA formulations include dopamine, HCl, heparin, iron dextran, and pentobarbitol. Conversely, some chemotherapy agents, such as cisplatin, cytarabine, and methotrexate, are not compatible with two-in-one PN

solutions, but they are compatible with IVLE-containing PN solutions because of the lipid solubility of these medications.[67]

9 IV Y-site administration of calcium, potassium phosphate, sodium phosphate, or magnesium with PN admixtures must be avoided. Given the characteristics of the PN (e.g., pH, amino acid concentration, calcium and phosphorus concentrations, and lipid concentration), the formulation may already be near the point of approaching solubility or stability limits. PN admixtures generally contain a fourfold higher concentration of calcium and a 25-fold higher concentration of phosphorus compared with serum (45 to 56 mg/L vs. 200 mg/L of calcium, respectively; 40 mg/L vs. 1,000 mg/L of phosphorus, respectively). Hence, rapid increases in pH (from the acidic pH of the PN solution to a neutral pH) and the heating of the PN to body temperature (resulting in increased calcium ion availability for interacting with phosphorus) as the PN solution flows from the bag to the body might make a marginal difference between solubility and precipitation.[80] Use of the same catheter tubing or lumen as the PN formulation for the treatment of hypocalcemia or hypophosphatemia can easily overwhelm calcium phosphate concentrations that exceed solubility limits, resulting in formation of dibasic calcium phosphate precipitants. These precipitants, which are virtually insoluble in water, pose the greatest threat and are implicated in reports of significant morbidity and mortality among patients receiving incompatible PN mixtures.[81,82] Another consideration beyond calcium phosphate precipitation is lipid stability. Phase separation (e.g., "oiling out") can occur when an excess of cations is added to an IVLE-containing PN formulation.[66,72] The higher the cation valence, the greater the destabilizing effect. Therefore, a trivalent cation such as iron is the most disruptive, followed by the divalent cations calcium and magnesium. Monovalent cations such as sodium and potassium are the least disruptive to the emulsifier, yet when given in high concentrations, they may produce instability.[66]

CONCLUSION

There are numerous issues related to the concurrent delivery of EN, PN, and medications. Because of these difficulties, considerations for the safe and effective administration of medications with EN and PN have been compiled and summarized in this chapter. The issues and provided recommendations should address many of the medication administration situations encountered in clinical practice. As more data become available, recommendations are likely to change. For drugs with a narrow therapeutic index, changes in the patient's pharmacotherapy need to be reevaluated with clinical monitoring for therapeutic efficacy or adverse effects, including serum concentrations of the medication.

ABBREVIATIONS

APPT: Activated partial thromboplastin time

EN: Enteral nutrition

HCl : Hydrochloric acid

IVLE: Intravenous lipid emulsion

$NaHCO_3$: Sodium bicarbonate

NPH: Neutral protamine Hagedorn (insulin)

PN: Parenteral nutrition

RHI: Regular human insulin

TNA: Total nutrient admixture (three-in-one parenteral nutrition)

CHAPTER 151

Parenteral Nutrition

TODD W. MATTOX AND CATHERINE M. CRILL

KEY CONCEPTS

1. Four steps to developing a successful nutrition plan include definition of nutrition goals, determination of nutrition requirements, determination of appropriate route of delivery of nutrients, and subsequent monitoring of the nutrition regimen to evaluate suitability of the regimen as a patient's clinical condition changes and to minimize or treat complications.
2. The appropriate route of nutrition support depends on the functional condition of the patient's gastrointestinal (GI) tract, risk of aspiration, expected duration of nutrition therapy, and clinical condition.
3. Identifying the patient who is most likely to benefit from parenteral nutrition (PN) therapy includes consideration of the patient's age, nutrition status, expected duration of GI dysfunction, and potential risks of initiating therapy.
4. PN formulations include intravenous (IV) sources of protein, dextrose, fat, water, electrolytes, vitamins, trace elements, and other additives.
5. PN solutions may be appropriately formulated for administration by peripheral or central venous access.
6. PN solutions may be infused continuously or intermittently.
7. Biochemical and clinical measurements considered necessary for effective monitoring of patients receiving PN include serum chemistries, vital signs, weight, total daily fluid intake and losses, and nutritional intake.
8. Non–catheter-related complications of PN therapy are minimized with application of age-appropriate nutrient dosing guidelines, frequent monitoring, and rational adjustments to the PN regimen when metabolic abnormalities occur.
9. Expenses associated with PN therapy may be minimized by using PN in appropriate patients, appropriate use of laboratory measurements associated with PN therapy, maximizing efficient purchasing practices for PN solutions and compounding supplies, implementing a standardized process for PN management, and minimizing PN waste.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Maintenance of adequate nutrition status during illness has been recognized for more than 50 years as an integral part of the medical treatment plan for patients who are unable to use normal physiologic means of nourishment. Successful techniques for providing intravenous (IV) nutrition support were introduced to clinical practice in adults and subsequently, infants in the late 1960s.[1] Use of central venous access was investigated to reduce risk of metabolic complications associated with fluid overload and electrolyte imbalances. The use of larger vessels permitted infusion of concentrated formulas, which decreased the fluid volume required and avoided the phlebitis that commonly occurred when hypertonic infusions were given peripherally.

Further clinical experience and research fostered development of protocols that promoted better patient care and resulted in a decline in complications associated with parenteral nutrition (PN) therapy.[2] The scope of practice for nutrition support clinicians has broadened as a result of increasing knowledge regarding the metabolic consequences associated with acute injury and chronic disease states. The pharmacist's role in providing safe and effective nutrition-support care requires knowledge of the principles of patient selection, initial therapy design, preparation and dispensing of the nutritional formulations, and outcome monitoring. Other responsibilities of the nutrition support pharmacist may include development of policy and procedures as well as quality improvement activities for patient care and operational processes associated with providing parenteral and enteral nutrition.[3–5] However, the role of other healthcare professionals may be similar because of the evolving interdisciplinary approach to nutritional support.[6–8] This chapter reviews indications for PN, components of PN formulations, routes of IV administration, practical aspects of regimen design, solution admixture, outcome monitoring, and management of complications for both adult and pediatric (neonates, infants, and children) patients.

DESIRED OUTCOMES

1. The primary objective of nutrition support therapy is to promote positive clinical outcomes of an illness and improve a patient's quality of life. Four fundamental steps are key to providing optimal care for patients who require nutrition support. They are definition of nutrition goals, determination of nutrient requirements for achievement of the nutrition goals, delivery of the required nutrients, and subsequent assessment of the nutrition regimen.[4,5]

A patient's nutrition goals can be established after a thorough nutritional assessment (see Chap. 149). Nutrient requirements and an appropriate route for delivery of the required nutrients can then be determined. Nutrition support goals include correction of the patient's caloric and nitrogen imbalances, and any fluid or electrolyte abnormalities, or known vitamin or trace element abnormalities. An additional goal is to lessen the metabolic response

to injury by minimizing oxidant stress and favorably modulating immune response. These interventions should not cause or worsen other metabolic complications.

Specific caloric goals include (a) adequate energy intake to promote normal growth and development in neonates, infants, and children, (b) energy equilibrium and preservation of fat calorie stores in well-nourished adults, and (c) positive energy balance in malnourished patients with depleted endogenous fat stores. Overweight patients with >120% of ideal body weight or a body mass index >30 kg/m^2) may require less caloric support than nonobese patients with the same clinical condition.[9] Specific nitrogen goals are positive nitrogen balance or nitrogen equilibrium and improvement in the serum concentration of visceral protein markers such as transferrin or prealbumin.

2 The gastrointestinal (GI) tract is the optimal route for providing nutrients unless obstruction, severe pancreatitis, or other GI complications are present (see Chap. 149).[10] Other considerations that may impact determination of an appropriate route for delivery of nutrition support include expected duration of nutrition therapy and risk of aspiration. Patients who have nonfunctional GI tracts or are otherwise not candidates for enteral nutrition may benefit from PN. Routine monitoring is necessary to ensure that the nutrition regimen is suitable for a given patient as the patient's clinical condition changes and to minimize or treat complications.

INDICATIONS FOR PARENTERAL NUTRITION SUPPORT

The association between malnutrition and development of complications and mortality is well documented for adult and pediatric patients.[11,12] Although improvement in nutrition status as defined by various clinical nutrition markers has been reported for patients who received PN, the impact on clinical outcome is difficult to demonstrate in many adult populations. Several investigations have reported a positive effect of PN on complications and mortality, whereas others have failed to demonstrate any difference.[11,13,14,15] Early studies have been criticized for defects in study design, such as small sample sizes, inappropriate randomization, and inconsistent baseline nutrition status among the study group, which hindered demonstration of the effectiveness of PN therapy. The impact of PN on clinical outcome has been more successfully demonstrated for critically ill infants and children, particularly those with acquired or congenital GI tract anomalies.[16] Consensus guidelines for PN use for adults (Table 151–1) and pediatric (Table 151–2) patients are based on clinical experience and investigations in specific patient populations.[13–19] Unfortunately, conflicting data have resulted in a lack of consistency in published guidelines from different sources, which complicates identification of the patient who is most likely to benefit from PN. However, these published reports may serve as resources for development of institution-specific standards.

3 The decision to initiate PN is based on the assessment that the patient cannot meet his or her nutritional requirements through the GI tract. This assessment must include an evaluation of the patient's nutrition status, clinical status, age, and potential risks of initiating therapy, such as infection and other metabolic abnormalities. The appropriate length of time to wait prior to starting PN therapy is dependent on patient age and clinical status.[10–19]

Adult PN therapy is not an emergent intervention and should not be initiated until the patient is hemodynamically stable.[10] In general, adults who are not candidates for enteral nutrition should be considered candidates for PN after 7 to 14 days of suboptimal nutritional intake.[10] Guidelines for use in infants and children are primarily influenced by age. The most appropriate time to initiate therapy for infants and children varies with age and nutritional status. Early PN

TABLE 151-1 Indications for Adult Parenteral Nutrition

1. Inability to absorb nutrients via the GI tract because of one or more of the following:
   a. Massive small bowel resection: usually patients with <100 cm (39 in) of small bowel distal to the ligament of Treitz without a colon or <50 cm (20 in) of small bowel with an intact colon
   b. Intractable vomiting when adequate EN is not expected for 7–14 days.
   c. Severe diarrhea
   d. Bowel obstruction
   e. GI fistulae: PN is indicated for patients with prolonged inadequate nutritional intake longer than 5–7 days who are not candidates for EN.
2. Cancer: antineoplastic therapy, radiation therapy, or HSCT
   a. PN may be used for moderately to severely malnourished patients receiving active anticancer treatment who are not candidates for EN.
   b. PN is not routinely indicated for well-nourished or mildly malnourished patients undergoing surgery, chemotherapy, or radiation therapy.
   c. PN is unlikely to benefit patients with advanced cancer whose malignancy is unresponsive to treatment. However, use may be appropriate for carefully selected patients who have failed trials of less-invasive medical therapies and have good performance status, an estimated life expectancy of longer than 40–60 days, and strong social and financial support.
   d. PN is appropriate for patients undergoing HSCT who are malnourished and who are anticipated to be unable to ingest and/or absorb adequate nutrients for 7–14 days. PN should be discontinued as soon as toxicities have resolved after stem cell engraftment.
3. Pancreatitis: PN may be used for patients with severe pancreatitis with prolonged inadequate nutritional intake longer than 5–7 days who are not candidates for EN. PN should be used when EN exacerbates abdominal pain, ascites, or fistula output.
4. Critical care
   a. PN should be used for those patients in whom EN is contraindicated or is unlikely to provide adequate nutritional requirements within 5–10 days.
   b. Organ failure (liver, renal, or respiratory): PN should be used for patients with moderate to severe catabolism when EN is contraindicated.
   c. Burns: PN should be used for those patients in whom EN is contraindicated or is unlikely to provide adequate nutritional requirements within 4–5 days.
5. Perioperative PN
   a. Preoperative: for 7–14 days for patients with moderate to severe malnutrition who are undergoing major GI surgery, if the operation can be safely postponed.
   b. Postoperative: PN should be used for patients in whom EN is contraindicated or is unlikely to provide adequate nutritional requirements within 7–10 days.
6. Hyperemesis gravidarum: when EN is not tolerated
7. Eating disorders: PN should be considered for patients with anorexia nervosa and severe malnutrition who are unable or unwilling to ingest adequate nutrition.

EN, enteral nutrition; GI, gastrointestinal; HSCT, hematopoietic stem cell transplantation; PN, parenteral nutrition; SBS, short-bowel syndrome.
From references 10, 13, 14, and 18.

TABLE 151-2 Indications for Pediatric Parenteral Nutrition

1. When enteral nutrition is unlikely to provide adequate nutritional requirements
   a. Premature infant within 24–48 hours
   b. Other pediatric patients within 5–7 days
2. When the GI tract is not functional or cannot be assessed
   a. Massive small bowel resection resulting in short-bowel syndrome
   b. Neonatal necrotizing enterocolitis
   c. Severe inflammatory bowel disease
   d. Intractable diarrhea and/or vomiting
   e. Graft-versus-host disease
   f. Postchemotherapy
3. Infants and children requiring extracorporeal membrane oxygenation
4. Organ failure (liver, renal, pulmonary, pancreas) when enteral nutrition is contraindicated and child is catabolic

From references 16, 17, 19.

within the first 24 hours of life has been recommended for infants with a birth weight of 1,500 g.[20–22] Protein loss in extremely low-birth-weight infants can be twofold higher than in term infants, and frequently results in a negative nitrogen balance that cannot be corrected by glucose as a sole nutrient. Early aggressive PN in neonates can enhance protein accretion and somatic growth.[20,22,23] While there has been some concern regarding protein tolerance with early initiation of PN, most clinicians now support the practice. Withholding PN for 2 to 3 days after birth, coupled with a slow advancement of substrate, only appears to contribute to the acute semistarvation and growth failure seen for many neonates.[20,22,23] PN should be initiated within 5 to 7 days for other pediatric patients who are unable to meet their nutrient requirements with enteral nutrition.[16,21] Earlier intervention should be considered for term infants (within 2 to 3 days), critically ill children (within 3 to 5 days), and children with preexisting malnutrition. Guidelines for older children are similar to those for adults.

CLINICAL CONTROVERSY

The most appropriate time to initiate PN in adults differs among various consensus reports because few data specifically address this issue. Some recommend initiating PN for patients who are not candidates for enteral nutrition as early as after 7 days of inadequate oral intake, whereas others recommend waiting up to 14 days for previously well-nourished or moderately malnourished patients.

COMPONENTS OF PARENTERAL NUTRITION

4 PN formulations include IV sources of protein, dextrose, fat, water, electrolytes, vitamins, trace elements, and other additives. PN solutions should provide the optimal combination of macro- and micronutrients to provide a patient's specific nutritional requirements. Macronutrients include water, protein, dextrose, and IV fat emulsion (IVFE) (Table 151–3). Micronutrients include vitamins, trace elements, and electrolytes. Both macronutrients and micronutrients are necessary for maintenance of normal metabolism. In general, macronutrients are used for energy (dextrose and fat) and as structural substrates (protein and fat). Micronutrients are required to support a variety of metabolic activities necessary for cellular homeostasis such as enzymatic reactions, fluid balance, and regulation of electrophysiologic processes. These components usually require individualized adjustments as the patient's clinical condition affects changes in metabolic stress, organ function, fluid and electrolyte balance, and acid–base status.

AMINO ACIDS

Protein in PN solutions is provided in the form of crystalline amino acids (CAAs), which are used primarily for protein synthesis. When oxidized for energy, 1 g of protein yields 4 cal (or ~17 J). However, including the caloric contribution from protein when calculating calories provided by the PN regimen is controversial.[24]

Commercially available CAA solutions may be categorized as standard amino acid solutions or modified amino acid solutions. Standard CAA solutions are designed for patients with "normal" organ function and nutritional requirements (see Table 151–3). Although standard CAA solutions differ in the proportion of specific amino acids, they contain a balanced profile of essential, semi-essential, and nonessential L-amino acids. Despite these differences, similar effects on markers of protein use have been reported.[25] The protein concentration, total nitrogen, and electrolyte content are also different among products. Because the nitrogen concentration of dietary protein is approximately 16%, 6.25 (100 g protein/16 g nitrogen) is commonly accepted as the conversion figure for calculating the nitrogen amount provided by CAA protein. Differences in nitrogen content per gram of amino acids among CAA products may affect calculation of nitrogen amounts infused when determining nitrogen balance.[25,26] The clinical significance of these differences in determining nitrogen balance for routine clinical use is unknown.[26]

Electrolyte composition of standard CAA solutions varies from small, obligatory amounts to the provision of maintenance requirements of most electrolytes for an adult. Electrolytes provided by CAA solutions must be considered when determining a patient's individual requirements. CAAs are available in several different concentrations, which facilitates compounding of patient-specific PN regimens. Use of highly concentrated products (15% to 20%) is attractive for critically ill patients who typically require fluid restriction but have large protein needs. Modified amino acid solutions are designed for patients who have altered protein requirements, such as those with hepatic encephalopathy, renal failure, and metabolic stress or trauma, as well as for neonates and pediatric patients (see Table 151–3). These solutions tend to be more expensive than

TABLE 151-3 Macronutrient Components of PN Solutions

Nutritional Substrate	Intravenous Source	Description
Fluid	Sterile water for injection USP	
Nitrogen	Crystalline amino acids standard solutions	Contain a balanced profile of essential, semi-essential, and nonessential L-amino acids.
	Disease-specific solutions	
	Hepatic encephalopathy	Amino acid profile includes higher BCAA concentrations and lower AAA and methionine concentrations.
	Renal failure	Amino acid profile includes higher EAA and histidine concentrations.
	Metabolic stress/ trauma	Amino acid profile provides standard essential, semi-essential, and nonessential amino acids with higher BCAA concentrations.
	Pediatrics	Amino acid profile includes standard essential, semi-essential, and nonessential amino acids with lower methionine, phenylalanine, and glycine concentrations; these solutions also contain taurine, glutamate, and aspartate.
Energy		
Carbohydrate	Dextrose	
	Glycerol	Used in ProcalAmine (B. Braun Medical, Inc.)
Fat	Intravenous fat emulsion	Fatty acid source
	LCT emulsions	Soybean
	Alternative fat emulsions (investigational)	MCT-LCT Olive oil Fish oil Mixed fat emulsions: SMOF (soybean oil, MCT, olive, and fish oils) MSF (MCT, soybean, and fish oils)

AAA, aromatic amino acids (includes phenylalanine and tyrosine); BCAA, branched-chain amino acids (leucine, isoleucine, and valine); EAA, essential amino acids (leucine, isoleucine, valine, phenylalanine, tryptophan, methionine, threonine, and lysine); LCT, long-chain triglycerides; MCT, medium-chain triglycerides; PN, parenteral nutrition

standard CAA solutions. The rationale for and clinical efficacy of modified amino acids in disease-specific PN regimens is controversial (see Chap. 153).

Several commercially available CAA solutions are designed to provide conditionally essential amino acids, which are considered nonessential during health because they are produced from other amino acids. However, under certain physiologic conditions, such as prematurity or sepsis, these amino acids cannot be synthesized in sufficient quantities.[25] CAA solutions specifically designed for neonates and pediatric patients contain increased amounts of taurine, aspartic acid, and glutamic acid. Other conditionally essential amino acids, such as cysteine, carnitine, and glutamine, are not available in commercial CAA solutions in pharmacologic amounts because they are relatively unstable or poorly soluble.[25]

Consequently, PN solutions may need to be modified to provide the desired amount of supplemental conditionally essential amino acids. For example, cysteine is a conditionally essential amino acid for preterm and term infants because of their enzymatic immaturity of the trans-sulfuration pathway. Cysteine may be added to PN solutions at the time of compounding as a supplement to CAA solutions and also to enhance calcium and phosphate solubility by decreasing solution pH.[27] Carnitine is a quaternary amine required for long-chain fatty acid transport into the mitochondria for β-oxidation and energy production. Newborns are at risk for carnitine deficiency because of their immature biosynthetic capacity. Decreased plasma carnitine concentrations have been reported for infants and children receiving PN without carnitine.[28] Supplemental carnitine may be added to the PN solution at the time of compounding. While the benefit of carnitine supplementation in PN has not been clearly identified, positive effects on nutritional markers, including improved fatty acid oxidation, weight gain, and nitrogen balance have been documented. In general, carnitine supplementation is reserved for neonates expected to receive PN support for 7 days or longer.[28]

Glutamine is the most abundant free amino acid in the body and is an important intermediate for many metabolic processes. Glutamine is reported to have an important role in maintaining intestinal integrity, immune function, and protein synthesis during conditions of metabolic stress.[25,29] Investigations in humans and animals have reported positive effects on nutritional markers such as nitrogen balance, whereas others have reported significant improvement in other outcome markers, such as decreased length of hospitalization, incidence of infections, and GI toxicities associated with chemotherapy or radiation.[29] However, the best adult candidate for response to glutamine therapy has not been clearly identified.[29] The clinical usefulness of glutamine in neonates is less clear.[30] Plasma glutamine concentrations increase with supplementation, but no beneficial effect on sepsis, enteral feeding tolerance, necrotizing enterocolitis, growth, or mortality has been reported.[30] The clinical use of glutamine is further complicated because there is no IV glutamine formulation commercially available in the United States. Currently available CAA solutions do not contain glutamine because of poor solubility and instability. Use of IV glutamine requires special manufacturing techniques not readily available in many institutional pharmacies.[31] Additional controlled trials are warranted to characterize the risks and costs associated with extemporaneous compounding before routine IV glutamine use can be recommended.[29,31] Dipeptide amino acids are a potential parenteral source for conditionally essential amino acids that may provide a solution to the instability and solubility limitations. Dipeptides are synthesized by combining two amino acids with a peptide bond. The resulting protein is more soluble and stable than the individual amino acids.[25] IV dipeptide formulations would be advantageous clinically because they incorporate higher concentrations of some specific amino acids as well as some low-solubility, low-stability amino acids that are omitted or present in small quantities in current CAA solutions. In addition, dipeptide use would allow formulation of CAA solutions with higher nitrogen content. Further studies are needed to assess long-term safety and optimal combinations of amino acids in different disease states. Dipeptide CAA formulations are currently not available in the United States.

CLINICAL CONTROVERSY

Although sufficient energy substrate should be provided to support amino acid use for protein synthesis, amino acid oxidation for energy has been demonstrated in critically ill patients and is thought to occur because of altered metabolism associated with severe metabolic stress. Hence, some practice settings may express calories provided by PN as total calories (protein, carbohydrate, fat calories), whereas others may use nonprotein calories (carbohydrate and fat).

DEXTROSE

The primary energy source in PN solutions is carbohydrate, usually in the form of dextrose monohydrate, which is available in concentrations ranging from 5% to 70%. When oxidized, each gram of hydrated dextrose provides 3.4 kcal (14.2 kJ). The appropriate IV dextrose dose depends on the patient's age, estimated caloric requirements, and clinical condition. For example, minimum dextrose requirements for neonates are estimated to be approximately 6 to 10 mg/kg/min.[22,32] However, IV dextrose infusion rates should not exceed 10 to 14 mg/kg per minute for infants and 4 to 7 mg/kg per minute for adults.[32–34] The recommended dextrose dose for routine clinical care rarely exceeds 5 mg/kg per minute for older critically ill children (1 to 11 years old) and adults.[33,35] Maintaining an age-appropriate dextrose infusion rate is necessary to minimize risk of adverse effects. If the dextrose infusion rate exceeds the glucose oxidation rate, metabolically expensive pathways, such as glycogen repletion and lipid synthesis, are favored, resulting in increased energy expenditure, increased oxygen consumption, and increased carbon dioxide production. Excessive dextrose infusion rates also may contribute to the development of hyperglycemia, excess carbon dioxide production, and increased biochemical markers for liver function associated with fatty infiltration of the liver.[33–35]

Carbohydrate sources that are not insulin dependent have been investigated as an alternative to dextrose to improve glycemic control for patients with impaired insulin secretion or activity who require PN. Glycerol, a sugar alcohol that provides 4.3 kcal/g (18 kJ/g), is the only dextrose alternative commercially available for clinical use. It is available as an isotonic, 3% solution in combination with 3% amino acids and supplemental electrolytes (ProcalAmine, B. Braun Medical, Irvine, CA). Although the solution may be peripherally infused, a major disadvantage of this formula is the dilute amino acid and carbohydrate concentrations. Most adult patients require up to 3 to 4 L/day of ProcalAmine solution together with IVFE as a caloric source to provide minimum energy requirements.[36] IV glycerol use for catabolic adults is safe and effective, but similar data are not available for infants and children.[37]

INTRAVENOUS FAT EMULSION

IVFE is used as a concentrated source of calories and essential fatty acids. While commercially available IVFE products have traditionally contained soybean oil or a combination of soybean oil and safflower oil, IVFE products containing safflower oil are no longer manufactured. Soybean-oil-based IVFE products are available in

various concentrations (10%, 20%, and 30%) and contain egg phospholipids as an emulsifying agent and glycerol to make the emulsion isotonic. Although the caloric contribution of fat is 9 kcal/g (38 kJ/g), the caloric content of IVFE is 1.1 kcal/mL (4.6 kJ/mL) for 10% emulsion, 2 kcal/mL (8.4 kJ/mL) for 20% emulsion, and 3 kcal/mL (12.6 kJ/mL) for 30% emulsion because of the caloric contribution of the egg phospholipid and glycerol.[38] The fatty acid composition of soybean-oil-based IVFEs is approximately 44% to 62% linoleic acid and 4% to 11% linolenic acid.[38] Linolenic acid, an omega-3 fatty acid, and linoleic acid, an omega-6 fatty acid, are both polyunsaturated long-chain triglycerides (LCTs).[39] IVFE products differ in phospholipid and triglyceride concentrations. Higher-concentrated IVFEs (20% and 30%) have a lower phospholipid-to-triglyceride ratio compared with 10% IVFE.[31,40] Because higher amounts of circulating phospholipids are associated with impaired triglyceride clearance in neonates and infants, 20% IVFE is the preferred product for this population.[31,40,41]

Soybean-oil-based IVFE is effective for treatment or prevention of essential fatty acid deficiency (EFAD). EFAD is the result of a biochemical deficiency of linoleic acid and arachidonic acid, which are considered essential for humans.[42] Linoleic and linolenic acids are important for a variety of functions such as cellular integrity, platelet function, postnatal brain development, and wound healing.[42] Normally, linoleic acid is converted to the tetraene arachidonic acid. When linoleic acid is not present in sufficient amounts, oleic acid is converted to the triene 5,8,11-eicosatrienoic acid, a fatty acid of lesser physiologic integrity, and EFAD occurs. EFAD may be prevented by providing 2% to 4% of total calories as linoleic acid and 0.25% to 0.5% of total calories as linolenic acid.[31] This may be achieved for most adult patients by giving approximately 100 g IVFE weekly.[31,33] Neonates and infants require a minimum of 0.5 to 1 g/kg daily.[40,41,43]

Plasma IVFE clearance is directly related to gestational age of infants and appears to be influenced by the infusion rate and the patient's clinical status.[40,41,43] The risk of developing hypertriglyceridemia decreases with longer infusion times.[31,40,43] Rapid IVFE infusions are reported to contribute to decreased oxygenation for neonates.[40,43] Adverse pulmonary effects are thought to be caused by polyunsaturated fatty acid (PUFA)-driven prostaglandin production, which results in altered vascular tone. Although the association between IVFE and pulmonary dysfunction is not clear, a black-box warning appears in the FDA labeling for soybean-oil-based IVFE that acknowledges deaths in preterm infants associated with pulmonary fat accumulation thought to be related to IVFE infusions.[40,43,44] In addition, data for animals and humans also suggest that rapid infusion of long-chain fatty acid formulations may have a negative impact on immunocompetence by saturating the reticuloendothelial system.[33,45]

As a caloric source, IVFE use may facilitate provision of adequate calories and minimize complications of nutrition therapy such as hyperglycemia, hepatotoxicity, or increased carbon dioxide production.[33] Although the frequency of acute adverse effects is reported to be <1% with current formulations, patients receiving their first IVFE dose should be monitored for dyspnea, chest tightness, palpitations, and chills. Headache, nausea, and fever also have been reported and might be associated with a rapid infusion rate. In general, IVFE use is contraindicated for patients with an impaired ability to clear fat emulsion, such as patients with pathologic hyperlipidemia, lipoid nephrosis, and hypertriglyceridemia associated with pancreatitis.[44] Finally, patients with a reported egg allergy should be evaluated carefully for the nature and severity of the reaction before deciding to initiate a fat-based PN regimen.

Commercially available 10% and 20% IVFE products may be administered by either the central or the peripheral route. They may be added directly to the PN solution as a total nutrient admixture (TNA), also referred to as a 3-in-1 system (lipids, protein, glucose, and additives), or they may be piggybacked with the CAA-dextrose solution, commonly referred to as a 2-in-1 solution.[31,38,44] The more concentrated 30% IVFE is only approved for use in the preparation of TNA and is not intended for direct IV administration.

Soybean-oil-based IVFEs have negative effects on immune function as the result of omega-6 PUFA influence on proinflammatory eicosanoid production. These negative effects on immune function have stimulated a search for alternative IVFE sources that provide adequate essential fatty acids but lower amounts of omega-6 FA.[39,45] Medium-chain triglycerides (MCTs) may offer several advantages, especially for critically ill patients. MCTs are hydrolyzed and cleared more rapidly than LCTs, and they do not accumulate in the liver. In addition, MCTs do not require carnitine for entrance into mitochondria for oxidation. However, MCTs are not a source of essential fatty acids. Subsequent studies of IV MCT-LCT mixtures in a number of patients demonstrate safety and efficacy comparable with standard LCT emulsions.[39,42,45] Several MCT-LCT products are available in Europe, although no IV MCT formulations are currently available commercially in the United States. Other IVFE that are available outside the United States include a fish oil-based emulsion, an olive-oil- and soybean-oil-based emulsion and mixed fat source emulsions including a soybean, MCT, olive oil, and fish oil combination and a soybean, MCT, and fish oil combination.[39,45] Fish-oil-based IVFE contain predominantly omega-3 PUFAs, which are metabolized to cytokine mediators that may be less inflammatory and immunosuppressive than those derived from omega-6 PUFAs. Olive-oil-based IVFEs provide essential fatty acids, are a rich source of vitamin E, and may have a neutral effect on immune function. The clinical effect of IVFE administration on immune function, as well as on patient morbidity and mortality, is not clear.[39,43,45] However, investigations of enteral solutions with a higher concentration of omega-3 PUFAs have reported decreased infections and improvement of in vitro immunologic indices in critically ill patients.[42,46] Recent evidence suggests that soybean-based IVFE, which contains phytosterols and predominantly omega-6 PUFAs, may play a greater role in the development of PN-associated liver disease (PNALD). Investigations of fish-oil-based IVFE have reported improved or reversal of PNALD.[47–49] Although IVFE products remain the most common source of parenteral fat, a number of drugs have been introduced that contain lipid either as a vehicle for delivery or as a portion of the drug molecular formulation. Propofol, an IV anesthetic, is delivered in a soybean-oil-in-water emulsion that has essentially the same composition and caloric concentration as 10% IVFE. This agent is used commonly for continuous sedation of ventilated patients and should be considered a potentially significant source of calories that may require adjustment of a patient's nutrition regimen.[31] The antifungal amphotericin B is available in several lipid-containing combinations such as liposomal and lipid complex formulations. The caloric contribution from these products when used in standard doses generally is small and is not relevant clinically.

VITAMINS

Maintenance guidelines for daily parenteral vitamin supplements were initially established by the Nutrition Advisory Group of the American Medical Association (NAG-AMA) for adults, children, and infants.[50] The NAG-AMA identified 13 essential vitamins that include 4 fat-soluble vitamins and 9 water-soluble vitamins based on requirements for healthy people. These original guidelines have been revised based on clinical experience and research for specific adult and pediatric patient groups who required PN. [21,43,51–53]

For example, the NAG-AMA guidelines for infants and children were later revised to primarily reflect changes for preterm infants

requiring PN.[53] In addition, the U.S. Food and Drug Administration (FDA) mandated reformulation of adult parenteral multiple-vitamin product guidelines to include 150 mcg of vitamin K in addition to higher doses of vitamins B1, B6, and C compared with the original AMA-NAG recommendations.[54]

Vitamin K was not included in previous parenteral multiple-vitamin formulations to minimize the risk of a drug–nutrient interaction for patients receiving anticoagulants, which antagonize vitamin K–dependent coagulation factors. The NAG-AMA recommendation for vitamin K for adults is 2 to 4 mg weekly. Other practitioners recommend larger doses of 0.5 to 1 mg/day or 5 to 10 mg weekly.[31] An investigation of patients receiving long-term IVFE-containing PN with vitamin K–free parenteral multivitamins at home suggests that supplemental vitamin K may not be necessary to maintain normal prothrombin times and plasma vitamin K concentrations.[55] Soybean oil used in IVFEs is a natural source of phylloquinone (vitamin K1). However, the vitamin K concentration is dependent on the soybean oil concentration in the IVFE.[54–56] Mean concentrations of 30.9 and 67.5 mcg/100 mL were reported for 10% and 20% Intralipid (Baxter Healthcare Corporation, Deerfield, IL), a soybean-oil-based IVFE. The bioavailability of vitamin K1 from IVFEs is unknown. Although hospitalized patients who received no additional vitamin K supplementation during short-term PN that included a low vitamin K–containing IVFE experienced minimal effects on international normalized ratio, supplemental vitamin K may be given intramuscularly or subcutaneously or added to the PN solution if needed.[54] Current recommendations suggest supplemental vitamin K is unnecessary when a vitamin K–containing multiple-vitamin product is used.[31]

Adult parenteral multiple-vitamin products formulated to comply with the FDA-mandated changes to the NAG-AMA guidelines are available commercially. In addition, a parenteral multiple-vitamin formulation containing no vitamin K is commercially available for adult patients receiving home PN and warfarin anticoagulation. (MVI-12, multivitamin infusion without vitamin K, Hospira Inc. Lake Forest, IL.) Two parenteral multiple-vitamin products are commercially available for use for pediatric patients. MVI-Pediatric (Hospira Inc., Lake Forest, IL) and Infuvite Pediatric (Baxter Healthcare Corporation, Deerfield, IL) are formulated to meet the revised NAG-AMA guidelines for infants weighing <1 kg (2.2 lb) to children up to 11 years old. However, there are no commercially available IV multivitamin products designed to specifically meet the unique requirements of premature infants, including higher vitamin A and lower doses of vitamins B1, B2, B6, and B12 compared with recommendations for term infants and older children.

Vitamin requirements may be altered in malnutrition and other specific disease states or with certain drug therapies. Individual and combination products are available to provide additional or tailored supplementation, which may be necessary to prevent development of vitamin toxicities or deficiencies caused by altered metabolism or drug therapy.

TRACE ELEMENTS

Many trace elements are an important part of metalloenzymes and also function as cofactors in a variety of regulatory metabolic pathways.[51,53] Although 17 trace elements have demonstrated biologic importance, clear deficiency syndromes in humans have been described only for cobalt (as vitamin B12), copper, iodine, iron, and zinc.[53,57,58] The NAG-AMA recognized chromium, copper, and zinc as being essential for IV supplementation for patients receiving PN.[59] Although a clear deficiency syndrome for manganese has not been reported in humans, the NAG-AMA considered manganese essential based on case reports of patients receiving PN with metabolic complications that corrected after manganese supplementation. Reports of syndromes associated with selenium and molybdenum deficiency suggest that they also may be essential.[53,57] Although iodine deficiency has not been reported for patients receiving short-term PN, it has been observed for patients receiving long-term PN and may be related to the use of chlorhexidine for central-line care instead of povidone–iodine.[60]

IV trace elements are available as single-trace element solutions and as multiple-trace element combinations. Most products for adults provide the daily requirements for the trace elements considered essential by the NAG-AMA (i.e., chromium, copper, manganese, selenium, and zinc). Currently available combination products for neonates and pediatric patients contain only chromium, copper, manganese, and zinc. Combination products containing iodide and molybdenum are no longer commercially available in the United States. Single entity IV products are available that allow for individualization of trace mineral supplementation of chromium, copper, iodine, manganese, selenium, and zinc.

Requirements for trace elements also change depending on the clinical condition of the patient. For example, higher doses of supplemental zinc likely are necessary for patients with high-output ostomies or diarrhea because the GI tract is the predominant excretion route for zinc. Manganese and copper are excreted through the biliary tract, whereas chromium, molybdenum, and selenium are excreted renally. Hence, these trace elements should be restricted or withheld from PN solutions for patients with cholestatic liver disease and renal failure, respectively.

ELECTROLYTES

Electrolytes such as sodium, potassium, calcium, magnesium, phosphorus, chloride, and acetate are necessary PN components for the maintenance of numerous cellular functions. Electrolytes may be given to maintain normal serum concentrations or to correct deficits. Patients who have "normal" organ function and relatively normal serum concentrations of any electrolyte should receive normal maintenance electrolyte doses when PN is initiated and daily thereafter. Specific electrolyte requirements vary according to the patient's age, disease state, organ function (see Chap. 153), previous and current drug therapy, nutrition status, and extrarenal losses. Electrolytes are available commercially as single- and multiple-nutrient solutions. Multiple-electrolyte solutions are useful for stable patients with normal organ function who are receiving PN. Concentrated multiple-electrolyte solutions designed for addition to PN solutions generally contain only sodium, potassium, calcium, and magnesium. Phosphorus must be added as a separate additive. Further information regarding metabolism and requirements of vitamins, trace elements, and electrolytes is given elsewhere.[31,61]

DESIGNING A PARENTERAL NUTRITION REGIMEN

5 Several factors, including the patient's venous access, fluid status, and macronutrient and micronutrient requirements, are important considerations when designing the PN regimen. A patient's venous access and fluid status determines how concentrated the PN solution may be compounded and, hence, have an impact on the nutrient amount that may be provided. PN solutions may be administered by central or peripheral venous access. The patient's clinical condition determines which route is most appropriate (Fig. 151–1).

PN solutions may be provided as a 2-in-1 formulation that contains dextrose, CAA, and other necessary micronutrients or as a 3-in-1 formulation or TNA that contains dextrose, CAA, and IVFE, as well as other necessary micronutrients. Use of TNA solutions offers several potential advantages, including reduced inventory

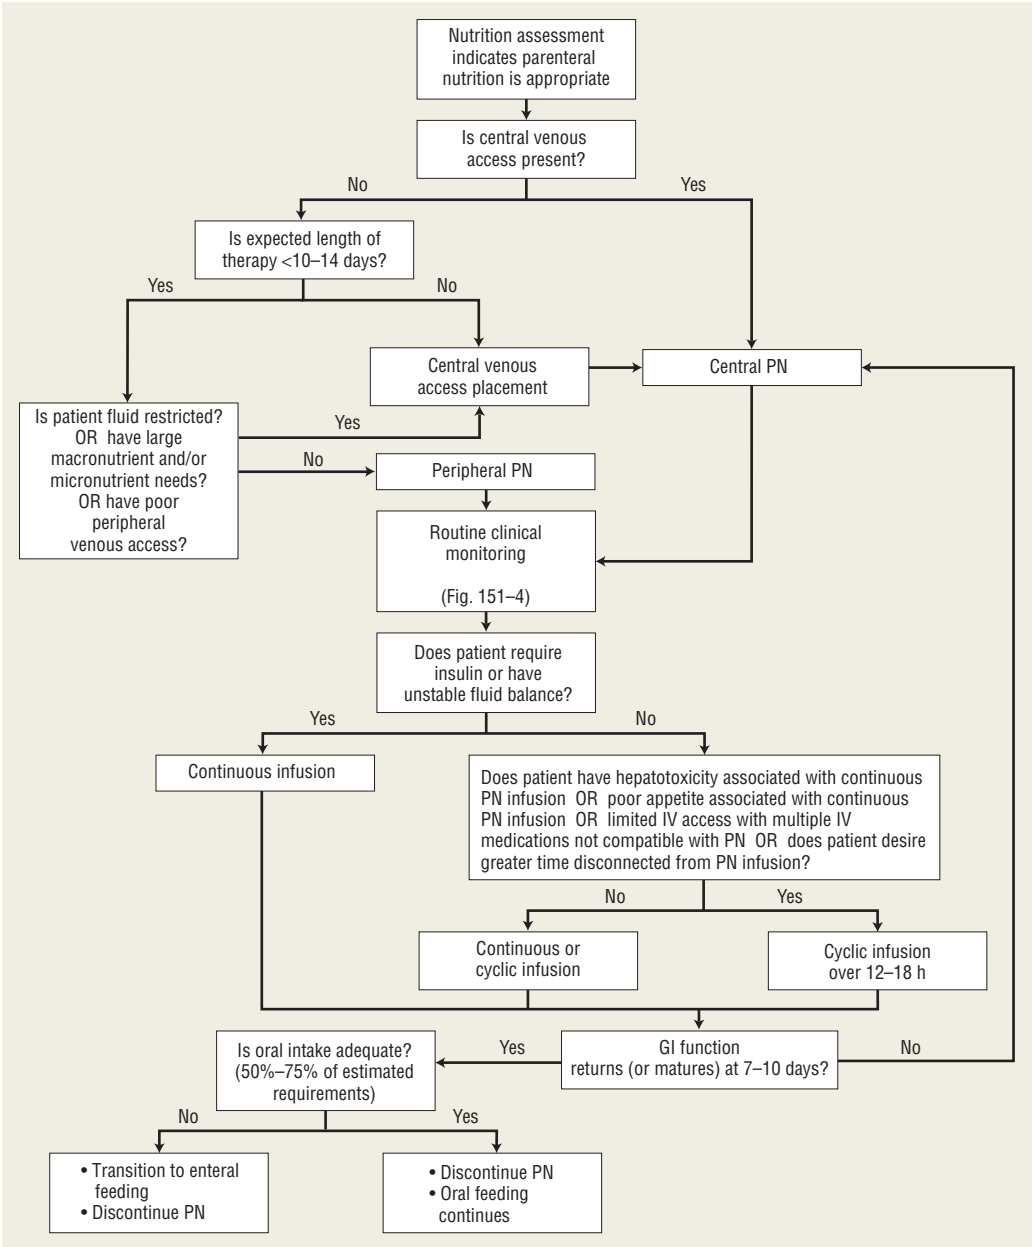

FIGURE 151-1. The route of parenteral nutrition (PN) and the infusion type depend on the patient's clinical status and the expected length of therapy.

(infusion pumps, tubing, and other related supplies), decreased time for compounding and administration, a potential decrease in manipulations of the infusion line (which should correspond with a decreased risk of catheter contamination), and ease of delivery and storage for patients receiving home PN.[62] Potential disadvantages include increased risk of infections and stability and compatibility concerns. For example, the stability of TNA solutions is less predictable than that of 2-in-1 solutions, which makes their use less desirable in specific patient populations such as neonates and infants.[31]

ROUTES OF PARENTERAL NUTRITION ADMINISTRATION

Peripheral Route

Peripheral parenteral nutrition (PPN) is an option for mild to moderately stressed patients for whom central access is unavailable or undesirable and function of their GI tract is expected to return within 10 to 14 days.[63] Potential PPN candidates should not be fluid restricted or require large nutrient amounts. Lower concentrations of amino acid (3% to 5% final concentration), dextrose (5% to 10% final concentration), and micronutrients compared with central parenteral nutrition (CPN) are necessary for peripheral administration. Because PPN solutions are relatively dilute, larger volumes are usually necessary to provide nutrient requirements. Additionally, many patients who receive PPN likely will require the use of IVFE to increase caloric support to levels more consistent with CPN regimens. The primary advantages of PPN include a lower risk of infectious, metabolic, and technical complications.[63] However, several other factors may complicate PPN use in many patient populations. Patients who have received multiple courses of chemotherapy, malnourished patients, premature infants, elderly patients, and others with an illness of long duration who have already been subjected to multiple venous accesses for fluid and medication administration

TABLE 151-4 Osmolarities of Select Parenteral Nutrients

Nutrient	Osmolarity
Amino acid	100 mOsm/%
Dextrose	50 mOsm/%
Lipid emulsion (20%)	1.3–1.5 mOsm/g
Sodium (acetate, chloride)	2 mOsm/mEq
Sodium phosphate	3 mOsm/mEq sodium
Potassium (acetate, chloride)	2 mOsm/mEq
Potassium phosphate	1.7–2.7 mOsm/mEq potassium
Magnesium sulfate	1 mOsm/mEq
Calcium gluconate	1.4 mOsm/mEq

are likely to have limited peripheral venous access. PPN use is also limited by relatively poor peripheral vein tolerance to hypertonic solutions. Thrombophlebitis is a commonly reported complication for patients receiving PPN. Although the risk of developing phlebitis is greater with solution osmolarities >600 to 900 mOsm/L (600 to 900 mmol/L), peripherally administered TNA with much higher osmolarities has been associated with low infusion-site complications in some centers.[63] Efforts to minimize development of phlebitis and/or infiltration sequelae for patients receiving PPN include addition of IVFE to the regimen as a possible venous lumen protectant, subtherapeutic heparin doses (0.5 to 1 unit/mL) to prevent thrombus formation, and/or small doses of hydrocortisone (5 mg/L) to minimize access site inflammation.[63] However, heparin is not compatible for use in TNA formulations. Midline catheter use may offer some advantage with reducing the risk of thrombophlebitis.[64] Although these catheters are not central venous access devices, they are longer and infuse into larger venous vessels that may dilute the PN solution to a more tolerable osmolarity. The osmolarity of a PN solution may be estimated by using the guidelines for osmolarities of selected PN components in Table 151–4.

Central Route

CPN is the preferred choice for PN delivery and is used predominantly for patients who require PN for periods of >7 to 14 days during hospitalization or indefinitely at home.[31,65] These patients may have large nutrient requirements, poor peripheral venous access, and/or fluctuating fluid requirements, such as metabolically stressed patients with extensive surgery, trauma, sepsis, multiple-organ failure, or malignancy. CPN solutions are highly concentrated hypertonic solutions that must be administered through a large central vein. Unlike peripheral veins, central veins have a higher blood flow, which quickly dilutes the hypertonic solutions. Disadvantages of CPN include risks associated with catheter insertion, routine catheter use, and care of the access site. Relative to peripheral venous access, central venous catheter access is associated with a greater potential for infection. In addition, the risk of more serious catheter-induced trauma and related sequelae and other serious technical or mechanical problems is greater than that with peripheral access.

The choice of central venous access site depends on a number of factors, including the patient's age and anatomy. Central venous catheters vary in composition, lumen size, number of injection ports, and other special features that affect ease or convenience of care and maintenance. Central venous catheters for short-term use for adults are commonly inserted percutaneously into the subclavian vein and advanced so that the tip is at the superior vena cava.[64] If this approach is not possible, the internal jugular vein can be used. Frequently, short-term central venous access is obtained for critically ill neonates via a catheter placed in the umbilical vein. Other sites for central venous access in infants and older children are similar to those in adults. When therapy is expected to last longer than 4 weeks, the catheter usually is tunneled subcutaneously before entering the central vessel, secured initially with retaining sutures, and anchored in place with a felt cuff that promotes subcutaneous fibrotic tissue growth around the catheter. The injection port may remain external or may be concealed entirely beneath the skin. Implanted central venous catheters have a larger port or reservoir that is surgically placed beneath the skin surface and anchored in the chest wall muscle. Peripherally inserted central catheters (PICCs) are venous access devices that are inserted into a peripheral vein (basilic, cephalic, or brachial) and advanced so that the tip is at the superior vena cava.[64] PICCs are increasingly used for both short- and long-term central venous access in acute or home care settings because of ease and economy of bedside placement.[31,65]

CONSTRUCTING THE PARENTERAL NUTRITION REGIMEN

Once the route of delivery is chosen, components of the PN regimen are determined based on the patient's nutritional assessment. Some healthcare systems may require the entire PN formula to be written in individual components and additives without the use of a standard order form. More commonly, the ordering process has been simplified by the use of order forms designed specifically for PN. These standardized order forms promote education of practitioners by providing brief guidelines for initiating PN and foster cost-efficient nutrition support by minimizing errors in ordering, compounding, and administration.[31] Standardized order forms also may include options for ordering certain related procedures, laboratory tests, protocols for patient management, or consultations with other medical services related to the patient's nutrition support. Standardized forms and protocols should be reviewed and updated periodically to reflect changes in the practices and patient population of a practice setting and advances in technology that may affect provision of nutrition support.

Adult Parenteral Nutrition Solutions

In general, there are two methods for ordering adult PN. The "standard formula approach" offers a variety of base formulations with a fixed nonprotein-calorie-to-nitrogen ratio. This method usually includes different formulas designed for mild to moderately stressed patients, renal failure patients, fluid-restricted patients, and liver failure patients. Because the nonprotein-calorie-to-nitrogen ratio is fixed, the amount of nutrient delivered depends solely on the infusion rate. Standard institutional PN formulations may be compounded; however, standardized commercial PN products or "premixed" solutions are available from manufacturers.[66] Use of a standard institutional formula may promote clinician prescribing of a complete, balanced formulation. Their use may also promote consistent provision of stable, compatible admixtures. However, efficiencies associated with use of the standard formula approach may be hindered if there is a frequent need to modify the PN formulation. Finally, standard PN formulations may be difficult to use in potentially complicated patients, such as neonatal or pediatric patients, or those with severe malnutrition, organ failure, glucose intolerance, large GI losses, or critical illness.[66]

The "individualized formula approach" permits compounding of patient-specific solutions. Compounding of the PN solution is limited only by the concentrations of stock solutions and stability of the additives. The nutrient amount delivered depends on the daily volume of the PN solution infused and the nutrient concentrations in the PN solution. The total daily amount of PN solution may be prepared in multiple bags or more cost-effectively in a single container.[31]

Traditionally, adult PN solutions have been ordered by expressing the final concentrations of each component in the solution. For example, CAA and dextrose are ordered commonly in final percentage, electrolytes in milliequivalents per liter, and other additives in amount (milliliters or units) per day. This inconsistency may promote confu-

Calculation of an Adult Parenteral Nutrition Regimen

Patient case: A patient's daily nutritional requirements have been estimated to be 100 g protein and 2,000 total kcal. The patient has central venous access and reports no history of hyperlipidemia or egg allergy. The patient is not fluid restricted. The PN solution will be compounded as an individualized regimen using a single-bag, 24-hour infusion of a 2-in-1 solution with intravenous fat emulsion (IVFE) piggybacked into the PN infusion line. Determine the total PN volume and administration rate by calculating the macronutrient stock solution volumes required to provide the desired daily nutrients. The stock solutions used to compound this regimen are 10% crystalline amino acids (CAA), 70% dextrose, and 20% IVFE.

1. Determine the daily IVFE calories and volume

   - 2,000 kcal/day × 30%–40% of total calories as fat = 600–800 kcal/day
     Choose IVFE 20% 250 mL/day × 2 kcal/mL = 500 kcal/day

2. Determine the 70% dextrose stock solution volume

   - Determine dextrose calories
     Dextrose calories = TOTAL – IVFE – Protein
     2,000 kcal – 500 kcal IVFE – (4 kcal/g × 100 g CAA) = 1,100 kcal
   - Calculate required dextrose (grams)
     1,100 kcal ÷ 3.4 kcal/g dextrose = 324 g dextrose
   - Determine 70% dextrose volume
     70 g/100 mL = 324 g/X mL 70% dextrose; X = 463 mL 70% dextrose

3. Calculate the 10% CAA stock solution volume

   - 10 g/100 mL = 100 g/X mL 10% CAA; X = 1,000 mL 10% CAA

4. Determine the 2-in-1 PN volume and administration rate

   - Calculate CAA/dextrose volume
     463 mL 70% dextrose + 1,000 mL 10% CAA = 1,463 mL CAA–dextrose
   - Add 100–200 mL for additives
     Total 2-in-1 volume = approximately 1,600–1,700 mL/day
   - Calculate the administration rate
     1,600–1,700 mL/day ÷ 24 hours = 67–71 mL/hour; round to 65–70 mL/hour

5. Choose final 2-in-1 PN regimen and determine provided nutrient amounts:

   - Final 2-in-1 regimen
     100 g CAA/324 gm dextrose in 1,680 mL/day to infuse at 70 mL/hour
     + 20% IVFE 250 mL to infuse at 2 mL/hour
   - Calculate macronutrient calories

20% IVFE calories:	250 mL × 2 kcal/mL =	500 kcal
Dextrose calories:	324 g × 3.4 kcal/g =	1,102 kcal
Protein calories:	100 g × 4 kcal/g =	400 kcal
Total kcal:		2,002 kcal
Nonprotein kcal:		1,602 kcal

FIGURE 151-2. Calculation of an adult parenteral nutrition (PN) regimen. To convert to energy units of kilojoules (kJ) multiply values with kilocalories as the numerator (kcal, kcal/mL, kcal/kg, kcal/g) by 4.18 to give the corresponding value in kilojoules (kJ, kJ/mL, kJ/kg, kJ/g).

sion and misinterpretation of PN solution contents that may result in harm, especially when patients are transferred between health system environments. To ensure that PN labels in all health system environments clearly and accurately reflect the PN solution contents, guidelines for standardized adult PN labeling have been recommended.[31] In addition to including a variety of other information on the label such as dosing weight and administration route, the guidelines recommend expressing PN ingredients in amounts per total volume, which minimizes the need for pharmaceutical calculations to determine the nutrient value of the admixture. Computer software for calculating PN solutions is widely available, and several programs have adapted the recommended labeling guidelines. Pharmaceutical calculations of a 2-in-1 PN regimen are briefly reviewed (see Fig. 151–2).

Several guidelines or clinical rules of thumb are available to help simplify calculation of a PN regimen after a patient's nutritional requirements have been decided. For example, adult patients receiving only PN therapy may need larger volumes of fluid to provide maintenance requirements and replace extrarenal losses. However, patients requiring other IV drug therapy may receive adequate fluid from an additional IV maintenance solution (e.g., 0.45% NaCl in 5% dextrose) and/or piggybacked medications. Depending on individual institutional practices, maximally concentrating the PN solution and using an inexpensive maintenance fluid to manage hydration may provide a cost-effective regimen that requires fewer adjustments. Another guideline that may be helpful in designing a PN regimen is to allow a volume of approximately 100 to 150 mL/L

of base solution (approximately 200 to 300 mL per day) for electrolytes and other additives. PN regimens for patients who require very small amounts of additives, such as patients with renal failure, may be further concentrated.

Pediatric Parenteral Nutrition Solutions

Pediatric PN solutions are typically ordered using an individualized approach because clinical practice guidelines often recommend nutrient intakes based on the patient's weight. To simplify pediatric PN ordering many institutions use a pediatric-specific PN order form that expresses daily nutrient amount based on weight. For example, protein and fat are ordered as grams per kilogram per day, dextrose as milligrams per kilogram per minute, and electrolytes as milliequivalents per kilogram per day. However, some institutions may order macronutrients by expressing the final concentration of each component in the solution. Current safe practice guidelines suggest that the pediatric PN label identify components as an "amount per day" with a secondary expression of components as "amount per kilogram per day."[31] Auxiliary labels may be needed when the format between PN ordering and PN labeling is different. Calculations for determining a pediatric PN solution are reviewed to illustrate fundamental concepts for ordering pediatric PN solutions (Fig. 151–3). Additional features of the pediatric PN label include the dosing weight, administration date and time, expiration date, infusion rate, and duration of infusion. Because infants and children generally receive daily maintenance fluid from the PN regimen, supplemental IV solutions are rarely needed. Pediatric PN may be provided as a 2-in-1 or TNA formulation. However, the TNA system is not recommended for compounding neonatal and infant PN because of IVFE instability with the often needed higher calcium and phosphorus concentrations.[31] The IVFE labeling guidelines for pediatric PN are similar to adult IVFE labeling recommendations.

Administration Techniques

PN solutions should be administered with an infusion pump. The IV administration line for CAA-dextrose solutions should include a 0.22 μm inline filter to remove particulate matter, air, and any microorganisms that may be present in the solution. IVFEs administered separately from the CAA-dextrose solution must be infused into the PN line by utilizing a y-site port beyond the inline filter because the average size of IVFE particles is approximately 0.5 μm.[31] The FDA recommends use of a 1.2 μm filter with TNA solutions, which may be effective in preventing catheter occlusion caused by precipitates or lipid aggregates.[31] This filter size is also reported to remove *Candida albicans*.

INITIATING AND ADVANCING THE PARENTERAL NUTRITION INFUSION

ADULT PARENTERAL NUTRITION

The patient's nutrition status, current clinical status, history of glucose tolerance, and dextrose concentration in the formula will dictate the infusion rate at which the adult PN solution should be initiated. Stable patients with normal organ function and stable baseline serum glucose concentrations have demonstrated minimal effect on serum glucose concentrations when abruptly initiating or discontinuing PN therapy.[67,68] However, another approach is to begin the PN infusion and increase the rate gradually over 12 to 24 hours to the desired rate. The infusion rate is likewise reduced in a stepwise fashion, such as decreasing the rate by 50% for 1 hour prior to discontinuation, when the PN therapy ends.[67] This approach should prevent development of hyperglycemia and rebound hypoglycemia, respectively. Alternatively, the PN regimen may be initiated at the goal infusion rate but with a hypocaloric dextrose dose. The dextrose dose can be increased daily to the goal based on patient response. Tapered initiation and cessation should be considered for patients receiving intermittent subcutaneous regular insulin, patients with severe renal or hepatic disease, and patients with other disease states that may increase the risk for development of hyperglycemia or hypoglycemia, such as severe diabetes or pancreatic malignancy.

Although the IVFE dose should not exceed 2.5 g/kg per day or 60% of total daily calories, lower doses of 1 g/kg per day not to exceed 30% of calories have been recommended to minimize negative effects associated with long-chain fatty acids.[31] Manufacturer's information recommends IVFE infusion over 4 to 8 hours for adults. However, infusion over 12 to 24 hours appears to be the best clinical strategy to promote IVFE clearance and minimize risk of negative effects on pulmonary and immune function.[31,40,43]

The manufacturer's guidelines recommend initiating IVFE for adults with a test dose of 0.5 to 1 mL/min for the first 15 to 30 minutes because of the potential for an immediate hypersensitivity reaction. For most patients, this is probably not necessary because of the relatively low incidence and benign nature of acute adverse reactions. In addition, infusion over 12 to 24 hours eliminates the need for a test dose because the infusion rate is within the range of the test dose rates recommended by the manufacturer. Appropriate electrolytes should be provided to patients with normal organ function based on standard nutrient ranges.[31] Adjustments may be necessary depending on the patient's clinical condition. Adults and children older than 11 years of age should receive daily amounts of trace elements and an adult vitamin formulation.

PEDIATRIC PARENTERAL NUTRITION

Pediatric PN solutions are typically initiated with a volume calculated to provide the patient's daily maintenance fluid requirements on the first day of therapy. Individual substrates are then advanced daily as tolerated with the goal PN regimen generally being achieved by day 3 of therapy. PN should be initiated with the goal protein dose. The initial dextrose dose for older infants and children is based on previous glucose tolerance. Although practices may vary, one approach is to start with 10% dextrose and advance the concentration in 5% increments daily as tolerated to a goal not to exceed 5 to 7 mg/kg per minute. Initial dextrose doses for premature infants should approximate fetal nutrient delivery rates of 5 to 6 mg/kg per minute. Frequently this mathematically translates into a final concentration range of 5% to 10% dextrose. The dextrose concentration for the neonatal PN should be advanced daily by 1% to 2.5% or by 2 to 4 mg/kg/min increments to a goal that does not exceed 12 to 14 mg/kg/min. IVFE is usually initiated at 0.5 g/kg/day for neonates and 0.5 to 1 g/kg/day for older children and increased daily by 0.5 to 1 g/kg/day. Incremental increases of IVFE dose allow daily serum triglyceride evaluation and early detection of those with impaired fat clearance. The IVFE dose should not exceed 60% of total daily calories for neonates and 30% of total calories for children, and the maximum IVFE dose should not exceed 3 g/kg/day (approximately 30 kcal/kg/day) for infants and children.[41] The best clinical strategy for minimizing the risk of adverse effects associated with rapid IVFE administration and promoting IVFE clearance is to infuse IVFE over 20 to 24 hours or at a rate of 0.15 g/kg/h.[40,41] This slow infusion also eliminates the need for a test dose because the infusion rate is less than the test-dose rate recommended by the manufacturer.

IV electrolytes, vitamins, and trace elements should be initiated on the first day of therapy and continued as a daily component of the PN solution.[31] Children younger than age 11 years should receive a vitamin

Calculation of a pediatric parenteral nutrition regimen

Patient case: A 30-week gestational age infant (weight 2 kg) with an estimated nutrition goal of 3 g/kg/day protein, 3 g/kg/day intravenous fat emulsion (IVFE), and 100 nonprotein kcal/kg/day. The infant has central venous access and no history of hyperlipidemia or egg allergy. The PN regimen will be compounded as an individualized regimen using a single-bag, 24-hour infusion of a 2-in-1 solution with 20% IVFE piggybacked into the PN infusion line. Determine the macronutrient calculations to deliver this infant's nutrition goals; 10% crystalline amino acids (CAA) and 70% dextrose stock solutions will be used to compound the solution.

1. Determine the goal daily IVFE amount, volume, and administration rate
   - 3 g/kg/day IVFE × 2 kg = 6 g/kg
   - Calculate 20% IVFE volume
     20 g/100 mL = 6 g/X mL X = 30 mL/day of 20% IVFE
   - Calculate the IVFE administration rate
     30 mL 20% IVFE ÷ 24 hours = 1.25 mL/hour
2. Determine the goal 2-in-1 PN volume and administration rate
   - PN volume based on maintenance fluid requirements
     120 mL/kg/day × 2 kg = 240 mL/day
   - PN infusion rate is 240 mL/day ÷ 24 hours/day = 10 mL/hour
3. Determine the daily protein amount and the corresponding 10% CAA volume
   - Calculate the goal protein amount
     3 g/kg/day × 2 kg = 6 g/day
   - Calculate the 10% CAA stock solution volume
     10 g/100 mL = 6 g/X mL 10% CAA X = 60 mL10% CAA
4. Determine the daily dextrose amount, corresponding 70% dextrose volume, and final dextrose concentration in the 2-in-1 PN solution
   - Goal is to provide approximately 14 mg/kg/min dextrose
     14 g × 2 kg × 1440 minutes/day ÷ 1000 mg/g = 40.3 g dextrose
   - Calculate the 70% dextrose volume
     70 g/100 mL = 40.3 g/X mL 70% dextrose X = 57.6 mL 70% dextrose
   - Calculate the final dextrose concentration of the PN solution
     40.3 g dextrose/240 mL = X g/100 mL X = 16.8% dextrose
5. Determine available volume for additives
   - 240 mL – 60 mL (10% CAA) – 57.6 mL (70% dextrose) = ~122 mL
     Sterile water for injection may be necessary to QS to total volume of 240 mL
6. Determine the final PN regimen and provided nutrient amounts
   - Final PN regimen
     3 g/kg/day CAA and 16.8% dextrose to infuse at 10 mL/hour
     3 g/kg/day (or 30 mL) 20% IVFE to infuse at 1.25 mL/hour
   - Macronutrient calories

20% IVFE:	30 mL × 2 kcal/mL =	60 kcal
Dextrose:	40.3 g × 3.4 kcal/g =	137 kcal
Protein:	6 g × 4 kcal/g =	24 kcal
Total kcal (kcal/kg):		221 kcal (111 kcal/kg)
Nonprotein kcal (kcal/kg):		197 kcal/kg (99 kcal/kg)

To convert to energy units of kilojoules (kj) multiply values with kcal as the numerator (kcal, kcal/mL, kcal/kg, kcal/g) by 4.18 to give the corresponding value in kJ (kJ, kJ/mL, kJ/kg, kJ/g).

FIGURE 151-3. Calculation of a pediatric parenteral nutrition (PN) regimen.

product formulated for pediatric patients. Two multivitamin dosing schemas have been suggested for infants and children.[31] One method recommends 2 mL/kg/day for infants weighing <2.5 kg (5.5 lb) and 5 mL/day for infants and children weighing more than 2.5 kg (5.5 lb). The other suggests 30% of a vial (1.5 mL/day) for infants weighing <1 kg (2.2 lb), 65% of a vial (3.25 mL/day) for infants weighing 1 to 3 kg (2.2 to 6.6 lb), and 100% of the vial (5 mL/day) for children weighing more than 3 kg (6.6 lb)(up to 11 years of age). Adult IV vitamin

formulations should not be used for infants because of potential neurotoxicity from accumulation of polysorbate and propylene glycol preservatives. Weight-based dosage recommendations for pediatric multiple-trace-element formulations are 0.3 mL/kg for children weighing <3 kg (6.6 lb) and 0.2 mL/kg for children weighing more than 3 kg (6.6 lb) (maximum 5 mL/day). Children weighing more than 25 kg (55 lb) should receive an adult trace-element formulation. However, weight-based doses do not provide the recommended daily intake for all trace elements, so individual dosing with single entity products may be necessary. This approach also allows for dose adjustment based on serum trace element assessment, individual patient characteristics (e.g., cholestasis, stool losses, wounds), and the need to minimize administration of trace elements that accumulate in patients receiving chronic PN such as chromium and manganese. Pediatric patients receiving PN commonly transition from PN support to enteral nutrition by gradually, over a period of days to weeks, decreasing the PN infusion rate while increasing the enteral intake. The PN infusion rate should be reduced for 1 to 2 hours prior to stopping the infusion for neonates and infants because of their immature counterregulatory mechanisms that contribute to an increased risk for developing rebound hypoglycemia.[16] Blood glucose concentrations should be checked within 15 to 60 minutes after the PN infusion ends.

CLINICAL CONTROVERSY

Initiation of IVFE earlier than 4 to 7 days of life for infants with a birth weight <800 g remains controversial because of the potential increased risk of chronic lung disease and death. Some clinicians advocate initiating IVFE at 1 to 1.5 g/kg/day within the first week of life and advancing the dose after the second week of life.

CONTINUOUS VERSUS CYCLIC INFUSIONS

6 Use of continuous infusions is attractive for patients with unstable fluid balance or glucose control (see Fig. 151–1). The intermittent or cyclic infusion of PN over a period of time <24 hours, usually for 12 to 18 hours each day, is useful for hospitalized patients with limited venous access in whom administration of multiple other medications requires interruption of the PN infusion.[67] Cyclic PN also may prevent or treat hepatotoxicities associated with continuous PN therapy. In addition, this delivery mode allows patients receiving PN at home the ability to resume a relatively normal lifestyle.[67] Various protocols have been reported that suggest incremental increases to the maximum infusion rate for a desired period of time followed by a gradual taper to discontinue the solution.[16,67] However, metabolically stable adults and older children (older than age 2 years) receiving fat-based PN regimens are likely candidates for abrupt initiation and discontinuation of their intermittent PN regimen.[16,67] Cyclic PN is not optimal for all patients and should be used with caution for those with severe glucose intolerance or diabetes, or unstable fluid balance.

EVALUATION OF THERAPEUTIC OUTCOMES

7 Thorough and consistent monitoring of patients who are receiving PN is necessary to ensure that the desired nutritional outcomes are achieved and to prevent the occurrence of adverse effects or complications. Routine evaluation should include the assessment of the patient's clinical condition with a focus on nutritional and metabolic effects of the PN regimen. Serial documentation of a patient's response to a particular regimen is a helpful guide for determining appropriate adjustments in fluid, electrolyte, and nutrient therapies.

Several biochemical and clinical measurements are necessary for effective monitoring of patients receiving PN. Serum concentrations of electrolytes, hematologic indices, and biochemical markers for renal function, liver function, and nutrition status should be measured prior to PN initiation and periodically thereafter depending on the patient's age, nutrition status, and clinical condition. The frequency of blood laboratory measurements for neonates and infants tends to be more conservative because of their smaller circulating blood volumes and, in some cases, lack of central vascular access. Other important clinical measurements include vital signs, weight, total fluid intake and losses, and nutritional intakes. Weekly measurements of height/length and head circumference are helpful for monitoring nutritional changes in neonates. Monitoring parameters considered important for patients receiving PN and the suggested frequency of measurement for each are outlined in Figure 151–4. Appropriate assessment and evaluation of patient data can identify potential complications that may be avoided or treated early. Monitoring protocols should be developed and tailored for the patient population, medical practices, and resources of individual practice settings.

COMPOUNDING, STORAGE, AND INFECTION CONTROL

The United States Pharmacopeia (USP) Chap. 797 details the procedures and requirements for compounding sterile preparations including PN formulations.[69] These standards apply to all healthcare settings in which sterile preparations are compounded and are used by boards of pharmacy, the FDA, and accreditation organizations such as the Joint Commission. Compounded sterile preparations are defined by risk level (immediate use, low, low with 12-hour beyond use date, medium, and high) based on the probability of microbial, chemical, or physical contamination. PN solutions are classified as a medium-risk compounded sterile preparation. In general, PN solutions should be prepared using aseptic technique in a device or room that meets International Organization for Standardization (ISO) Class 5 standards that is located in an ISO Class 7 buffer area with an ISO Class 8 ante area.[69] Personnel must be trained adequately for personnel cleansing and garbing procedures and aseptic manipulations. Supervision by a pharmacist experienced in compounding IV solutions and knowledgeable about stability, compatibility, and storage of PN solutions is necessary. Quality assurance procedures should be developed to maintain safe and accurate admixture preparation. A standardized process for PN ordering, labeling, determining nutrient requirements, screening of the PN order, PN administration, and monitoring has been recommended to minimize risk of potentially life-threatening compounding errors.[31,66,70,71] The potential risk of infectious complications associated with PN solution contamination can be decreased greatly when pharmacy-based admixture programs follow specific guidelines developed to ensure proper compounding of PN solutions.[69]

In general, the type of solution being prepared dictates the methods of compounding, storage, and infusion. Currently, the two most commonly used types of PN solutions are 2-in-1 solutions with or without IVFE piggybacked into the PN line and TNAs. Methods for compounding PN solutions vary based on a healthcare system's patient population and medical practices and the number of PN solutions that need to be prepared. PN base solutions may be prepared by using gravity-driven transfer of CAA stock solutions to partially filled bags of concentrated dextrose stock solutions.[31,72] Other practice settings may use standardized

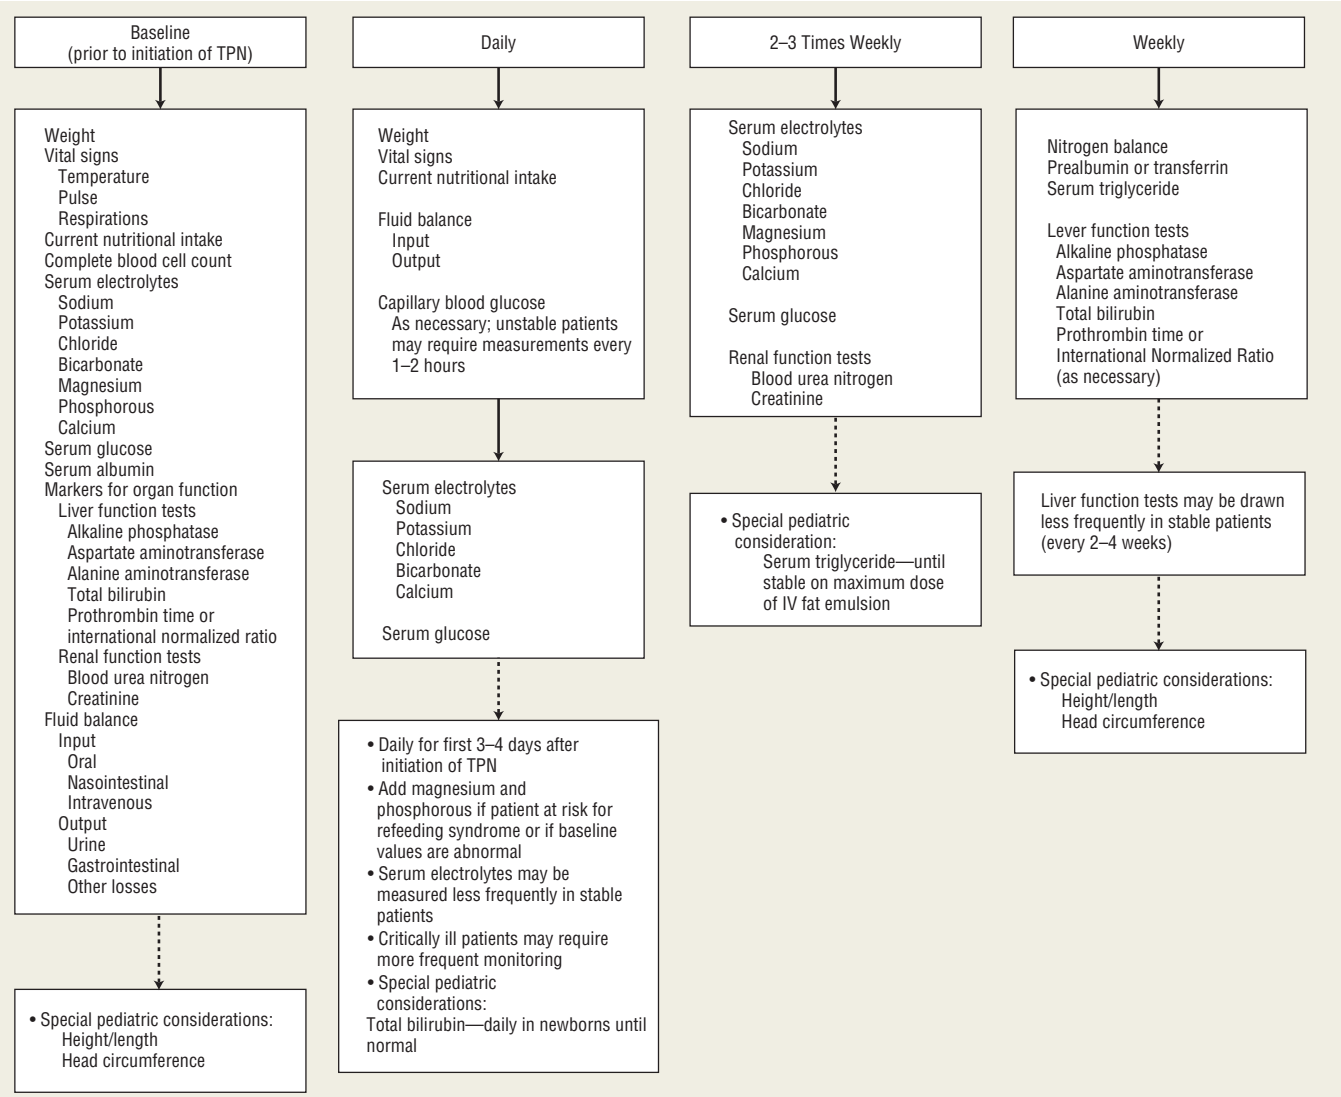

FIGURE 151-4. Monitoring strategy for patients receiving parenteral nutrition (PN).

commercial PN products with CAA and dextrose separated within a single bag that must be mixed prior to use.[31,66] Advances in compounding technology have facilitated use of automated compounders for preparing PN solutions. Automated compounders are computer-based systems that perform the calculations necessary to determine volumes of nutrient stock solutions for PN formulations. In addition, most automated compounder systems include software that communicates the determined calculations directly to a transfer pump device that delivers fluid from the source container to the final container by either a volumetric or gravimetric fluid pumping system.[72] Advantages associated with automated compounders include reduced personnel time and compounding materials and improved compounding accuracy. Disadvantages include the potential for equipment failure and power outages.

Assurance of solution sterility during compounding, storage, and administration is necessary to reduce the risk of infection and related complications. Because of their acidic pH and hypertonicity, 2-in-1 PN formulations are poor media for microbial growth.[31,73] However, several characteristics of IVFE such as isoosmotic tonicity, near-neutral to alkaline pH, and glycerol content favor microbial growth, particularly at room temperature.[31] When IVFEs are added to dextrose-CAA solutions to make TNAs, the growth potential is decreased, presumably due to the protective effects of the hypertonic dextrose-CAA solution and decreased pH.[64,74]

CAA-dextrose solutions generally are stable for 30 days if refrigerated at 4°C (39.2°F) and protected from light.[27] However, because of the risk for microbial contamination, manufacturers recommend storage of PN solutions for as little time as possible after preparation. The USP 797 standards recommend storage times of not more than 30 hours at controlled room temperature [20°C (68°F) to 25°C (77°F)] and not more than 9 days at cold temperatures [2°C (36°F) to 8°C(46°F)] for all medium-risk compounded sterile preparations, including PN solutions.[69]

Because IVFEs support growth of gram-positive and gram-negative bacteria as well as fungi, the Centers for Disease Control and Prevention (CDC) recommend that infusion time for IVFE administered as a separate infusion should not exceed 12 hours, unless volume considerations require more time, in which case the infusion should be completed within 24 hours.[64] The CDC guidelines also recommend use of administration sets for 2-in-1 PN for up to 72 hours, but those used for TNA solutions and IVFE should be changed every 24 hours.[64]

Compliance with recommendations for safe IVFE administration to pediatric patients is challenging. First, the maximum recommended rate of IVFE infusion for infants typically requires an infusion time >12 hours, the recommended infusion time to minimize the risk of IVFE contamination. For example, an infant receiving the maximum recommended IVFE dose (3 g/kg/day) at the maximum recommended rate of 0.15 g/kg/h would require at least a 20-hour infusion.[41] Some institutions attempt to comply with a 12-hour hang time by dividing the daily dose into two unit volumes and infusing them over 12 hours each. Second, commercially available IVFE products are not manufactured in unit volumes consistent with the daily volumes usually prescribed to infants, which may be as low as 2 mL/day. Infants receiving unit volumes larger than those prescribed are at risk for adverse events associated with IVFE infusion-related errors. Finally, use of TNA formulations, which would allow IVFE infusion over 24 hours with decreased contamination risk, are not an option because they are not recommended for neonates and infants.[31] Because of these reasons, some institutions aseptically transfer IVFE into plastic syringes for syringe pump infusion to improve safety and to comply with IVFE administration rate recommendations.[74–76] Use of repackaged IVFE preparations, however, has been associated with increased risk of contamination during compounding or infusion because of IV line manipulation.[74,76] There are no consistent recommendations for an acceptable infusion time of repackaged IVFE preparations for non-TNA use. In fact, the CDC recommendations do not address use of repackaged IVFE preparations.[64] Given the well-documented risk of microbial contamination with IVFE manipulation, however, a 12-hour maximum infusion time for repackaged IVFE seems prudent.

CLINICAL CONTROVERSY

Repackaging IVFE for administration to neonates and infants has been heavily debated. While some clinicians argue that the benefits of cost effectiveness and increased patient safety outweigh the risks of microbial contamination, other clinicians continue to advocate for the delivery of IVFE direct from the manufacturer's container to decrease infection risk. Other IVFE practices vary greatly from institution to institution, including the most appropriate IVFE infusion rate, hang times for repackaged and nonrepackaged IVFE, and the number of IVFE units prepared and administered per patient per day based on established IVFE hang times.

STABILITY AND COMPATIBILITY

Comprehensive current information regarding compatibility and stability of PN solutions can be found in several reference sources such as *Handbook on Injectable Drugs*[73] and *King Guide to Parenteral Admixtures*.[77] In many cases, the answer to a compatibility question may not be readily available, and a review of the primary literature may be necessary. When information is not available, clinical judgment and experience must be used carefully to resolve the situation.

The stability of a PN formulation is determined by the rate or degree of component degradation and any resulting changes in chemical integrity or pharmacologic activity that may render the formulation unsuitable for safe administration. In general, the sterile combination of PN components accelerates the rate of physicochemical destabilization of all of the components in the formulation; certain amino acids, vitamins, and IVFE are the most susceptible nutrients.[31] When compounded and stored appropriately, the degree of degradation is usually not clinically relevant for most patients receiving short-term PN because many patients have sufficient stores of those susceptible nutrients to support any short-term periods of suboptimal intake thereby minimizing risk of clinical symptoms of deficiency. However, nutrient degradation that is more extensive may be problematic for patients with marginal nutrient stores who receive long-term PN. TNAs present additional stability challenges because of the presence of IVFE in the solution. IVFE stability in TNAs is affected by amino acid and dextrose concentration, solution pH, order of mixing, electrolyte amounts, and final TNA volume as well as container material, storage conditions, and addition of nonnutrient drugs. Stability studies on the effect of specific electrolyte concentrations on TNA stability are limited. In general, IVFE stability is affected by the PN cation content. Divalent and trivalent cation additives such as calcium and magnesium have a greater destabilizing potential compared with monovalent cation additives such as sodium and potassium. However, when given in sufficiently high concentrations, monovalent cation additives may also produce instability. Cations act to reduce the surface potential of the emulsion droplet, thereby enhancing tendency to aggregate and ultimately, in some cases, destabilize the solution to coalescence or a "cracked" admixture.[27,31,78] When a cracked IVFE occurs, the oil phase separates from the water phase resulting in the appearance of free oil fat globules. Early stages may appear as subtle changes in the uniformly white appearance of the TNA, which may progress to yellow oil streaks throughout the bag or development of an amber oil layer at the top of the admixture bag. TNA formulations with any visible free oil should be considered unsafe for parenteral administration because infusion of circulating fat globules may be of sufficient size to accumulate in the pulmonary vasculature and potentially compromise respiratory function. In general, the likelihood of preparing an unstable TNA formulation can be minimized by maintaining the final concentrations of CAA >4%, dextrose >10%, and IVFE >2%.[78] Specific guidelines for compounding TNA formulations are reviewed elsewhere.[27]

Because of differences in pH among various CAA products and in phospholipid content among IVFE products, the manufacturer of each product should be consulted for compatibility and stability information prior to routine mixing of components. One approach to compounding TNA formulations manually is to first combine CAA, dextrose, and sterile water (if necessary). Add electrolytes, vitamins, and trace elements, and then visually inspect the solution for precipitate or other particulates. Finally, add IVFE and visually inspect the solution to ensure a uniform emulsion exists.[27,44] However, mixing components in this specific order and time sequence may not be possible with the use of automated compounders. Although CAA, dextrose, and IVFE may be simultaneously transferred to an admixture container, the compounder's manufacturer should be consulted for the optimal mixing sequence to ensure safe compounding of TNA solutions.

The precipitation of calcium and phosphorus is a common interaction that is potentially life-threatening.[27,31,79] Factors that enhance the risk of precipitate formation include high concentrations of calcium and phosphorus salts, use of the chloride salt of calcium, decreased amino acid and dextrose concentrations, increased solution temperature, increased solution pH, use of an improper sequence when mixing calcium and phosphorus salts, and the presence of other additives including IVFEs.[27,31,79] In general, steps to minimize risk of calcium and phosphate precipitation in PN formulations include use of calcium gluconate instead of calcium chloride because it is less reactive, adding phosphate salts early in the mixing sequence, adding calcium last or nearly last, and agitating the mixture throughout the admixture process to achieve homogeneity. PN formulations with a lower final pH should be used when clinically appropriate. Higher final concentrations of dextrose and CAA and

lower final concentrations of IVFE favor a lower admixture pH. CAA product-specific solubility curves that are available from the manufacturer or primary literature should be used for determining solubility. Use of a calculation to derive a sum or product of calcium and phosphate concentrations should not be used as the sole criterion for determining solubility since products of calcium and phosphate concentrations vary inconsistently as calcium concentration decreases and phosphate concentration increases.[79]

Electrolyte stability in TNA solutions is difficult to assess because of poor visualization of a precipitate should one occur. PN solutions for neonates and infants tend to have larger calcium and phosphorus amounts, as well as other divalent cations, that limit the use of TNA formulations. Because of the relatively limited amount of published stability information, the use of a 2-in-1 formulation with separate administration of IVFEs is recommended for neonates and infants.[31] In general, alternative methods of delivering electrolytes or other medications should be pursued in any clinical situation in which compatibility information involving a TNA solution is lacking. Because the addition of bicarbonate to acidic PN solutions may result in the formation of carbon dioxide gas and insoluble calcium and magnesium carbonates, sodium bicarbonate use in PN solutions is not recommended.[31] Use of a bicarbonate precursor salt such as acetate usually is preferred.

Vitamins may be affected adversely by changes in solution pH, presence of other additives, storage time, solution temperature, and exposure to light.[27] Because of variable stabilities of individual vitamins, IV vitamin solutions should be added to the PN solution as near to the time of administration as is clinically feasible and should not be in the PN solution longer than 24 hours.

Increased peroxide concentrations have been reported in IVFE and dextrose-amino acid solutions after addition of IV multivitamins and/or exposure to air or light.[80] Multiple in vitro experiments have reported negative effects of peroxides and associated metabolites on organ and immune function. Peroxides are associated with neonatal hypoxic–ischemic encephalopathy, intraventricular hemorrhage, periventricular leukomalacia, chronic lung disease, retinopathy of prematurity, and necrotizing enterocolitis.[80] Neonates and infants are at increased risk for harmful effects of peroxides because they receive a higher daily peroxide load from PN solutions and they have lower endogenous antioxidant levels. Protecting PN and IVFE solutions from light is therefore recommended to minimize peroxide formation.[21,80]

Many patients receiving PN also receive other IV medications. The compatibility of these medications and other IV solutions is an important concern. Although some medications may be added directly to the PN solution and administered at the same rate as the PN infusion, most are administered as a separate admixture piggybacked in the PN line. Several criteria should be considered before medications are added directly to the PN solution because of the potential for ineffective drug therapy or other complications associated with physiochemical incompatibility and stability of the PN solution.[31] First, the drug should be stable for at least 24-hours and should have pharmacokinetic properties appropriate for continuous infusion. Second, there should be documented chemical and physical compatibility of the medication with PN mixture components and other medications that may be piggybacked concomitantly into the PN line. Advantages of using PN admixtures as drug vehicles include consolidation of dosage units, improved pharmacodynamics for certain drugs, conservation of fluid in volume-restricted patients, fewer venous catheter violations, and decreased compounding and administration times. However, a major disadvantage to the use of PN solutions as drug-delivery vehicles is the lack of compatibility and stability data for the PN solutions that are used commonly in clinical practice. Medications frequently added to PN solutions include regular insulin and histamine-2 receptor antagonists.[31,73,77]

COMPLICATIONS OF PARENTERAL NUTRITION

MECHANICAL OR TECHNICAL COMPLICATIONS

Mechanical or technical complications include malfunctions in the system used for IV delivery of the solution, such as infusion pump failure, problems with administration sets or tubing, and problems with the catheter. While problems associated with infusion pumps and administration sets can be decreased by appropriate equipment selection and routine care and monitoring, catheter-related complications are potentially life threatening. Pneumothorax, catheter misdirection or migration into the wrong vein or improperly positioned within the cardiac chambers, arterial puncture, bleeding, and hematoma formation may occur during surgical placement of the catheter. Many of these complications, in addition to venous thrombosis and air embolism, can occur after insertion. Catheters occasionally occlude or break during use. If these problems cannot be rectified easily, the catheter may need to be surgically replaced.

INFECTIOUS COMPLICATIONS

Infectious complications can be a major hazard for patients receiving CPN because of the increased risk associated with the presence of an indwelling central venous catheter (CVC). The source of a CVC infection may be skin organisms at the catheter insertion site, contamination of the catheter hub, or hematogenous seeding of the catheter from a distant site. In addition, patients receiving PN therapy are often predisposed to infection because of compromised immunity and/or concomitant infection. Frequent use of broad-spectrum antibiotic therapy and malnutrition are also predisposing factors for development of infection. The risk of catheter infection is increased for those who require multiple manipulations of the line used for PN administration. The risks for infection are also increased for those who experience failure of in-line bacterial filter, poor catheter placement technique, and poor CVC and insertion site care.[64]

Infection rarely develops secondary to solution contamination.[64,81] Strict adherence to protocols for preparation of PN solutions should minimize this occurrence.[31,69] Catheter-related bloodstream infection (CRBSI), defined as the presence of clinical manifestations of infection (e.g., fever, chills, and/or hypotension), associated with bacteremia or fungemia resulting from no apparent source other than the catheter is a common source of systemic infection.[81] Before this diagnosis can be made, there should be evidence of more than one positive blood culture obtained from the peripheral vein with growth of the same organism from a blood culture obtained from the catheter or catheter segment. When a CRBSI is suspected or confirmed, appropriate antimicrobial therapy is initiated. Retention or removal of the central catheter depends on the patient's severity of illness, the suspected or identified pathogen, and the type of catheter involved. The catheter may be removed and replaced in the same site; the catheter may be removed and replaced at a different anatomic location, or it may not be replaced.[81] Recently, the use of 70% ethanol lock therapy has shown promising results for the prevention and treatment of CRBSI for patients receiving long-term PN.[82,83] Specific guidelines for treatment of CRSBI have been recently reviewed.[81]

METABOLIC AND NUTRITIONAL COMPLICATIONS

8 Metabolic and nutritional complications associated with PN therapy are numerous, frequently multifactorial in origin, and if left untreated, some are potentially fatal. Metabolic abnormalities

TABLE 151-5 Metabolic Abnormalities Associated with PN Macronutrients

Abnormality	Possible Etiologies
Hyperglycemia	Metabolic stress, infection, corticosteroids, pancreatitis, diabetes mellitus, peritoneal dialysis, excessive dextrose administration
Hypoglycemia	Abrupt dextrose withdrawal, excessive insulin
Excess carbon dioxide production	Excess dextrose administration
Hypertriglyceridemia	Metabolic stress, familial hyperlipidemia, pancreatitis, excess IVFE dose; rapid IVFE infusion rate
Abnormal liver function tests (elevated ALT, AST, Alk Phos, Bili)	Metabolic stress, infection, excess carbohydrate intake, excess caloric intake, EFAD; long-term PN therapy

ALT, alanine aminotransferase (SGPT); AST, aspartate aminotransferase (SGOT); Alk Phos, alkaline phosphatase; Bili, bilirubin; EFAD, essential fatty acid deficiency; EN, enteral nutrition; IVFE, intravenous fat emulsion; PN, parenteral nutrition.

related to substrate intolerance, fluid and electrolyte disorders, and acid–base disorders are summarized in Table 151–5 and multiple review articles.[31,33,42,43,61,67,84–94]

Parenteral Nutrition–Associated Liver Disease

PN-associated liver disease (PNALD) as evidenced by elevations in total bilirubin, aspartate aminotransferase, alanine aminotransferase, and alkaline phosphatase is well documented.[84,85] No single etiology has been identified, although several risk factors have been reported. Risk factors for children include degree of prematurity, sepsis, hypoxia, lack of enteral nutrition, small bowel bacterial overgrowth, GI conditions requiring surgical intervention, duration of PN therapy, and long-term administration of excessive calories.[43,84,85] PNALD in infants is characterized clinically by a serum direct bilirubin concentration >2 mg/dL (34.2 μmol/L).[84] Taurine deficiency has been proposed as an etiology of cholestasis for preterm infants and neonates.[84,85] Taurine is a conditionally essential amino acid that is not present in standard CAA solutions but is important for neonatal and infant bile metabolism. However, the effectiveness of PN regimens with CAA solutions containing supplemental taurine is unclear. Recent studies have focused on the potential relationship between IVFE and the development of PNALD.[47–49] Soybean-oil-based IVFEs contain large concentrations of plant sterols or phytosterols which are inefficiently metabolized to bile acids by the liver. Experimental data suggest parenteral phytosterols may impair bile flow. Improvement or reversal of PNALD has been reported for patients who received a fish-oil-based IVFE that is not currently commercially available in the United States.

Risk factors for PNALD in adults include preexisting liver diseases, sepsis, preexisting malnutrition, extensive bowel resection, prolonged duration of PN therapy, lack of enteral intake, nutrient deficiencies such as choline deficiency, and long-term administration of excessive calories.[84,85] PNALD in adults typically presents as steatosis and steatohepatitis on biopsy. Clinically, PNALD is characterized by mild elevations in serum liver enzymes, usually less than three times the upper limit of normal, with peak enzyme levels usually occurring between 1 and 4 weeks after initiating PN. In many cases, the liver abnormalities improve or resolve with manipulation of substrate intake or discontinuation of PN therapy. However, in severe cases, liver dysfunction may progress to overt failure and death despite use of traditional therapies such as using cyclic PN, ursodiol, and oral antibiotics for bacterial overgrowth; maximizing enteral feeding; and avoiding sepsis and parenteral overfeeding.[84,85] Intestinal transplant with or without liver transplantation has become a treatment option for those PN-dependent patients who have progressive PNALD.

Hypertriglyceridemia

Hypertriglyceridemia, defined as serum triglyceride concentrations >400 mg/dL (4.52 mmol/L) for adults and 150 mg/dL (1.70 mmol/L) to 200 mg/dL (2.26 mmol/L) for preterm infants, neonates, and older pediatric patients, may occur for patients receiving IVFE-based PN. Risk factors include preexisting liver or pancreatic dysfunction, sepsis, multiple-organ failure, degree of prematurity, IVFE infusion rate, and dose.[31,40,43]

IVFE-associated hypertriglyceridemia is generally thought to be caused by defective lipid clearance or an excessive rate of IVFE administration.[31,41] Premature infants and neonates have relatively slower lipid clearance than do adults because of immature metabolic pathways, including decreased lipoprotein lipase activity.[40,41,43] Reducing the IVFE infusion rate or dose or withholding IVFE therapy should be considered when patients present with hypertriglyceridemia or lipemic serum.[31,41] Use of low-dose heparin (1 unit/mL of 2-in-1 PN formulation) to stimulate lipoprotein lipase activity has been suggested as a potential therapeutic intervention to treat IVFE-associated hypertriglyceridemia in neonates.[16,41] However, others have suggested that the risk associated with heparin delivery via PN outweighs clinical benefits because of the potential for compounding errors associated with heparin and insulin confusion.[70] The role of carnitine for treatment of IVFE-associated hypertriglyceridemia is not clear.[16,41]

CLINICAL CONTROVERSY

Carnitine may be considered conditionally essential for neonates, particularly preterm neonates, due to lack of placental carnitine transfer in the third trimester and immature neonatal biosynthetic capacity. While some clinicians refrain from using carnitine beyond the neonatal period, others argue that a trial of carnitine supplementation for patients with hypertriglyceridemia receiving standard doses of IVFE is warranted.

Hyperglycemia

Hyperglycemia is one of the most common complications associated with PN administration and is associated with a history of diabetes, metabolic stress, adverse effects of medications such as glucocorticoids and excessive carbohydrate administration. In the pediatric population, additional risks for hyperglycemia include prematurity and surgery. The optimal blood glucose concentration for acutely ill hospitalized patients receiving PN is not known. A target range of 100 to 150 mg/dL (5.6 to 8.3 mmol/L) has been suggested, but a recent investigation of blood glucose control for critically ill adult medical and surgical patients reported decreased mortality when blood glucose was maintained in a target range of 144 to 180 mg/dL (8.0 to 10.0 mmol/L).[31,86] Clinical management of PN patients with hyperglycemia has not been well studied and is largely empiric. Blood glucose concentrations can be controlled with regular insulin, which may be given subcutaneously or added to the PN formulation. One approach for adult PN patients requiring insulin or oral hypoglycemic agents prior to starting PN therapy is to initiate PN with approximately 100 to 200 g of dextrose and add 0.05 to 0.1 units of regular insulin per gram of dextrose in the PN solution for those patients with mild hyperglycemia [130 to 150 mg/dL (7.2 to 8.3 mmol/L)]. The insulin dose may be increased to 0.15 to 0.2 units per gram of dextrose for patients with moderate hyperglycemia [151 to 200 mg/dL (8.4 to 11.1 mmol/L)]. [31,87] Blood glucose concentrations should be monitored every 4 to 6 hours. Blood glucose measurements above the goal range should be treated with regular insulin administered subcutaneously according to an

appropriate sliding scale. The insulin dose is modified daily by adding 60% to 100% of the sliding-scale insulin given over the previous 24 hours to the PN formulation daily until blood glucose concentrations are stable and within the target range. Once blood glucose measurements are stable, the dextrose dose may be advanced. The frequency of monitoring blood glucose concentrations may be decreased once blood glucose concentrations are stable within the target range at the goal dextrose dose. Use of a separate IV insulin infusion is most commonly used for pediatric patients, but it may also provide better and safer glycemic control for patients with very large insulin requirements or unstable marked fluctuations in their blood glucose concentrations.

Refeeding Syndrome

Severe and rapid declines in serum phosphate, potassium and magnesium concentrations, fluid retention, and other micronutrient deficiencies are common features of the refeeding syndrome.[88,89] Individuals at risk for refeeding syndrome include those who are severely malnourished with significant weight loss and who receive aggressive nutritional supplementation. Other examples of patients receiving PN therapy who may be at risk for developing refeeding syndrome abnormalities include those who are unfed for 7 to 10 days with evidence of stress or nutritional depletion; those with chronic diseases causing undernutrition such as cancer, cardiac cachexia, chronic obstructive pulmonary disease, or cirrhosis; and those individuals who were previously morbidly obese and have experienced massive weight loss.[88] The mechanism of the electrolyte abnormalities appears to be related to acute provision of macronutrient substrates that promote anabolism in an environment of depleted total body stores of phosphorus, potassium, and magnesium. Recommendations for initiating PN in adults at risk for refeeding syndrome include providing 25% to 50% of the calculated nonprotein caloric requirements initially. The dextrose dose should be initiated at approximately 100 to 200 g/day. Calories should be advanced over 3 to 4 days to the desired goal. Because the metabolic abnormalities described with refeeding syndrome appear to be related primarily to acute provision of large amounts of dextrose, the goal protein dose may be provided with the initial PN infusion. Pediatric PN regimens are usually advanced over several days as a general practice for all pediatric patients. Additional recommendations for minimizing the risk of refeeding syndrome for pediatric patients include provision of additional phosphorus and potassium above standard nutrient requirements at the time PN is initiated.[43]

Complications Associated with Long-Term PN

Other nutritional complications of PN therapy may develop over a prolonged course of therapy (weeks to months) as a result of inappropriate intake of a particular nutrient. Certain conditions, such as metabolic stress in a previously malnourished patient, may elicit symptoms of deficiency much earlier if a nutrient is not appropriately provided. For example, lactic acidosis and other life-threatening complications associated with severe thiamine deficiency have been reported for patients who received PN solutions without multivitamin supplementation.[90] Maintenance doses of vitamins, trace elements, and essential fatty acids should be provided to all patients with normal age-related organ function receiving PN.

Essential Fatty Acid Deficiency

Patients receiving PN regimens without IVFEs for extended periods (weeks to months) are at risk for development of EFAD. Clinical signs of EFAD include hair loss, desquamative dermatitis, thrombocytopenia, and malabsorption and diarrhea resulting from changes in intestinal mucosa.[31,42] EFAD also may be diagnosed by evaluating plasma fatty acid profiles. Although this assessment is not routinely available, it can be provided by several larger regional labs. A triene-to-tetraene ratio more than 0.4 is biochemical evidence for EFAD. Although the time in which EFAD may develop is dependent on the patient's nutrition status, disease state, and age, these manifestations may occur 2 to 4 weeks after initiation of fat-free PN in adults and within 48 hours in newborn infants[40,42] (see Chap. 149).

Metabolic Bone Disease

Metabolic bone disease has been reported for adults and children receiving long-term home PN.[84] This disorder in adults is characterized by osteomalacia with or without osteoporosis that may present without associated clinical, radiologic, or biochemical abnormalities. The diagnosis may not be made for premature infants until after the development of bone fractures or overt rickets. The etiology is poorly understood and likely multifactorial. Treatment options include pharmacologic intervention, calcium and vitamin D supplementation, and exercise. Since excessive vitamin D has also been implicated in the development of metabolic bone disease, others have recommended removal of vitamin D from the PN for patients with a normal 25-hydroxyvitamin D concentration and low serum parathyroid hormone and 1,25-hydroxyvitamin D concentrations.[16,84]

Trace Elements and Vitamin Complications

Clinical symptoms of trace element deficiencies, although rare, have been reported for patients receiving PN. More commonly, decreased serum trace element concentrations have been reported in a variety of patient populations. However, the clinical significance of decreased concentrations of many trace elements is not known because serum concentrations often do not correlate with total body stores.[57,58] Occasionally, patients may develop clinical toxicities from elevated vitamin or trace element intakes or decreased metabolism. These abnormalities are frequently associated with an underlying disease state such as severe renal or hepatic failure and may necessitate reduction in vitamin and trace element intake. (See Chap. 153.)

Many trace elements are present in PN components as contaminants.[50] Some investigations of patients with normal organ function who were receiving PN supplemented with commercially available parenteral multiple trace element solutions have reported concern with elevated serum concentrations of trace elements such as chromium and manganese.[91] Aluminum is a common contaminant of many sterile IV solutions, including those used for compounding PN. Calcium and phosphorus solutions are among those components with higher levels of aluminum contamination.[92,93] Aluminum accumulation may occur during long-term PN therapy, especially for patients with renal insufficiency, and is associated with abnormal neurologic and hematologic function and metabolic bone disease in adults and premature infants.[84,92,93] Preterm infants are at higher risk of aluminum toxicities because they receive larger doses (micrograms per kilogram) from PN solutions than adults.[92] Preterm infants are also more likely to retain aluminum because of immature renal function. Although the maximum safe level of IV aluminum intake is unknown, the FDA has reported that parenteral doses of 4 to 5 mcg/kg/day were associated with central nervous system and bone toxicity for patients with impaired renal function, including premature neonates.[94] Even smaller amounts may result in tissue accumulation but no documented toxicity.

Recent data suggest that the aluminum content of sterile solutions used for compounding PN has declined as a result of awareness of toxicity and improvements in industrial PN component preparation.[92] However, in 2004 the FDA implemented a restriction of aluminum content in large-volume PN stock solutions

(CAA, dextrose, sterile water for injection, IVFE) to a maximum of 25 mcg/L and a requirement for manufacturers to indicate the maximum aluminum concentration at expiration for both large and small volume parenteral products used for PN.[94] After the FDA standards were in effect, a study evaluating the amount of aluminum in parenteral products revealed that aluminum content varied considerably during the shelf life of the product and tended to increase with time due to leaching from glass containers. The amount of aluminum contamination delivered to patients receiving long-term parenteral therapy, such as chronic PN patients or dialysis patients, is substantially reduced if newer stock is used for their therapy.[93]

HOME PARENTERAL NUTRITION

Advances in technology for the delivery of IV solutions have allowed medically stable patients who require extended PN therapy to be maintained indefinitely on IV nutrition. An increasing concern for cost containment of healthcare services has fostered use of sophisticated infusion devices to provide PN at home. Numerous programs are now available outside the traditional healthcare setting to support patients with various long-term or permanent medical conditions. Standards have been developed to promote safe and effective care.[95] Home PN services may be coordinated and administered through a hospital or by a commercial home care company.

Many factors are considered in selecting candidates for home PN therapy. Significant benefit must be expected from the therapy. Examples of patients who have been maintained successfully with home PN include those with severe GI dysfunction secondary to Crohn disease, ischemic bowel disease, severe GI motility disorders, extensive intestinal obstruction, and congenital bowel dysfunction.[96] The patient and the patient's caregiver must be willing to complete training and assume numerous responsibilities for managing the new daily routine in the home. Other logistics such as funding, procurement of solutions and supplies, and clinical management and followup must be evaluated, resolved, and individualized for each patient in order to achieve the desired outcomes.[95]

Patients commonly receive PN solutions from the home care provider. IV vitamins or other additives may be added daily by the patient or caregiver, depending on the arrangement with the home care provider. The solution generally is administered through the night by infusion pump over 10 to 12 hours.[67] A cycled regimen allows the patient time away from the pump during daylight hours and provides many patients with the freedom to have a reasonably normal daily routine. Clinical management and followup are performed periodically according to the needs of the patient and the protocol of the home care provider or the managing healthcare team. A coordinated effort among several healthcare professionals, including physicians, pharmacists, nurses, social workers, and the patient and the patient's caregiver, as well as the suppliers, is paramount to providing safe and effective management. Home PN affords some patients the potential for an ambulatory lifestyle while maintaining an IV feeding regimen that was previously only available in the hospital setting. For others, home PN may contribute to a better quality of life in the comfort of their home.[96]

PHARMACOECONOMIC CONSIDERATIONS

9 Because numerous variables have an impact on the provision of PN support and the response to therapy, determining the true cost of PN is difficult.[96–99] In general, PN is an expensive intervention, and cost varies depending on the underlying indication for treatment and whether PN is provided at home or in an acute care setting.[96–99] Expenses associated with PN therapy may be categorized as direct and indirect costs.[100] Direct costs may be further categorized as fixed or variable costs. Fixed costs do not depend on the volume of patients receiving therapy. For example, an automatic compounder and the tubing sets required to transfer volumes of stock solutions to the administration bag would be considered fixed costs in many practice settings. These costs per patient tend to be highest in low-volume environments. Variable costs such as PN administration bags depend directly on the number of patients receiving PN. Other direct costs include ancillary services required by patients receiving PN and costs related to the management of nutritionally associated complications.

Benefits and other clinical effects of PN (i.e., length of stay and frequency of complications) in specific patient populations have been evaluated.[15,16,18,19] Few investigations have reported an economic assessment of the therapy. However, economic data from many of these reports would not necessarily reflect current costs. Indeed, the direct cost of PN solution components generally has declined over the past 10 to 15 years. Attempting to measure the cost or cost savings associated with reported benefits of PN therapy and other clinical effects based on results of controlled clinical trials is difficult.[97,98] Clinical outcomes measurements and hence economic outcomes are influenced by multiple factors, including experimental design, sample size, and specific health system practices. Several investigations used for determining costs and benefits of PN therapy have been criticized for such biases.[99]

Although the results of economic analyses of PN remain controversial, similarities among several reports provide a basis for minimizing the costs of PN therapy. These similarities include the following:

1. Use PN only for the most appropriate patients as described by institution-specific criteria based on current consensus statements.[101] The costs and complications associated with enteral nutrition are demonstrated to be less than those associated with PN.[102]
2. Reassess the need for routine laboratory measurements used for monitoring PN therapy. In general, the level of laboratory monitoring should decrease as a patient's clinical condition stabilizes.
3. Minimize the direct cost of PN by using efficient purchasing practices for PN solutions and compounding supplies through contract purchasing, streamlined compounding procedures, standardized administration times, and 24-hour hang times to reduce waste, single-bag PN solutions, and optimized monitoring plans.

CONCLUSIONS

Appropriate patient selection, assessment, and monitoring are key to successful PN therapy and the prevention of unnecessary complications. Because pharmacists are actively involved in the provision of PN at many levels, including direct patient care, education, and research, nutrition support is recognized as a pharmacy practice specialty.[103] In addition, as the interdisciplinary approach to specialized nutrition support has evolved, standards of practice have been defined for pharmacists as well as for other healthcare professionals who provide nutrition support care.[3,6–8] Standardized order forms and monitoring protocols are useful tools to ensure appropriate administration and monitoring of PN therapy. The future of PN therapy and the role of the nutrition-support clinician will be affected primarily by new insights from clinical research and economic challenges in the healthcare environment.

CHAPTER 152

Enteral Nutrition

VANESSA J. KUMPF AND KATHERINE HAMMOND CHESSMAN

KEY CONCEPTS

1. The GI tract defends the host from toxins and antigens by both immunologic and nonimmunologic mechanisms, collectively referred to as the gut barrier function. Whenever possible, enteral nutrition (EN) is preferred over parenteral nutrition (PN) because it is as effective, may reduce metabolic and infectious complications, and is less expensive.
2. Candidates for EN are those who cannot or will not eat, those who exhibit a sufficiently functioning GI tract to allow adequate nutrient absorption, and in whom enteral access can be safely obtained.
3. The most common route for both short- and long-term EN access is directly into the stomach. The method of delivery may be either continuously via an infusion pump, intermittently via a pump or gravity drip, or by gravity or syringe bolus administration.
4. Patients unable to tolerate feeding directly into the stomach because of impaired gastric motility and for those at high risk of aspiration, feeding tube tip placement into the duodenum or jejunum may be indicated. When feeding into the small bowel, the continuous method of delivery via an infusion pump is required to enhance tolerance.
5. Selection of the enteral feeding formulation depends on nutritional requirements, the patient's primary disease state and related complications, and nutrient digestibility and absorption. A standard polymeric formulation will meet the needs of the majority of adult patients and children.
6. Measurement of gastric residual volumes can be used to monitor GI tolerance in patients receiving gastric feeding. Although not always reliable, excessive residual volumes may be associated with nausea, abdominal distension, and increased risk for aspiration.
7. Management of diarrhea in patients receiving EN should focus on identification and correction of the most likely cause(s). Tube feeding–related causes include too rapid delivery or advancement, intolerance to the formula composition, and occasionally formula contamination.
8. Prior to administering medications through a feeding tube, the feeding tube tip location should be verified (stomach or small bowel) and the most suitable dosage form selected. Medications that should not be crushed and administered through a tube include enteric-coated or sustained-release capsules or tablets and sublingual or buccal tablets.
9. The coadministration of medications with EN can result in alterations in bioavailability and/or changes in the desired pharmacologic effects of several medications, including phenytoin, warfarin, selected antibiotics, antacids, and proton-pump inhibitors.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Enteral nutrition (EN) is defined as the delivery of nutrients by tube or by mouth into the GI tract. This chapter focuses on nutrient delivery through a feeding tube rather than the oral ingestion of food. The terms *enteral nutrition* and *tube feeding* are thus used interchangeably in this context. The goal of EN is to provide calories, macronutrients, and micronutrients to those patients who are unable to achieve these requirements from an oral diet. Over the past 20 to 30 years, EN has replaced parenteral nutrition (PN) as the preferred method of specialized nutrition support in many patients who are at risk of malnutrition. Improvements in enteral access techniques and feeding formulations and the recognition of methods to prevent and manage complications have resulted in an increased use of EN across all healthcare settings.

In this chapter, principles and practices related to the successful use of EN support are described. Digestive and absorptive physiology is reviewed, and the beneficial effects of EN are presented. The indications for EN and descriptions of various enteral access and administration methods are also summarized. Characteristics of commercially available enteral feeding formulations are presented, as well as administration and monitoring guidelines. Strategies to prevent and manage complications are discussed, and clinical therapeutic controversies are highlighted. In addition, issues of drug compatibility, drug–nutrient interactions, and drug administration via feeding tubes are discussed. Finally, the effectiveness and pharmacoeconomics of EN in enhancing nutrition and disease outcome goals are reviewed.

GASTROINTESTINAL TRACT PHYSIOLOGY

DIGESTION AND ABSORPTION

Digestion and absorption are GI processes that generate the body's usable fuels.[1,2] Digestion consists of the stepwise conversion of a complex chemical and physical nutrient into a molecular form that is absorbable by the intestinal mucosa. Absorption from the

TABLE 152-1 Gastrointestinal Enzymes and Hormones

Enzyme/Hormone	Site of Secretion	Main Actions
Amylase	Salivary glands, pancreas	Converts carbohydrates, starch, and glycogen to simple disaccharides
Cholecystokinin	Duodenum, jejunum	Stimulates pancreatic enzyme secretion and gallbladder contraction
Chymotrypsinogen	Pancreas	Breaks down proteins into peptides
Enteroglucagon	Duodenum, small intestine	Inhibits pancreatic enzyme secretion and bowel motility
Gastric inhibitory peptide	Small intestine	Decreases gastric motility and stimulates insulin secretion
Gastrin	Stomach, duodenum	Stimulates gastric acid secretion and mucosal growth
Glucagon	Pancreas	Stimulates hepatic glycogenolysis and inhibits motility
Lipase	Pancreas	Hydrolyzes dietary fat to release fatty acids
Pancreatic polypeptide	Pancreas	Inhibits gallbladder contraction and pancreatic and biliary secretion
Pepsinogen	Stomach	Converts large proteins into polypeptides
Secretin	Small intestine	Stimulates hepatic and pancreatic water and bicarbonate release
Trypsinogen	Pancreas	Breaks down proteins into peptides
Vasoactive inhibitory peptide	Small intestine, pancreas	Vasodilator; stimulates water and bicarbonate secretion, release of insulin and glucagon, and production of small intestinal secretions

GI tract is a multistep process that includes the transfer of a nutrient across the intestinal cell membrane. The nutrient ultimately reaches the systemic circulation through the portal venous or splanchnic lymphatic systems, provided the GI or biliary tract does not excrete it. Ingested nutrients are primarily large polymers that cannot be absorbed by the intestinal cell membrane unless they are transformed into an absorbable molecular form. In addition, a coordinated interplay of GI motility and neurohormonal secretion is required to facilitate adequate digestion and absorption.

Nutrient digestion involves the complex coordination of multiple mechanical, enzymatic, and physiochemical processes.[1,2] Mechanical dissolution of food occurs by chewing, then mixing and grinding the stomach contents. Food stimulates the secretion of numerous hormones and enzymes from the salivary glands, stomach, liver and biliary system, pancreas, and intestines (Table 152–1). As food passes along the gut lumen, these hormones modulate GI motility and the secretions from subsequent organs of the digestive system. Nutrient digestion occurs within the gut lumen and is a specific function of the intestinal cell membrane, which is comprised of fingerlike projections called villi. Each individual villus is made up of epithelial cells called enterocytes. The enterocyte surface contains special luminal projections called microvilli, which provide an increased surface area that is referred to as the brush-border membrane.

Figure 152–1 illustrates the digestion and absorption of carbohydrate, fat, and protein within the small intestine. Carbohydrates are presented to the small intestine in either a digestible or a nondigestible form. Polysaccharides (starches) and oligosaccharides (sucrose and lactose) undergo enzymatic digestion within the small intestine to produce simple sugars. The simple sugars are absorbed via active and passive transport mechanisms and are eventually released into the portal vein. Polysaccharides, such as cellulose complexes and other fiber components, pass undigested to the colon, where they are digested by bacteria and enzymes to form short-chain fatty acids. Absorption of short-chain fatty acids by the colon stimulates sodium and water reabsorption, serves as an energy source, and provides nourishment to the colonic mucosa cells.

Fat is presented to the small intestine as long-chain triglycerides. Its digestion requires pancreatic enzyme release and formation of mixed bile salt micelles, which then facilitate absorption across the intestinal enterocyte. Within the enterocyte, triglycerides are reesterified and packaged into chylomicrons for release into the lymphatic system. Medium-chain triglycerides (MCTs) can be absorbed intact by the mucosal membrane and are acted on by intracellular lipase within the enterocyte to release free fatty acids that pass directly into the portal vein.[3]

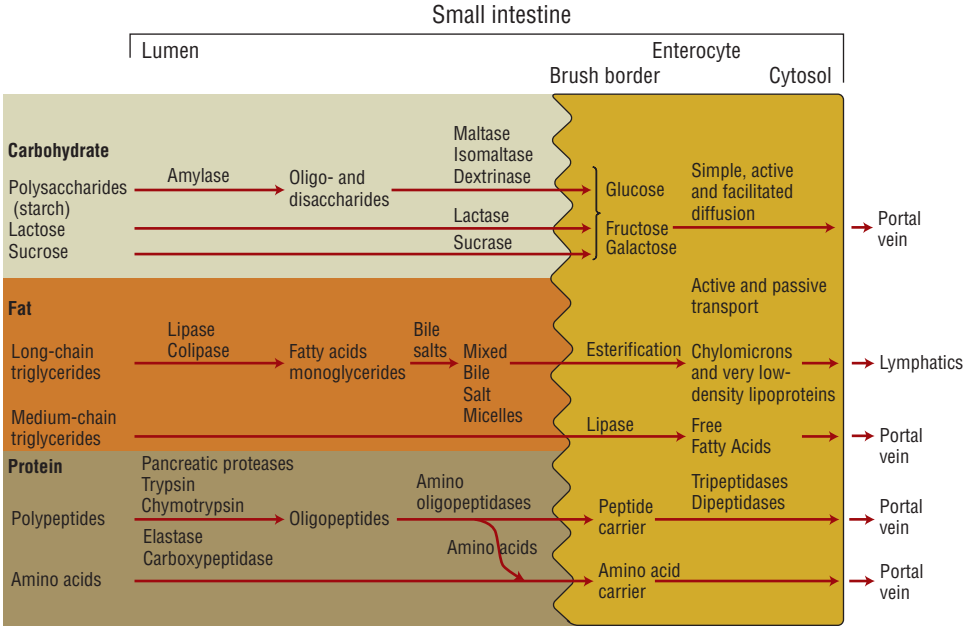

FIGURE 152-1. Schematic of carbohydrate, fat, and protein digestion.

Protein is presented to the small intestine primarily as large polypeptides and to a small extent as free amino acids because of the denaturation of protein within the stomach. Luminal polypeptide digestion generates oligopeptides, which are further hydrolyzed to dipeptides and tripeptides. Absorption of peptides occurs via a peptide transport system; free amino acids are carried via specific amino acid transport systems. The carriers for the peptides are very efficient, whereas absorption of free amino acids appears to be more limited and less efficient.[2]

Understanding the mechanisms of digestive and absorptive physiology can greatly enhance the rational use of EN during conditions of normal or altered GI anatomy and/or function. Several circumstances may alter the efficacy of nutrient digestion and absorption. For example, the functional immaturity of the neonatal gut may lead to clinical problems associated with inadequate digestion and absorption of EN. These factors, as they relate to successful EN practice, are discussed in detail throughout this chapter.

GUT HOST DEFENSE MECHANISMS

1 Besides digesting and absorbing nutrients to maintain nutritional health, the GI tract is actively involved in defending the host from toxins and antigens by means of both immunologic and nonimmunologic mechanisms.[4] These gut host defense mechanisms are collectively referred to as the gut barrier function. The gut barrier acts to prevent the spread of intraluminal bacteria and endotoxins to systemic organs and tissues. Hydrochloric acid secreted by the stomach kills most of the bacteria ingested with food. Under normal circumstances, a mucus layer coats the intestinal epithelium and thereby alters the adherence of bacteria to the cells of the GI tract and provides a favorable environment for anaerobic bacteria. Anaerobic bacteria, which normally colonize the mucus layer, aid in preventing tissue colonization by potential pathogens. Small bowel peristalsis further prevents bacterial stasis and overgrowth. The gut barrier function is also maintained by the intestinal immune system, known as the gut-associated lymphoid tissue (GALT). GALT regulates the local immune response to antigens within the GI tract. Specific immunoglobulins are secreted to kill the remaining organisms and neutralize any toxins they produce. The liver Kupffer cells help to maintain gut barrier function by clearing the portal blood of gut-derived bacteria and endotoxins. The integrity of gut barrier function may be affected negatively by numerous pathogenic insults, such as physiologic stress and ischemia, and a variety of drugs, including chemotherapeutic agents. The administration of certain probiotics can modify intestinal flora and may have beneficial effects in various disease states and patient populations by positively affecting the maintenance of gut barrier function and intestinal immune function.[5,6]

INDICATIONS FOR ENTERAL NUTRITION

2 The decision to initiate EN is based on a variety of factors. Suitable candidates are those who cannot or will not eat a sufficient amount to meet nutritional requirements, those who exhibit a sufficient functioning GI tract to allow the absorption of nutrients, and those in whom a method of enteral access can be safely obtained.[7–9] EN may be indicated in a variety of conditions or disease states (Table 152–2). For example, patients who have neurologic disorders, such as a cerebrovascular accident, and have difficulty swallowing often require EN. Patients unable to eat because of conditions such as facial or jaw injuries, lesions of the oral cavity or esophagus, esophageal stricture, or head and neck cancer may also be candidates for EN delivered distal to the affected site. Extreme prematurity necessitates tube feeding because the suck–swallow mechanism has not yet developed sufficiently to allow safe oral intake.

TABLE 152-2 Potential Indications for Enteral Nutrition

Neoplastic disease	**GI disease**
Chemotherapy	Inflammatory bowel disease
Radiation therapy	Short bowel syndrome
Upper GI tumors	Esophageal motility disorder
Cancer cachexia	Pancreatitis
Organ dysfunction	Fistulas
Liver disease/failure	Gastroesophageal reflux disease (severe)
Kidney insufficiency/failure	Esophageal or intestinal atresia
Cardiac cachexia	**Neurologic impairment**
ARDS/ALI	Comatose state
Bronchopulmonary dysplasia	Cerebrovascular accident
Congenital heart disease	Demyelinating disease
Organ transplantation	Severe depression
Hypermetabolic states	Cerebral palsy
Closed head injury	**Other indications**
Burns	AIDS
Trauma	Anorexia nervosa
Postoperative major surgery	Complications during pregnancy
Sepsis	Failure-to-thrive
	Geriatric patients with multiple chronic diseases
	Extreme prematurity
	Inborn errors of metabolism
	Cystic fibrosis

AIDS = acquired immune deficiency syndrome, ALI = acute lung injury, ARDS = acute respiratory distress syndrome.

Critically ill patients who are endotracheally intubated for mechanical ventilation represent a large percentage of patients requiring EN. Traditionally, EN in the critically ill population was regarded as supportive care designed to provide nutrients during the period of time the patient was unable to maintain oral dietary intake. Recently, the use of EN has been initiated to modulate the stress response to critical illness and improve patient outcomes. Nutrition guidelines support the initiation of EN in critically ill adults[10,11] and children[12] who are unable to maintain volitional intake. Some of these patients may have reduced gastric motility and emptying caused by sepsis, GI surgery, anesthetic agents, opioid analgesics, and underlying pathology, such as diabetic gastroparesis. However, successful EN can often be achieved by bypassing the stomach and placing the tip of the feeding tube beyond the pylorus into the duodenum, or preferably into the jejunum. Small bowel feeding may also be appropriate for patients with gastric outlet obstruction and those with pancreatitis.

The only absolute contraindications for EN are mechanical intestinal obstruction[13] and necrotizing enterocolitis.[14] However, conditions such as severe diarrhea, protracted vomiting, enteric fistulas, severe GI hemorrhage, and intestinal dysmotility may result in significant challenges to the successful use of EN.

BENEFITS OF ENTERAL NUTRITION

The importance of maintaining nutrient delivery through the GI tract in patients without a contraindication to its use is well supported. The beneficial effects of EN, specifically in the critically ill patient, are further enhanced if EN is initiated within 24 to 48 hours of admission to an intensive care unit (ICU).[10]

ENTERAL VERSUS PARENTERAL NUTRITION

Clinical studies comparing EN and PN in the critically ill patient demonstrate a decrease in infectious complications and thus

improved outcomes with the use of EN.[15–19] Infectious complications are less common with EN in part because EN supports the functional integrity of the gut by stimulating bile flow and the release of endogenous trophic agents, such as cholecystokinin, gastrin, and bile salts. Provision of enteral nutrients appears to help maintain the villous height of the intestinal mucosa and support the mass of secretory immunoglobulin A (IgA)–producing immunocytes that comprise the GALT. In the setting of critical illness or injury, adverse changes in gut permeability and gut barrier function that result in increased risk for systemic infection and multiorgan dysfunction syndrome often have been noted. By supporting gut integrity, the enteral route of feeding is more likely than the parenteral route to lower the risk of infection and minimize organ failure.[10]

Critical reviews of available prospective randomized, controlled trials comparing EN with PN in the critically ill adult patient with an intact GI tract suggest a significant reduction in infectious complications associated with EN.[10,11,14] Decreased infectious complications have been documented in patients with abdominal trauma, burns, severe head injury, major surgery, and acute pancreatitis. The reduced infectious complications are primarily the result of a lower incidence of pneumonia and catheter-related bloodstream infections in most of these patient populations and a decrease in abdominal abscess in trauma patients. EN is thus preferred over PN for the feeding of critically ill adult patients requiring specialized nutrition support.[10,11] There are no randomized, controlled trials that compare the use of EN and PN in children.[12]

EN is more physiologic than PN in terms of nutrient utilization and therefore is generally associated with fewer metabolic complications, such as glucose intolerance and elevated insulin requirements.[20] Enteral formulations contain both complex and simple carbohydrates compared with the simple carbohydrate in the form of dextrose that is used in PN. This may account for better blood glucose control when carbohydrate is given via the enteral route. An additional physiologic benefit of enteral feeding is that it stimulates bile flow through the biliary tract and thus reduces the risk of developing cholestasis, gallbladder sludge, and gallstones, conditions that have been associated with long-term PN and bowel rest.[21] Also, EN avoids the potential infectious and technical complications associated with the placement and use of a central venous access device required for PN. Finally, EN is less costly than PN when all factors are considered.

EARLY VERSUS DELAYED INITIATION

The timing of initiation of EN in the critically ill patient is of clinical significance. Initiating EN in the first 24 to 72 hours following admission appears to attenuate the stress response and may reduce disease severity and infectious complications when compared with the initiation of feedings after 72 hours.[10,11] Early EN has also been associated with a decrease in the release of inflammatory cytokines and fewer alterations in gut permeability.[22] Clinical studies demonstrating a decrease in infectious complications with the use of EN compared with PN in the critically ill patient initiated feeding within 24 to 48 hours of hospital admission.[10,11,15,22,23] The benefits of decreased infectious complications are not apparent when the initiation of EN is delayed. A review of available studies comparing early versus delayed EN in critically ill patients showed a trend toward a reduction in infectious complications with early EN.[10,11] In addition, a trend toward reduction in mortality associated with early EN has been noted.[10,11,24]

In critically ill patients who are hemodynamically unstable, early EN may result in gut ischemia because of poor gut blood flow and increased oxygen demand. Consequently, it is recommended that initiation of EN be delayed until the patient is fluid resuscitated and has an adequate perfusion pressure. Once this goal is achieved, often within 6 hours of hospitalization, the initiation of EN at a low administration rate is considered appropriate, along with clinical monitoring to ensure GI tolerance.[25,26] Therefore, early EN (within 24–48 hours after hospital admission) is recommended in critically ill adult patients.[10,11] Although no randomized, controlled trials have assessed early EN in critically ill children, initiation of EN within 48 to 72 hours of admission is common.[12] Early initiation of EN is not warranted for the mild to moderately stressed adult patient who is otherwise well nourished. It is reasonable to delay the initiation of EN in these patients until oral intake is inadequate for 7 to 14 days.[7] In the mild to moderately stressed adult patient with inadequate oral intake who is malnourished, it is unclear when to initiate EN, but most clinicians would not wait more than 7 days.

ENTERAL ACCESS

Advances in enteral access techniques have contributed to the expanded use of EN for conditions in which PN had previously been used. In particular, improved methods of achieving jejunal access for feeding have allowed for the use of EN during the early postoperative and postinjury period when gastric motility is typically impaired. As outlined in Table 152–3, various factors influence the selection of enteral access site and device, including anticipated duration of use (short- or long-term) and whether to feed into the stomach or small bowel. Figure 152–2 illustrates the predominant enteral access options.

SHORT-TERM ACCESS

3 Short-term enteral access is easier to initiate, less invasive, and less costly than the establishment of long-term access.[27] The most frequently used routes for short-term enteral access are established by inserting a tube through the nose and passing the tip into the stomach (nasogastric [NG]), duodenum (nasoduodenal), or jejunum (nasojejunal). In general, these tubes are used in the hospitalized patient when the anticipated tube feeding duration is less than 4 to 6 weeks. The orogastric route is generally reserved for patients in whom the nasopharyngeal area is inaccessible or in young infants who are obligate nasal breathers. Because these routes do not require surgical intervention, they are the least invasive. The feeding tube is frequently held in place only by a piece of tape on the nose or face; therefore, it can be inadvertently pulled out relatively easily.

NG tubes vary in diameter size and stiffness. The large-bore (≥14F) rigid NG tubes are used primarily to decompress the stomach but can also be used for feeding. There is a low incidence of clogging with these tubes, and they provide a reliable way to measure gastric residual volumes. The major disadvantage associated with the use of these tubes is patient discomfort. Small-bore nasal tubes designed solely for feeding are available in varying lengths (16–60 inches [41–152 cm]) and diameter sizes (4F to 12F) to accommodate both pediatric (including neonates) and adult patients. The tip of the tube can be placed into the stomach, duodenum, or jejunum. These tubes consist of a lightweight, pliable silicone or polyurethane material that is more comfortable for the patient. A disadvantage of the small-bore tubes is that they may become easily occluded, often as a result of improper medication administration or tube-flushing technique.

4 In general, the stomach is the least expensive and the least labor-intensive access site to use for enteral feeding; however, feeding into the stomach is not as well tolerated. Patients with impaired gastric motility may be predisposed to aspiration and pneumonia when feedings are delivered into the stomach. Many critically ill, injured, and postoperative patients exhibit delayed gastric emptying, limiting their ability to tolerate gastric feeding.

TABLE 152-3 Options and Considerations in the Selection of Enteral Access

Access	EN Duration/Patient Characteristics	Tube Placement Options	Advantages	Disadvantages
Nasogastric or orogastric	Short term Intact gag reflex Normal gastric emptying	Manually at bedside	Ease of placement Allows for all methods of administration Inexpensive Multiple commercially available tubes and sizes	Potential tube displacement Potential increased aspiration risk
Nasoduodenal or nasojejunal	Short term Impaired gastric motility or emptying High risk of GER or aspiration	Manually at bedside Fluoroscopically Endoscopically	Potential reduced aspiration risk Allows for early postinjury or postoperative feeding Multiple commercially available tubes and sizes	Manual transpyloric passage requires greater skill Potential tube displacement or clogging Bolus or intermittent feeding not tolerated
Gastrostomy	Long term Normal gastric emptying	Surgically Endoscopically Radiologically Laparoscopically	Allows for all methods of administration Low-profile buttons available Large-bore tubes less likely to clog Multiple commercially available tubes and sizes	Attendant risks associated with each type of procedure Potential increased aspiration risk Risk of stoma site complications
Jejunostomy	Long term Impaired gastric motility or gastric emptying High risk of GER or aspiration	Surgically Endoscopically Radiologically Laparoscopically	Allows for early postinjury or postoperative feeding Potential reduced aspiration risk Multiple commercially available tubes and sizes Low-profile buttons available	Attendant risks associated with each type of procedure Bolus or intermittent feeding not tolerated Risk of stoma site complications

EN = enteral nutrition, GER = gastroesophageal reflux.

In addition, patients with diabetic gastroparesis or patients with severe gastroesophageal reflux disease or intractable vomiting are at a higher risk for aspiration of gastric contents, resulting in pneumonia. In these patients, placing the tip of the tube into the duodenum or jejunum (also referred to as transpyloric placement) may be required to enable successful enteral feeding. However, studies have yet to prove definitively that transpyloric tube feedings actually do decrease the risk of aspiration and pneumonia. One meta-analysis of studies comparing gastric and transpyloric feeding in critically ill patients demonstrated no difference in the incidence of pneumonia;[28] another critical review of the same patient population suggested that small bowel feedings were associated with a reduction in gastroesophageal regurgitation and a lower rate of ventilator-associated pneumonia.[29] Thus, the true difference in aspiration and pneumonia risk associated with gastric and small bowel feeding remains unclear.

In general, small bowel feeding may be beneficial in patients who do not tolerate gastric feeding and offers an alternative to PN.[10–12] Nasoenteric feeding tubes can be inserted at the patient's bedside by trained medical personnel. However, greater skill is required to advance the tip of the feeding tube beyond the pylorus. Several techniques have been described in the literature to help facilitate bedside placement. Variable success rates have been reported with these techniques and are largely dependent on clinician experience. Electromagnetic tube placement devices that can be used at the bedside to guide tip position into the small bowel have been shown to be safe and cost-effective for small bowel feeding tube placement.[30] Alternatively, a variety of endoscopic and fluoroscopic techniques have been described to insert transpyloric tubes.[27] Radiographic confirmation of appropriate tip placement for feeding tubes inserted by bedside techniques should be obtained prior to use.[7,8]

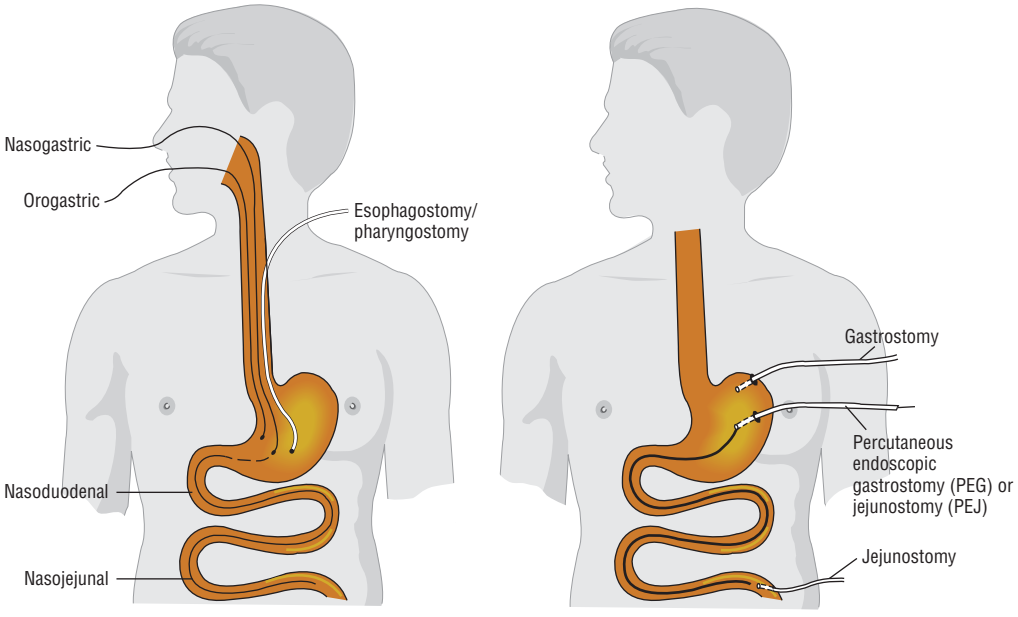

FIGURE 152-2. Access sites for tube feeding.

LONG-TERM ACCESS

Feeding tubes used for short-term enteral access are usually not optimal for long-term use because of patient discomfort, long-term complications, and mechanical failures that develop over time. Long-term access should generally be considered when EN is anticipated for longer than 4 to 6 weeks. Many techniques can be used to establish long-term enteral access, including laparotomy, laparoscopy, endoscopy, and fluoroscopy. The ability to perform the various techniques will be somewhat dependent on the expertise and facilities available within each institution. Long-term enteral access options include gastrostomy and jejunostomy tubes.

A gastrostomy is the most common type of long-term enteral access. It eliminates the nasal irritation and discomfort associated with nasoenteric feeding tubes and inadvertent removal is uncommon. In addition, because feeding gastrostomies use large-bore tubes, clogging is less of a problem. Multiple techniques for insertion of a gastrostomy tube have been described, including surgical laparotomy, endoscopy, radiography, and laparoscopy. The most common technique is the percutaneous endoscopic gastrostomy (PEG). It is minimally invasive and can be performed safely and cost-effectively in an endoscopy suite or at the bedside using conscious sedation and local anesthesia. Young children, however, will usually require general anesthesia for the procedure. Numerous kits are available for PEG placement in both children and adults and vary in size (12F–28F; 1–4.5 cm shaft lengths), material used, internal and external bolsters, and insertion techniques. There are, however, ethical implications regarding determination of appropriate candidates for PEG placement.[31–33] Because of its relative ease of placement, the PEG tube is often placed inappropriately based on unrealistic expectations of what EN can accomplish in patients who are unable to eat. In adults, PEG placement is associated with an unexpectedly high 30-day mortality rate, which suggests that the procedure is being performed in patients who have multiple coexisting morbid conditions.[31] Evaluation by a multidisciplinary team is warranted for those patients near end of life to establish whether the benefit outweighs the risk of PEG placement.[8,31]

For patient convenience and comfort, a low-profile skin-level gastrostomy device may be placed in 2 to 3 months, once the gastrostomy tract has matured, if this type of device was not placed initially. This "gastric button" consists of a short, silicone, self-retaining conduit with either a mushroom tip or a balloon at the internal end and a one-way valve and small flange at the skin surface. Because this averts the external tube presence, it tends to be preferred in children or ambulatory adults who are receiving intermittent feedings. The exit site of all gastrostomies requires general stoma care to prevent inflammation and infection.

In patients at high risk of gastroesophageal reflux disease and aspiration who require long-term enteral access, a jejunostomy may be the most appropriate option.[34] Jejunostomies may also be indicated in patients unable to tolerate gastric feeding as a result of impaired gastric motility or delayed gastric emptying. These tubes can be inserted surgically, endoscopically, radiologically, or laparoscopically. The most appropriate technique depends on the expertise and facilities available. A surgical jejunostomy may be preferred if the patient requires a laparotomy or laparoscopy for other reasons. Endoscopic placement of a jejunostomy can be done by various methods. Typically, a small-bore jejunal extension tube (6F, 8F, or 10F) is inserted through a PEG and advanced through the pylorus into the duodenum or jejunum. This procedure has been referred to as percutaneous endoscopic jejunostomy (PEJ). A PEG/PEJ is a dual-lumen gastrojejunal tube that is used for patients who need simultaneous gastric decompression and small bowel feedings. Jejunostomy placement can also be laparoscopically or radiologically guided.[34] Because jejunostomies use smaller-bore tubes, occlusion occurs more commonly than with gastrostomy tubes.

Pharyngostomies and esophagostomies are invasive because the tube is located in the neck and passes through the skin into the pharynx or esophagus, respectively. They have been used in patients with head and neck malignancies and in those with impaired swallowing caused by neuromuscular disorders. However, better long-term enteral access techniques have replaced the need for the pharyngostomy and esophagotomy routes. They are rarely performed today because of the high complication rate and extreme difficulty associated with their care.[31]

ADMINISTRATION METHODS

EN may be administered by continuous, cyclic (i.e., a continuous rate over a portion of the day), or bolus methods and may be accomplished by syringe, gravity, or pump-controlled techniques. The method of delivery depends on the location of the tip of the feeding tube, the clinical condition and intestinal function of the patient, the environment in which the patient resides, and the patient's tolerance to the tube feeding.

CONTINUOUS

In hospitalized patients, the continuous administration of EN is most commonly used for initiation and is generally the preferred method.[35,36] When initiating feeding into the stomach, the continuous method of delivery is usually better tolerated than the intermittent bolus method. Once tolerance is established, a conversion to intermittent bolus administration may be warranted. When EN is delivered into the small intestine, the continuous method is preferred because it is associated with enhanced tolerance. The rapid delivery of feeding into the small intestine, especially hyperosmotic formulations, may contribute to abdominal distension, cramps, hyperperistalsis, and diarrhea. Therefore, conversion to intermittent bolus administration is not recommended for those who have an access placed into the duodenum or jejunum.

The delivery system for continuous administration generally includes a feeding reservoir or bag attached to an extension set that is connected to a pump. The delivery system is then attached to the patient's enteral access tube. Continuous administration may increase nursing time because routine checks are needed, but this disadvantage is offset by the improved tolerance. For adults, EN administration rates generally range from 50 to 125 mL/hour, although higher rates have been used without complications. In infants and children, goal administration rates vary with age and weight and should be sufficient to meet caloric needs while maintaining good GI tolerance. The primary disadvantage to this method of administration is the cost and inconvenience associated with the pump and administration sets. In the home care setting, battery-operated ambulatory enteral pumps are available to allow the patient greater mobility.

CYCLIC

A patient who is not eating well during the day because of complaints of fullness and lack of appetite may benefit from a trial of cyclic EN, in which the enteral feeding is held during the day and administered only at night. In addition, the administration of EN only at night will free the patient from the pump during the day and allow for greater mobility. This increased mobility may be particularly useful for the home patient or patient requiring rehabilitation. Because a pump controls the rate of administration, this method may be used in patients with either gastric or small bowel access.

BOLUS

The bolus administration of EN is commonly used for patients in long-term care settings who have a gastrostomy. This administration technique involves the delivery of the enteral feeding formulation over 5 to 10 minutes. Essentially, the only equipment needed is a syringe to instill the feeding solution into the tube. Depending on the patient's nutritional requirements, an instillation volume of 240 to 500 mL is generally used and repeated four to six times daily. From a convenience standpoint, it is generally preferable to adjust the bolus volume in increments of the feeding formulation container size (usually 240–250 mL). Bolus volumes given to infants and children vary with age and weight (usually 30–240 mL) and should be sufficient to meet the calorie needs of most patients. In neonates, the bolus regimen is usually begun with an every 3-hour schedule; as the child grows, feedings may be given less frequently.[37] In patients with duodenal or jejunal access, bolus delivery may result in cramping, nausea, vomiting, aspiration, and diarrhea. Bolus administration also should be avoided in patients with delayed gastric emptying and in patients who are at high risk of aspiration.

INTERMITTENT

If a patient is experiencing intolerance to bolus administration over 5 to 10 minutes, it may be helpful to administer the prescribed volume over a longer time period, generally 20 to 60 minutes. For this method, the desired volume of feeding formulation is emptied into a reservoir bag or container and administered by an enteral pump or via gravity drip using a roller clamp. The bolus method of administration is more consistent physiologically with normal eating patterns than the continuous method. One study in infants demonstrated that normal gallbladder emptying did not occur with continuous feedings but was present in those infants receiving bolus feedings.[38] Thus, those patients who need long-term EN and PN, especially children, may benefit when this approach is used because it may minimize the development of cholestatic liver disease.

INITIATION AND ADVANCEMENT PROTOCOL

Guidelines for the initiation and advancement of enteral feeding formulations vary greatly, and scientific support for any of the guidelines is weak or nonexistent. The typical recommendation for continuous administration of EN for adults is to start at 20 to 50 mL/hour and advance by 10 to 25 mL/hour every 4 to 8 hours until the desired goal is achieved. For intermittent administration, the typical recommendation is to start with 120 mL every 4 hours and advance by 30 to 60 mL every 8 to 12 hours.[8,36] In children, the recommendation for continuous administration is initiation at a rate of 1 to 2 mL/kg per hour (25–30 mL/h) or 2 to 4 mL/kg per bolus (30–90 mL) with advancement by similar amounts every 4 to 24 hours. In premature infants, feedings may be initiated at lower rates usually 10 to 20 mL/kg per day and advanced by similar rates daily. Schedules for progression of tube feeding from initial to target rates are important and may influence tolerance. If the protocol is too conservative, it may take an excessively long period of time to reach nutrient goals. The practice of diluting enteral feeding formulations is not routinely recommended unless necessary to increase fluid intake.[8,36] The development of an EN protocol within an institution that outlines initiation and advancement criteria may be a useful strategy to optimize achievement of nutrient goals.[10,11] Such a protocol should allow nursing to advance the rate (i.e., 25 mL/hour every 4 hours until the goal rate is achieved) based on GI tolerance. Clinical signs of intolerance include abdominal distension, abdominal cramping, high gastric residual volumes, aspiration, and diarrhea.

ENTERAL FEEDING FORMULATION SELECTION

Historically, enteral formulas were created to provide essential nutrients. Over the years, enhancements have been made to meet specific patient needs and improve tolerance. For example, nutrient composition has been enhanced by changing the content of the amino acids (e.g., glutamine and arginine), changing the omega-3 polyunsaturated fatty acid content, and adding ribonucleic acid to enhance immune function and improve therapeutic outcomes. These specific nutrients have been called nutraceuticals or pharmaconutrients because of the intent to use them to modify the disease process and improve clinical outcomes. Currently, enteral feeding formulations are categorized by the FDA as medical foods.[8] They are considered components of supportive care and are simply regulated to ensure sanitary manufacture. Unfortunately, they are not subject to rules governing health claims, and promotion of medical foods for therapeutic intent is currently not regulated by the FDA.[39,40]

The macronutrient content of enteral formulas (namely, protein, carbohydrate, and fat) varies in nutrient complexity (Table 152–4). Nutrient complexity refers to the amount of hydrolysis and digestion a substrate requires prior to intestinal absorption. Polymeric or intact substrates are of similar molecular form as the food we eat. Enteral formulas that contain partially hydrolyzed or elemental substrates are characterized as elemental or defined-formula diets. The caloric contribution of each of the macronutrients is as follows: carbohydrates, 4 kcal/g (17 kJ/g); protein, 4 kcal/g (17 kJ/g); and fat, 9 kcal/g (38 kJ/g). Micronutrients, including electrolytes, vitamins, trace elements, and water, do not contribute to caloric content.

PROTEIN COMPOSITION

The essential amino acid content of the protein source determines the quality of the protein, and most commercially available enteral feeding formulations contain proteins of high quality. The molecular form of the protein source in enteral formulas will determine the amount of digestion that is required for absorption within the

TABLE 152-4 Enteral Formula Nutrient Complexity

Nutrient	Polymeric or Intact	Partially Hydrolyzed or Elemental
Carbohydrate	Starches	Oligosaccharides
	Fruit, vegetable, cereal solids	Maltodextrins
	Glucose polymers	Disaccharides
	Corn syrup solids	Maltose, sucrose, lactose
	Polysaccharides	Monosaccharides
		Glucose
		Galactose
Fat	Long-chain triglycerides	Medium-chain triglycerides
	Polyunsaturated fatty acids	Coconut oil
	Corn oil	Palm kernel oil
	Safflower oil	Free fatty acids
	Soybean oil	Linoleic
	Canola oil	
	Marine oils	
Protein	Whole	Oligopeptides
	Egg, milk, wheat, whey	Dipeptides
	Isolates	Tripeptides
	Caseinate salts	L-amino acids
	Lactalbumin	

small bowel. Polymeric or intact protein sources require digestion to smaller peptides and free amino acids before absorption from the GI tract. Therefore, enteral formulation protein sources such as meat, milk, eggs, and caseinates require digestion by hydrochloric acid, specific protein enzymes, and pancreatic proteases. Enteral formulations may also contain protein sources that are partially hydrolyzed to peptides or L-amino acids. As the molecular form of protein is reduced in size, the osmotic load of the enteral formulation is increased. Many commercially available enteral feeding formulations contain combinations of intact and partially hydrolyzed protein sources.

CONDITIONALLY ESSENTIAL AMINO ACIDS

Glutamine and arginine are generally considered nonessential amino acids. However, during periods of high physiologic stress, the need for these nutrients may be increased beyond the body's synthetic ability; consequently, these amino acids are characterized as conditionally essential. Because they are usually present in low amounts in most enteral feeding formulations, those formulations targeted for the critically ill may be supplemented with glutamine and/or arginine.

Glutamine serves as a key fuel for rapidly dividing cells, including enterocytes, endothelial cells, lymphocytes, and fibroblasts. The primary site of glutamine production is skeletal muscle. During critical illness, the catabolism of skeletal muscle provides an increased supply of glutamine, but this may not be enough to meet the high rate of glutamine use by cells of the immune system and other cells involved in recovery and repair. Glutamine depletion may develop, particularly during prolonged periods of metabolic stress. Favorable outcomes have been documented in critically ill patients when enteral formulations have been supplemented with glutamine.[10,41,42]

Arginine has been added to some immune-modulating enteral formulations in concentrations that range from 4.5 to 14 g/L. However, arginine supplementation remains controversial, especially in patients with sepsis.[43,44] Many of the physiologic effects of arginine are mediated by its conversion to nitric oxide, which, in turn, modulates immune function, inflammation, and response to sepsis. Some of these effects may be potentially harmful in the patient with sepsis, especially when higher arginine intakes are used.[10,11]

CARBOHYDRATE COMPOSITION

The carbohydrate component of enteral feeding formulations usually provides the major source of calories. Polymeric or intact enteral formulations contain starches and numerous types of glucose polymers, which require digestion to monosaccharide moieties prior to intestinal absorption (see **Fig. 152–1**). As the hydrolysis of carbohydrate increases within an enteral formulation, the osmolality of the formulation increases. Elemental carbohydrates, such as glucose and galactose, contribute significantly to the osmolality of enteral formulations. Consequently, polymeric entities, rather than elemental sugars, are preferred in enteral formulas. Glucose polymers provide a useful carbohydrate source that is tolerated by most individuals (see **Table 152–4**). The polymers are large chains that provide minimal osmotic load, yet are absorbed easily in the intestine. The one shortcoming of glucose polymers and oligosaccharides is that they are not as sweet as simple glucose and thus may decrease the palatability of orally consumed products. Finally, almost all commercially available enteral feeding formulations used in adults and older children are lactose-free because disaccharidase production within the gut lumen is reduced during illness and periods of prolonged bowel rest. Additionally, there is a high incidence of lactose intolerance in those of certain ethnic decent: rates range from 5% in white northern Europeans, North Americans, and Australians to over 50% in people from South America, Africa, and Asia.[45] Infant formulas are available with or without lactose.[37]

FAT AND FATTY ACID COMPOSITION

Fat is an important constituent in the diet because it provides a concentrated calorie source and serves as a carrier for fat-soluble vitamins. Sufficient linoleic acid is required to prevent essential fatty acid deficiency and should approximate 1% to 3% of total daily calories. The most common sources of fat in enteral feeding formulations are vegetable oils (soy or corn) rich in polyunsaturated fatty acids. The concentration of fat varies between less than 2% to 45% of total calories. High fat content of the diet is associated with delayed gastric emptying. Enteral feeding formulations can also contain fat in the form of MCTs derived from palm kernel or coconut oils. Because MCTs do not contain linoleic acid, most enteral formulations that contain MCTs will also have a source of long-chain triglycerides to provide essential fatty acids. Potential advantages of MCTs compared as opposed to long-chain triglycerides are that they are more water soluble, undergo rapid hydrolysis, require little to no pancreatic lipase or bile salts for absorption, and do not require carnitine for transport into the mitochondria, where they are converted to energy. They also do not require chylomicron formation for small bowel enterocyte absorption.

The source of long-chain fat within some enteral formulations has been modified from omega-6 to omega-3 fatty acids in an effort to modulate the inflammatory response in patients with acute respiratory distress syndrome (ARDS), acute lung injury (ALI), and sepsis.[46] The omega-6 fatty acids serve as precursors to certain cytokines that are potent inflammatory mediators and also decrease cell-mediated immune response. The omega-6 fatty acids are high in linoleic acid and are derived from vegetable oil, whereas the omega-3 fatty acids, derived from coldwater fish oils, are high in linolenic acid. It has been proposed that if the dietary proportion of omega-3 fatty acids is increased and omega-6 fatty acids is decreased, less inflammation and immunosuppression may occur during metabolic stress.

Docosahexaenoic acid (DHA) and arachidonic acid (ARA) are two fatty acids abundant in human milk, but until recently, they were not contained in commercial infant formulas. Although the role of ARA supplementation is unclear, DHA is known to be important in both brain and eye development. In some studies, DHA and ARA supplementation provided benefits to a child's visual function and/or cognitive and behavioral development.[47] The FDA has classified plant-based fatty acid blends of DHA and ARA as generally recognized as safe (GRAS), and most infant formulas, as well as some products for pregnant and lactating women, are supplemented with these fatty acids.

FIBER CONTENT

Fiber, in the form of soy polysaccharides, has been added to several enteral feeding formulations intended for use in both children and adults in amounts ranging from 5.9 to 24 g/L. Infant formulas generally do not contain fiber; however, at least one formula intended for use in infants with diarrhea contains soy fiber. Fiber supplementation is common in clinical practice, primarily because fiber-free enteral formulations are implicated as a contributing factor to both diarrhea and constipation. Ingested fiber undergoes bacterial degradation within the colon to produce short-chain fatty acids. Potential benefits of fiber are the trophic effects on the colonic mucosa and the promotion of sodium and water absorption within the colon. Fiber supplementation may help regulate bowel function in both normal individuals and those with altered colonic motility. In addition, the resulting short-chain fatty acids are an excellent energy source. Although beneficial effects of fiber supplementation have not been clearly proven in clinical studies, there is experimental evidence that fiber may play an integral role in normal nutrition,

and risk is generally minimal.[48] Fiber supplementation may be beneficial when long-term EN is required or in patients who experience diarrhea or constipation while receiving a fiber-free enteral formulation. Soluble fiber may also be beneficial in the critically ill patient who is hemodynamically stable and develops diarrhea while receiving EN.[10,49] Insoluble fiber should be avoided in all critically ill patients due to case reports of bowel obstruction.[10]

OSMOLALITY AND RENAL SOLUTE LOAD

Osmolality and renal solute load can affect tolerance to enteral feeding formulations. The osmolality of a given enteral formulation is a function of the size and quantity of ionic and molecular particles, primarily related to the protein, carbohydrate, electrolyte, and mineral content within a given volume. The unit of measure of osmolality is milliosmoles per kilogram (mOsm/kg) or millimoles per kilogram (mmol/kg). Iso-osmolar is considered to be ~300 mOsm/kg (300 mmol/kg). Enteral formulations with greater amounts of partially hydrolyzed or elemental substrates have a higher osmolality than formulations containing polymeric or intact substrate forms. Therefore, formulations that contain sucrose or glucose, dipeptides and tripeptides, and amino acids are generally hyperosmolar. Increased caloric density also increases the osmolality of an enteral formulation. In general, the osmolality of commercially available enteral feeding formulations ranges from 300 to 900 mOsm/kg (300–900 mmol/kg). The American Academy of Pediatrics recommends that enteral formulations for use in infants have an osmolality of 450 mOsm/kg (450 mmol/kg) or less.

Symptoms of gastric retention, diarrhea, abdominal distension, nausea, and vomiting have been attributed to enteral formulations having high osmolality based on the assumption that a higher osmolality will draw water into the gut lumen. However, clinical evidence to support the relationship between osmolality and GI tolerance is lacking. The practice of diluting hyperosmolar formulations has not been shown to enhance tolerance and should be discouraged unless dilution is done to increase fluid intake.[8,36] Factors such as concurrent antibiotic therapy, method of enteral feeding administration, and the formulation's composition are likely to play a greater role in GI tolerance than the osmolality.

The renal solute load is determined by the protein, sodium, potassium, and chloride content of the enteral formulation. Formulations that contain a greater solute load increase the obligatory water loss via the kidney. It is estimated that 40 to 60 mL of water is the minimal amount necessary to excrete 1 g of nitrogen. Those receiving high-protein enteral formulations unable to ingest more water, such as a geriatric patient and a patient with altered mental status, may be at risk for significant dehydration.

CLASSIFICATION OF ENTERAL FEEDING FORMULATIONS

5 Although most patients' needs can probably be met using three or four different formulations, certain disease states or clinical conditions may warrant the use of a specialty feeding formulation. Development of an effective formulary system should focus on clinically significant characteristics of available formulations, avoid duplicate feeding formulations, and use only those specialty formulations with evidence-based indications. Categorizing enteral feeding formulations according to therapeutic class is necessary in developing a formulary system for adults (Table 152–5) and children (Table 152–6).

TABLE 152-5 Adult Enteral Feeding Formulation Classification System

Category	Features	Indications
Standard polymeric	Isotonic 1–1.2 kcal/mL (4.2–kJ/mL) NPC:N 125:1 to 150:1 May contain fiber	Designed to meet the needs of the majority of patients Patients with functional GI tract Not suitable for oral use
High protein	NPC:N <125:1 May contain fiber	Patients with protein requirements >1.5 g/kg/day, such as trauma patients and those with burns, pressure sores, or wounds Patients receiving propofol
High caloric density	1.5–2 kcal/mL (6.3–8.4 kJ/mL) Lower electrolyte content per calorie Hypertonic	Patients requiring fluid and/or electrolyte restriction, such as kidney insufficiency
Elemental	High proportion of free amino acids Low in fat	Patients who require low fat Use has generally been replaced by peptide-based formulations
Peptide-based	Contains dipeptides and tripeptides Contains MCTs	Indications/benefits not clearly established Trial may be warranted in patients who do not tolerate intact protein due to malabsorption
Disease-specific		
Kidney	Caloric dense Protein content varies Low electrolyte content	Alternative to high caloric density formulations, but generally more expensive
Liver	Increased branched-chain and decreased aromatic amino acids	Patients with hepatic encephalopathy
Lung	High fat, low carbohydrate Antiinflammatory lipid profile and antioxidants	Patients with ARDS and severe ALI
Diabetes mellitus	High fat, low carbohydrate	Alternative to standard, fiber-containing formulation in patients with uncontrolled hyperglycemia.
Immune-modulating	Supplemented with glutamine, arginine, nucleotides, and/or omega-3 fatty acids	Patients undergoing major elective GI surgery, trauma, burns, head and neck cancer, and critically ill patients on mechanical ventilation Use with caution in patients with sepsis Select nutrients may be beneficial or harmful in subgroups of critically ill patients
Oral supplement	Sweetened for taste Hypertonic	Patients who require supplementation to an oral diet

ALI = acute lung injury, ARDS = acute respiratory distress syndrome, GI = gastrointestinal, MCT = medium-chain triglyceride, NPC:N = nonprotein calorie-to-nitrogen ratio.

TABLE 152-6 Pediatric Enteral Feeding Formulation Classification System

Formula Type	Features	Indications
Infants		
Cow's milk-based	Standard energy density for feeding: 20–24 kcal/oz (2.8–3.3 kJ/mL); also available in concentrate (40 kcal/oz [5.6 kJ/mL]) and powder forms Standard formulation contains lactose, but also available as lactose-free	Normal, healthy infant
Soy protein-based	Standard energy density for feeding: 20 kcal/oz (2.8 kJ/mL); also available in concentrate (40 kcal/oz [5.6 kJ/mL]) and powder forms Lactose free May contain added soy fiber	Lactase deficiency or intolerance, galactosemia, diarrhea (fiber added)
Prematurity	Standard energy density for feeding: 24 kcal/oz (3.3 kJ/mL); also available in 20 (2.8 kJ/mL) and 30 kcal/oz (4.2 kJ/mL) forms Provide increased protein, mineral, electrolytes, and vitamins compared with term infant formulations	Preterm infants weighing <2–3 kg (4.4–6.6 lb)
Transition	Standard energy density for feeding: 22 kcal/oz (3.1 kJ/mL) Provide higher calcium and phosphorus content compared with term infant formulas	Preterm infants weighing <3 kg (6.6 lb) and ready for discharge
Semielemental/ elemental	Standard energy density for feeding: 20 kcal/oz (2.8 kJ/mL) Hydrolyzed protein and free amino acids May contain ARA and DHA Lactose free Typically contain MCTs ranging from 5% to 86% of fat content	Malabsorption, cow's milk protein allergy, chylothorax, cystic fibrosis, biliary atresia, short bowel syndrome, food allergies
Special diets	Low electrolyte/mineral content	Kidney disease
Children ages 1–10 years		
Standard	Standard energy density for feeding: 30 kcal/oz (1 kcal/mL [4.2 kJ/mL]) Intact protein; 30–38 g/L May contain added fiber	Functioning GI tract requiring tube feedings
Semielemental/ elemental	Standard energy density for feeding: 20–30 kcal/oz (2.8–4.2 kJ/mL) Hydrolyzed protein and free amino acids Lactose-free MCTs range from 33% to 87% of fat content	Malabsorption, cow's milk protein allergy, chylothorax, cystic fibrosis, biliary atresia, short bowel syndrome, food allergies

ARA = arachidonic acid, DHA = docosahexaenoic acid, GI =gastrointestinal, MCT = medium-chain triglyceride.

STANDARD POLYMERIC

A large number of commercially available enteral feeding formulations fall within the category of a standard polymeric formulation. These formulations are approximately isotonic (300 mOsm/L [300 mmol/L]), provide about 1 kcal/mL (4.2 kJ/mL), and are composed of intact nutrients in a nutritionally balanced mix of carbohydrate, fat, and protein. They are provided with or without dietary fiber. The nonprotein calorie-to-nitrogen ratio of these products is ~125:1 to 150:1. This ratio is a useful parameter for assessing protein density in relation to calories provided. Certain feeding formulations in this category may be promoted as high nitrogen but fall within standard protein amounts. To maintain their isotonicity, many products within this category are not sweetened, making them not very palatable and generally suited only for tube feeding and not oral supplementation; however, flavored products are available. The nutrient requirements of the majority of adult patients and children older than 1 year receiving EN can generally be met using feeding formulations in this category. Many infant formulas will also fall into this category because they provide 20 to 30 kcal/oz (2.8–4.2 kJ/mL).[37]

HIGH PROTEIN

Enteral feeding formulations with a nonprotein calorie-to-nitrogen ratio less than 125:1 can be categorized as high protein. The lower the ratio, the higher the protein density in relation to calories provided. In patients with high protein requirements, it is generally unacceptable to use a feeding formulation with standard protein amounts because the volume necessary to meet protein requirements will often result in excessive calorie intake. Patients who may be candidates for a high-protein feeding formulation are critically ill patients and those with pressure sores, surgical wounds, and high fistula output. In general, adult patients with estimated protein requirements exceeding 1.5 g/kg per day may benefit from a high-protein formulation. High-protein formulations may also be beneficial in mechanically ventilated patients who are receiving propofol for sedation. The vehicle for propofol is a soybean fat emulsion that contains 1.1 kcal/mL (4.6 kJ/mL). At therapeutic dosages, the use of propofol can significantly contribute to caloric intake, and a high protein formulation may be beneficial in allowing for the provision of protein requirements while minimizing the risk of overfeeding.

HIGH CALORIC DENSITY

High caloric density formulations are concentrated to provide less fluid and electrolyte intake in comparison to a standard polymeric formulation. They provide ~2 kcal/mL (8.4 kJ/mL) and will achieve similar calorie and protein intake as a standard polymeric formulation, using half the volume. High caloric density formulations are often necessary for patients who require fluid and/or electrolyte restriction, such as those with kidney insufficiency or congestive heart failure. Although specialty enteral formulations targeted for acute and chronic kidney failure are also available, many patients with kidney failure can be managed using a product in this category (see Chapter 153).

ELEMENTAL/PEPTIDE BASED

Formulations in this category contain protein and/or fat components that are hydrolyzed into smaller, predigested forms. Traditionally, enteral formulations in this category were referred to as elemental and contained a high proportion of protein in the form of free amino acids and a low amount of fat. Although still commercially available, the use of these formulations has been replaced in clinical practice with formulations containing a portion of the protein in the form of dipeptides and tripeptides and thus fewer free amino acids. These formulations are referred to as peptide based. This alteration in protein composition was made in an effort to optimize protein absorption in patients with impaired digestive or absorptive capacity. Results from human and animal intestinal perfusion studies indicate that the partially hydrolyzed sources of protein provide an absorptive advantage over formulas that contain only free amino acids.[50] Peptide-based formulations are generally

higher in fat than the older, elemental formulations and use MCTs in varying proportions as the fat source.

Evidence to support the use of elemental or peptide-based formulations is limited, and their routine use is generally not recommended. Patients who do not tolerate standard, intact nutrient formulations as a result of malabsorption or short bowel syndrome might be candidates for a trial of a peptide-based formulation. In addition, elemental or peptide-based products that have higher percentages of MCTs and small amounts of long-chain triglycerides may be beneficial for patients with severe pancreatic insufficiency, such as chronic pancreatitis and cystic fibrosis; severe abnormalities of the intestinal mucosa, such as untreated celiac disease; biliary tract disease, such as biliary atresia or severe cholestasis; or chylothorax.

DISEASE SPECIFIC

Newer enteral feeding formulations have been designed to meet unique nutrient requirements and manage metabolic abnormalities associated with specific disease states. Conditions for which specialized enteral feeding formulations exist include kidney and liver failure, lung disease, including ARDS, diabetes mellitus, wound healing, and metabolic stress. Chapter 153 discusses specific nutrient concerns during organ failure. Specialized enteral formulations designed to modulate the inflammatory response in patients with severe metabolic stress have been referred to as immune-modulating formulations or immunonutrition. These specialized formulations are supplemented with nutrients such as glutamine, arginine, branched-chain amino acids, nucleotides, and omega-3 polyunsaturated fatty acids, as a result of their potential role in regulating immune function; guidelines for their use in critically ill patients have been published.[10,11,51] Positive results have been reported in patients undergoing major elective GI surgery and major cancer surgery of the head and neck, patients with severe trauma or burns, and critically ill patients on mechanical ventilation. Multiple meta-analyses have shown that the use of immune-modulating enteral formulations in these select patient populations is associated with significant reductions in infectious complications, hospital length of stay, and duration of mechanical ventilation.[52,53] However, use of immune-modulating formulations has been associated with increased mortality in patients with preexisting severe sepsis and should therefore not be used or used with caution in these patients and in those who become septic while receiving these products.[10] Because of the lack of evidence to support their use, immune-modulating formulations are not recommended for use in children.[12]

CLINICAL CONTROVERSY

Although there appears to be a role for immune-modulating enteral formulations in critically ill patients, the optimal pharmaconutrient composition and type of critically ill patient most likely to benefit are unclear. Available literature has been criticized for the heterogeneity of studies, including a wide range of patient populations and a variety of enteral formulations. The specific effects and optimal dose of individual nutrient components contained in immune-modulating enteral formulations also remain unclear. Caution is suggested in patients with severe sepsis due to arginine content, but available evidence is conflicting.

In patients with ARDS, improved outcomes from using a low carbohydrate formulation supplemented with specific fatty acids (eicosapentaenoic acid and γ-linolenic acid) and antioxidants have been documented.[44,56] When compared with a high fat formulation, the specialized diet was associated with fewer days of ventilatory support, fewer ICU days, and fewer new organ failures. Consequently, it is recommended that this specialized formulation be used for patients with ARDS and severe ALI.[10,11,51]

There are no disease-specific enteral products currently marketed for use in infants or children from 1 to 10 years of age. The use of modular supplements is often necessary in children with special nutrition needs (see Modular Products below).

ORAL SUPPLEMENTS

In general, oral supplements are not intended for tube feeding but to enhance an oral diet. They are sweetened to improve taste and therefore are hypertonic (~450–700 mOsm/kg [450–700 mmol/kg]). Osmolality is generally not a problem in the patient with a functioning GI tract. However, in the tube-fed patient, a sweetened product is unnecessary and may contribute to GI intolerance, particularly diarrhea. Powder supplements that are mixed with milk should be avoided in lactose-intolerant patients. In addition to liquid supplements, puddings, gelatins, bars, and milkshake-like supplements are available.

MODULAR PRODUCTS

A module is a powder or liquid form of nutrients (e.g., protein, carbohydrate, or fat) that is used to supplement a commercially available enteral formulation. Addition of a modular product may be necessary, especially in children, to achieve a nutrient mix not supplied by a single commercially available product.[37,57] Alternatively, formulations available in powder or concentrate can be mixed with less water than needed for the standard dilution to deliver more nutrients in less volume. Infant formulas generally are concentrated beyond their standard concentration in this way. The mixing process required for modular components increases the potential for bacterial contamination and incorrect preparation. Contamination is a particular concern with the use of blenders and reconstitution of powders.[8,58] Human milk fortifiers are available for supplementation of human milk so that it meets the needs of a premature infant. Human milk fortifiers add calories, protein, and minerals and have been shown to improve nutritional outcomes in human milk–fed premature infants.[37,59–62]

REHYDRATION

Oral rehydration formulations are useful in maintaining hydration or treating dehydration in adult and pediatric patients with high GI output. Such formulations are available commercially in powder or liquid form or can be extemporaneously compounded. They can be administered orally or given via a feeding tube. The glucose content of oral rehydration solutions is important because it stimulates active transport systems, which, in turn, stimulate passive sodium and water uptake simultaneously with the glucose. Therefore, oral or enteral administration of rehydration solutions may decrease fecal water loss and generate a positive electrolyte balance.[63]

FORMULARY AND DELIVERY SYSTEM CONSIDERATIONS

The selection of a product for an individual should be based on the patient's nutritional requirements. In general, no more than one product is necessary per category of enteral feeding formulation, and it may be possible to omit certain categories based on the specific patient population within a given institution. Additional selection criteria include container size and type, liquid or powder form, shelf life, ease of use, and cost.

Most enteral products are available as ready-to-use, prepackaged liquids, and a few are available in the powdered state and require reconstitution prior to use. Advantages of ready-to-use liquid formulations are convenience and lower susceptibility to microbiologic contamination. One disadvantage is that more storage space is required. The ease or convenience of a ready-to-use liquid is especially important for self-care patients, the disabled, and those who have difficulty reading or following printed instructions. Ready-to-use liquid enteral formulations are generally available in rigid plastic containers, cans, or closed, ready-to-hang bags. Bolus administration of EN is usually achieved using formulas available in cans. However, when formula from a can is used for continuous or cyclic administration, it must first be poured into a bag or bottle to allow for administration via a pump. This "open system" differs from the closed, ready-to-hang containers from the standpoint of microbial contamination risk. The use of a powder formula is also considered an open system of delivery.

Contaminated enteral feeding formulations are a potential source of infectious complications.[8,63] The GI tract may serve as a portal of entry for bacteria into the systemic circulation, especially in patients who are receiving multiple antibiotics, have undergone a surgical procedure, are immunosuppressed, or have GI tract stasis from a variety of causes. The contamination of enteral feeding formulations is associated with a lack of attention to proper handling techniques, inability to disinfect preparation equipment, and nonsterile or contaminated tube-feeding additives. Unlike liquid formulations, powdered products are not guaranteed by the manufacturer to be sterile because of the inability to properly sterilize the powder without destruction of some of its components. Occasional contamination of milk powder and consequently powdered infant formulas with *Enterobacter sakazakii* (*Cronobacter* species) has been reported.[58] Contamination of one infant formula with *E. sakazakii* at the manufacturing site was implicated in the death of an infant in a neonatal ICU, prompting FDA warnings regarding the use of powdered formulations in premature neonates and other immunocompromised infants. Because powder formulations require reconstitution, often in a blender that is difficult to sterilize, they are also more susceptible to contamination at the time of preparation. Stringent handling procedures are recommended during all aspects of enteral feeding preparation and delivery to minimize contamination risk. The closed-system containers supply a ready-to-hang, prefilled, sterile supply of formula in volumes of 1 to 1.5 L. Numerous, but not all, enteral formulations intended for use in adults and some of the pediatric formulations are available in the closed-administration system. The closed-administration system also offers the advantage of not requiring refrigeration and allowing hang times beyond 24 to 36 hours, whereas the conventional open-delivery system necessitates hang times of generally 4 to 8 hours.

COMPLICATIONS AND MONITORING

The majority of complications associated with EN are metabolic, GI, and mechanical. The early detection and management of potential complications is necessary to allow for the successful use of EN. In addition, measures to avoid complications should be incorporated into the management of all patients receiving EN (Table 152–7).

TABLE 152-7 Suggested Monitoring for Patients on Enteral Nutrition

Parameter	During Initiation of EN Therapy	During Stable EN Therapy
Vital signs	Every 4–6 hours	As needed with suspected change (i.e., fever)
Clinical assessment		
Weight	Daily	Weekly
Length/height (children)	Weekly–monthly	Monthly
Head circumference (<3 years of age)	Weekly–monthly	Monthly
Total intake/output	Daily	As needed with suspected change in intake/output
Tube-feeding intake	Daily	Daily
Enterostomy tube site assessment	Daily	Daily
GI tolerance		
Stool frequency/volume	Daily	Daily
Abdomen assessment	Daily	Daily
Nausea or vomiting	Daily	Daily
Gastric residual volumes	Every 4–8 hours (varies)	As needed when delayed gastric emptying suspected
Tube placement	Prior to starting, then ongoing	Ongoing
Laboratory		
Electrolytes, blood urea nitrogen/serum creatinine, glucose	Daily	Every 1–3 months
Calcium, magnesium, phosphorus	3–7 times/week	Every 1–3 months
Liver function tests	Weekly	Every 1–3 months
Trace elements, vitamins	If deficiency/toxicity suspected	If deficiency/toxicity suspected

EN = enteral nutrition, GI = gastrointestinal.

METABOLIC COMPLICATIONS

Metabolic complications associated with EN are similar to those associated with PN, but the incidence tends to be lower. EN is associated with a lower incidence of hyperglycemia than PN.[64] Complications related to hydration and electrolyte imbalance and altered glucose control are observed more frequently in critically ill patients, especially those with underlying organ dysfunction. The micronutrient and water contents within enteral feeding formulations are in fixed amounts intended to meet recommended dietary allowances for the average patient. Consequently, the frequency of clinical and laboratory assessment to monitor hydration, electrolyte, organ function, and glucose control adequately for a patient who is critically ill is greater than for a stable patient residing in a rehabilitation unit or at home. Patients receiving long-term EN at home may require laboratory monitoring only every 2 to 3 months, depending on their clinical status. Besides macronutrient content, it is important to evaluate the actual content of water and micronutrients provided by the enteral formulation, especially in critically ill patients at high risk of metabolic complications. Supplemental fluid and electrolytes may be required in some patients. Conversely, for patients who have fluid retention or increased serum electrolytes, the enteral formulation may need to be changed to one that is more concentrated or provides less of a particular nutrient.

GASTROINTESTINAL COMPLICATIONS

6 The GI complications associated with tube feeding include nausea, vomiting, abdominal distension, cramping, aspiration, diarrhea, and constipation. Gastric residual volume refers to the volume of contents in the stomach and is measured by using a syringe and aspirating from a large-bore NG or gastrostomy tube. For patients receiving tube feeding into the stomach, gastric residual volumes are widely used as an indicator of tolerance. It is believed, although not well documented, that patients with high gastric residual volumes

are at higher risk of vomiting and/or aspiration. The frequency of measuring gastric residual volumes generally varies between 4 and 8 hours, and most institutions follow a protocol that directs the frequency of monitoring and when to hold feedings.[65]

CLINICAL CONTROVERSY

Clinicians disagree as to what constitutes excessive gastric residual volume. In adults, the definition of a high residual volume ranges from greater than 200 mL to 500 mL. In children, residual volumes greater than 2 to 3 times the bolus volume or twice the hourly infusion rate for continuous gastric feedings are considered excessive.

If high gastric residuals occur, the response is often to withhold the next scheduled bolus or stop or decrease the rate of a continuous feeding. However, frequent interruptions in the delivery of EN can adversely affect the attainment of nutrient goals. Because gastric residual volumes are unreliable, symptoms such as abdominal distension, fullness, bloating, and discomfort are generally more reliable indicators of EN intolerance and should be assessed frequently. A trend in elevated gastric residual volumes is generally more important than an isolated high measurement. If symptoms are present, and residual volumes are elevated, a decrease in tube-feeding rate may be warranted. In general, abruptly stopping tube feeding should be reserved for patients with overt regurgitation or aspiration.[66] Gastric residual volumes should generally be reinstilled through the tube to the patient unless they are excessive (greater than 500 mL in adults).[8,35,66] It may be beneficial to initiate a prokinetic agent such as metoclopramide or erythromycin to increase the gastric emptying rate and decrease residual volume, thereby enhancing tolerance.[35,67,68] If high gastric residual volumes persist, a transpyloric feeding tube may be considered for feeding into the small bowel. Other interventions may include a trial of a proton-pump inhibitor or histamine$_2$-receptor antagonist to decrease the volume of gastric secretions and minimizing the use of narcotics, sedatives, or other agents that may delay gastric emptying.[35,36]

Aspiration pneumonia is considered the most serious complication associated with tube feeding and is potentially life-threatening. Although aspiration is a fairly common event for critically ill patients receiving tube feeding, progression to aspiration pneumonia is difficult to predict. Risk factors for aspiration include a previous aspiration episode, decreased level of consciousness, neuromuscular disease, structural airway or GI tract abnormalities, endotracheal intubation, vomiting, persistently high gastric residual volumes, and prolonged supine positioning.[35] Identification of these risk factors, along with close monitoring of gastric residual volumes, is recommended for the management of critically ill patients receiving tube feeding. Historically, blue food coloring had been added to enteral formulations in an attempt to detect aspiration. However, because of its low sensitivity for detection and association with several serious adverse events, including death, the addition of blue food dye to enteral formulations is no longer advised.[10,35,69] There are currently no reliable methods available to detect aspiration in enterally fed patients.[10,70]

Strategies to decrease aspiration risk include keeping the patient's head of the bed elevated to a 30- to 45-degree angle during feeding and for 30 to 60 minutes after intermittent boluses, in addition to those mentioned above. This positioning makes it more difficult for the EN formulation to migrate up the esophagus against gravity. Changing from bolus or intermittent to continuous administration may also reduce the risk, although this has not been proven. Aspiration may occur with improper feeding tube placement or displacement; therefore, regular assessment of tube position is recommended.[8,35]

The reported incidence of diarrhea in patients receiving EN ranges from 20% to 70% because of the lack of a standard definition and the number of contributing factors.[36,71,72] When monitoring for diarrhea, stool frequency, consistency, and volume should be evaluated, and previous bowel habits should be considered. One commonly accepted definition of diarrhea is the occurrence of more than three to five liquid stools daily or a stool volume >250 to 500 mL/day (10 mL/kg per day in children) for at least 2 consecutive days.[71] Therefore, the occurrence of one or two loose stools does not constitute diarrhea or require intervention.

7 Diarrhea in patients receiving tube feeding may be caused by a number of factors, and management should be directed at identifying and correcting the most likely cause(s). Tube feeding–related factors that may contribute to diarrhea include too rapid delivery or advancement of formula, intolerance to the formula composition, administration of large volumes of feeding into the small bowel, and formula contamination. Measures to prevent or manage the development of diarrhea related directly to the tube feeding should address these potential causes.[63,72] If diarrhea occurs when using a fiber-free formulation, consider switching to a fiber-containing formulation. If using a high-fat formulation, it may be beneficial to switch to a formulation lower in fat or having a proportion of the fat supplied as MCTs. Finally, it is important to assess the risk of bacterial contamination of the formula and take steps to minimize any potential risk factors. Once infectious etiologies have been excluded, pharmacologic intervention may be required to control severe diarrhea, including the use of opioids, diphenoxylate, and loperamide.

A common cause of diarrhea that is unrelated to tube feeding is drug therapy, particularly the use of broad-spectrum antibiotics. Another drug-related cause is the sorbitol contained in many liquid medication formulations. Sorbitol is used as a sweetening agent to enhance palatability, but it acts as an osmotic laxative. In addition, many drugs available in a liquid form are hyperosmolar, which may contribute to diarrhea. Because many patients receiving tube feeding also receive medications in a liquid form, all medications should be evaluated for their potential contribution. Infectious causes of diarrhea, such as antibiotic-induced bacterial overgrowth by *Clostridium difficile* or other intestinal flora, need to be considered when diarrhea develops. Diarrhea also may occur as a result of malabsorption, secondary to the underlying disease state or condition.

MECHANICAL COMPLICATIONS

Mechanical complications of EN are those associated with the feeding tube, including tube occlusion or malposition, and nasopulmonary intubation. Feeding tube occlusion is usually a result of the improper administration of medications and/or flushing technique. Kinking of the tube also may cause occlusion. The tube should be flushed with at least 30 mL of water before and after administering any medication. The recommended volume used in children is generally less than 30 mL and depends on the size of the tube. The frequency of flushing should be at least every 8 hours during continuous feeding and before and after each intermittent feeding. If tube occlusion occurs, an attempt to irrigate the tube with warm water should be made. Other fluids such as colas and cranberry juice have been used to irrigate occluded tubes but have not been shown to be any better than warm water. Some success in reestablishing patency has been shown with the use of pancreatic enzymes mixed in sodium bicarbonate.[73] Declogging devices that are specifically designed to unclog feeding tubes are available. They have been designed to either mechanically break through or remove the occlusion or provide an applicator and syringe prefilled with pancreatic enzymes and various powders targeted to restore patency.

CLINICAL CONTROVERSY

The source of water used to flush the feeding tube and maintain patient hydration via the feeding tube is controversial. Tap water is adequate for the otherwise healthy, immunocompetent patient. However, the acute or chronically ill patient receiving EN may be at higher risk from exposure to nonsterile tap water and may benefit from the use of purified water. Nosocomial infections from contaminated tap water sources have been reported in critically ill patients. The use of purified water for tube-feeding flushes in at-risk patients has been recommended by some clinicians.

Inadvertent tube removal or displacement has been reported in ~40% of patients receiving EN.[74] An agitated or confused patient may pull at the feeding tube and cause its removal or malposition. Measures to decrease agitation and confusion should be attempted. Various manipulations done to the patient throughout the day may also cause malposition. Securing the tube with tape may be helpful, as well as marking the tube with permanent ink at the exit site to assess for change in position. A recently developed nasal bridle that uses a magnetic retrieval system has proven to be a simple and effective method for securing nasoenteric feeding tubes and preventing accidental tube removal.[74]

When a feeding tube is inserted nasally or orally, there is a risk that the tube may inadvertently enter the tracheobronchial tree. The risk may be higher in patients who have an impaired cough or gag reflex and when a stylet is used for tube insertion. Proper positioning of the tube should always be confirmed by radiography prior to feeding initiation and routinely reassessed to avoid inadvertent administration of enteral formula into the lung.

OTHER COMPLICATIONS

Infectious complications of feeding tube placement include sinusitis (with nasoenteric placement), exit site-related infections (e.g., cellulitis, subcutaneous abscess, and necrotizing fasciitis), and intraabdominal infections (e.g., peritonitis and abscess). Leaking and bleeding around the exit site can also occur.[31,34] Formation of excessive granulation tissue around the exit site is often the cause of leaking and bleeding and can be managed by applying a line layer of silver nitrate.

A unique complication of tube feedings in children, especially in the first year of life, is the development of feeding disorders as a consequence of oral hypersensitivity, poor oral/motor skills, and food aversion. In these children, transitioning from tube to oral nutrition is often difficult and protracted. The involvement of an occupational or speech therapist, behavioral psychologist, or other trained individual, as well as perseverance by the family, often is necessary to improve oral intake. Avoidance of a strict nothing by mouth (NPO) status, if possible, and oral stimulation programs for those children who must remain NPO are recommended to avoid this complication.[75]

DRUG DELIVERY VIA FEEDING TUBE

Using enteral feeding tubes to deliver drugs is a common practice and offers an alternative for patients unable to take drugs by the oral route. However, in addition to complications of tube occlusion, effects on drug bioavailability and other potential interactions need to be considered when using this route. Medications have been given as a concomitant bolus administration via the feeding tube or admixed with the enteral feeding formulation.

CONCOMITANT DRUG ADMINISTRATION

8 Concomitant administration of medications with enteral feedings requires awareness of certain limitations. Medications delivered directly into the stomach allow for the normal process of drug dissolution. Medications delivered into the small bowel may result in alterations of drug dissolution because the stomach is bypassed. In addition, therapeutic effect designed to occur within the stomach, such as with antacids and sucralfate, may be influenced by the feeding tube route. Because many drugs are best absorbed in the fasting state, they should be administered on an empty stomach whenever possible. Patients on bolus gastric feeding may receive medications appropriately spaced between the feedings, but patients on continuous feeding will require interruption for drug administration.

Selecting the proper medication dosage form for coadministration with the tube feeding is another important consideration. Medications in sublingual form, sustained-release capsules or tablets, and enteric-coated tablets should not be crushed and therefore should not be administered via enteral feeding tubes.[8,76] Solid dosage forms that are appropriate to crush should be prepared as a very fine powder and mixed with 15 to 30 mL of water or other appropriate solvent before administering through the tube. In addition, many capsules may be opened and the contents administered in the same manner. Pellets contained inside microencapsulated dosage forms should generally not be crushed. It may be acceptable to administer intact pellets through feeding tubes, provided that the pellets are small enough and drug absorption is not compromised.[76–79] To avoid the need to crush a solid dosage form and mix with water, liquid dosage preparations have been used for administration through feeding tubes. However, the risk of GI intolerance should be considered because of the hyperosmolality of many liquid formulations and possible sorbitol content.[76–78] Although the use of a liquid dosage preparation may be more convenient than a solid dosage form, it may not be the best choice if GI intolerance is an issue.

As previously mentioned, adherence to proper flushing technique is necessary to prevent occlusion when administering medication through a feeding tube. At least 15 mL of water should be given before and after medication administration to clear the drug through the tube and help get the drug into the stomach.[8] If more than one medication is scheduled for a given time, each should be administered separately, and the tube should be flushed with at least 15 mL of water between them.[8,76] Flush volume will be less for children but generally should be at least 5 mL to ensure adequate flushing of the tube.[8]

ADMIXTURE OF DRUGS WITH ENTERAL FEEDING

Mixing liquid medications with certain enteral feeding formulations is associated with several types of physical incompatibilities, including granulation, gel formation, separation, and precipitation.[76,77] Not only can these physical incompatibilities inhibit drug absorption, but gel formation potentially may clog small-bore feeding tubes. Physical incompatibility with medications is more common in formulations that contain intact protein than in those with hydrolyzed protein. Also, medication and enteral formula incompatibilities are more common with the use of acidic pharmaceutical syrups. The most prudent recommendation is to avoid the routine admixture whenever possible, especially for nonaqueous preparations and syrups. In the clinical setting, exceptions do exist, such as adding electrolyte injections of potassium or sodium to enteral formulas to assist in maintaining or repleting electrolytes.

TABLE 152-8 Medications with Special Considerations for Enteral Feeding Tube Administration

Drug	Interaction	Comments
Phenytoin	Reduced bioavailability in the presence of tube feedings Possible binding of phenytoin to calcium caseinates or protein hydrolysates in enteral feeding	To minimize interaction, holding tube feedings 1–2 hours before and after phenytoin has been suggested; this has no proven benefit Adjust tube-feeding rate to account for time held for phenytoin administration Monitor phenytoin serum concentration and clinical response closely Consider switching to IV phenytoin route if unable to reach therapeutic serum concentration
Fluoroquinolones Tetracyclines	Potential for reduced bioavailability because of complexation of drug with divalent and trivalent cations found in enteral feeding	Consider holding tube feeding 1 hour before and after administration Avoid jejunal administration of ciprofloxacin Monitor clinical response
Warfarin	Decreased absorption of warfarin because of enteral feeding; therapeutic effect antagonized by vitamin K in enteral formulations	Adjust warfarin dose based on INR Anticipate need to increase warfarin dose when enteral feedings are started and decrease dose when enteral feedings are stopped Consider holding tube feeding 1 hour before and after administration
Omeprazole Lansoprazole	Administration via feeding tube complicated by acid-labile medication within delayed-release, base-labile granules	Granules become sticky when moistened with water and may occlude small-bore tubes Suggested that granules be mixed with acidic liquid when given via a gastric feeding tube An oral liquid suspension can be extemporaneously prepared for administration via a feeding tube

INR= International Normalized Ratio, IV = intravenous(ly).

DRUG–NUTRIENT INTERACTIONS

9 The most significant drug–nutrient interactions that can occur during continuous enteral feeding are those in which the bioavailability of the drug is reduced, and the desired pharmacologic effect is not achieved (Table 152–8). Unfortunately, limited clinical studies are available to document the extent of this problem with enteral feeding. Most of the observations are anecdotal case reports involving few patients. One of the most studied interactions has been the interaction between phenytoin and enteral feeding that results in decreased phenytoin bioavailability. The interaction was first reported in 1982,[80] yet the precise mechanism for the interaction remains unclear. Phenytoin serum concentrations may decrease by as much as 50% to 75% when phenytoin is given concomitantly with EN, possibly as a result of the binding of phenytoin to calcium caseinates or protein hydrolysates in the enteral formulation. Patients typically require higher than normal phenytoin doses while receiving EN.[76,77,81] The patient's clinical response and phenytoin serum concentrations should be monitored closely if phenytoin is given enterally during continuous enteral feeding and after its discontinuation.

Decreased bioavailability of certain antibiotics, particularly quinolones, has been documented when coadministered with enteral feeding.[76,77,82] Although the practice of holding tube feeding for 30 minutes before and 30 minutes after quinolone administration has been recommended, it has not been shown to improve drug absorption. There is evidence to suggest that ciprofloxacin absorption is significantly decreased when given via a jejunostomy tube, so this practice should be avoided.[82]

Warfarin resistance has been documented during enteral feeding, possibly as a consequence of decreased absorption or the antagonist effects of vitamin K. Before 1980, it was thought that the content of vitamin K (up to 1,330 mcg/1,000 kcal [or 317 mcg/1000 kJ] of enteral feeding formula) was contributing to the pharmacologic interaction with warfarin. Subsequently, the vitamin K content within formulas intended for use in adults was reformulated to less than 200 mcg/1,000 kcal (or 48 mcg/1000 kJ). However, warfarin resistance continues to be reported, and a warfarin dosage increase may be required in patients receiving EN.[76,77,83] The patient's International Normalized Ratio should be closely monitored in patients receiving both warfarin and enteral feedings. Conversely, when EN is discontinued, a reduction in warfarin dose may be required.

NUTRITION OUTCOME GOALS

Nutrition outcome goals of EN are to promote an adequate nutritional state in adults and promote growth and development of infants and children. Assessing the outcome of EN includes monitoring objective measures of body composition, protein and energy balance, and subjective outcome for physiologic muscle function and wound healing. Besides an improvement in nutrition outcome, a goal of EN is to reduce disease-related morbidity and mortality. Measures of disease-related morbidity include length of hospital stay, infectious complications, and the patient's sense of well-being. Such clinical outcome goals are extremely difficult to document with the use of EN, in part because other factors, such as age, underlying comorbidities, extent of injury, immunocompetence, and end-organ complications, also affect disease outcome. However, no disease process improves significantly with prolonged starvation. Ultimately, the successful use of EN can avoid the need for PN in patients unable to meet nutrient requirements with an oral diet.

PHARMACOECONOMIC CONSIDERATIONS

EN has consistently been shown to be less expensive than PN. The pharmacoeconomic comparison between EN and PN should include an evaluation of therapeutic outcome relative to the cumulative cost associated with providing the therapy. Therapy costs should include costs related to placement and maintenance of enteral or parenteral access; costs of nutrients and related supplies; time spent by professional staff in ordering, compounding, delivering, administering, and managing therapy; costs of laboratory monitoring; and costs of managing complications that result from therapy. However, it is very difficult to capture all of these costs and separate actual cost from charge-based estimates. None of the existing pharmacoeconomic analyses incorporate all costs related to EN and PN therapy, but selected cost comparisons derived from clinical research trials in institutional settings have been published.[84–86] The cost of EN has been reported to be ~25% to 50% that of PN. Incorporating the cost of managing complications related to therapy greatly increases the overall cost of PN compared with EN.[86] In situations in which improved outcome has not been demonstrated with PN, EN appears preferable on a cost basis.[7]

ABBREVIATIONS

ALI: Acute lung injury
ARA: Arachidonic acid
ARDS: Acute respiratory distress syndrome
DHA: Docosahexaenoic acid
EN: Enteral nutrition
IgA: Immunoglobulin A
MCT: Medium-chain triglyceride
NG: Nasogastric
NPO: Nothing by mouth
PEG: Percutaneous endoscopic gastrostomy
PEJ: Percutaneous endoscopic jejunostomy
PN: Parenteral nutrition

CHAPTER 153

Nutritional Considerations in Major Organ Failure

BRIAN M. HODGES AND MARK DELEGGE

KEY CONCEPTS

1. Carbohydrate calories absorbed and protein lost via renal replacement therapy must be accounted for when designing a parenteral (PN) or enteral nutrition (EN) regimen for patients with renal failure.
2. Administration of renally excreted or regulated electrolytes, such as potassium, magnesium, and phosphorus, should be limited in patients with renal failure unless refeeding syndrome is present or continuous renal replacement therapies are used.
3. Hyperglycemia is common in cirrhosis. Patients with fulminant hepatitis are prone instead to hypoglycemia.
4. Folic acid and thiamine supplementation is important in patients with liver disease for the prevention of anemia and Wernicke encephalopathy, respectively.
5. In short bowel syndrome, PN should be used to meet nutritional needs in the immediate postoperative period after intestinal resection.
6. Increased fluid and electrolyte replacement is often necessary in patients with short bowel syndrome to replace GI losses. Patients may need increased calcium, magnesium, zinc, and other trace elements because of decreased absorption and/or excessive GI losses.
7. Patients with ileal resection commonly develop vitamin B_{12} deficiency, necessitating therapy with parenteral cyanocobalamin.
8. As small bowel adaptation occurs, some patients with short bowel syndrome receiving PN can be transitioned successfully to EN. Early initiation of enteral intake affects adaptation because intraluminal nutrients are a stimulus for this process.
9. Care should be taken to avoid overfeeding of patients with respiratory failure, as excessive carbon dioxide production may limit the patients' ability to have mechanical ventilation discontinued.
10. Excessive fluid administration should be avoided in patients with pulmonary disease because it may worsen already compromised pulmonary function.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Because organ failure may alter absorption, use, and excretion of nutrients, administration of standard nutrients to patients with organ dysfunction may be inappropriate. Individualization of a nutritional regimen for these patients often requires a planned, disease-specific approach. Different laboratory testing or more frequent monitoring of traditional markers may be necessary to ensure that the desired therapeutic goals are achieved. For example, it is impossible to collect a 24-hour urine specimen to measure urea nitrogen and nitrogen balance in an anuric patient. In this situation, an alternative method of calculating urea nitrogen appearance is required.

Patients with acute organ failure requiring nutrition support often are hospitalized in intensive care units (ICUs). With advances in treating chronic organ failure, increasing numbers of older, chronically ill patients will require nutritional support on a long-term basis. It therefore will become increasingly common for nutrition support to be provided in community and ambulatory settings. Regardless of the setting, the clinician needs a firm pathophysiologic foundation on which to build a pharmaceutical care plan to ensure appropriate outcomes for patients requiring nutritional support.

This chapter discusses the nutritional needs of patients with renal, hepatic, GI, and pulmonary failure. The predominant approaches to ensure delivery of safe and efficacious nutrients to patients with these disorders are critically reviewed.

RENAL FAILURE

Major differences exist between the metabolic, fluid, and electrolyte management of patients with acute kidney injury (AKI) versus those with stable chronic kidney disease (CKD) and those with an AKI episode that complicates preexisting CKD. For example, positive nitrogen balance is more difficult to achieve in patients with AKI because of the increased rate of protein catabolism. Additionally, patients with AKI are more likely to develop hyperglycemia during nutritional support and frequently are dialyzed by modalities that are not used commonly for those with end-stage kidney disease. Because of these differences, the nutritional management of patients with AKI is discussed separately.

ACUTE KIDNEY INJURY

Epidemiology

AKI, as defined in Chapter 51, is a decrease in glomerular filtration rate occurring over hours to weeks that is associated with an increase in the serum concentrations of waste products, such as urea and creatinine. AKI has been observed in as many as 5% of hospitalized patients and in up to 50% of patients receiving care in an ICU.[1] The mortality rate of AKI patients who require renal replacement therapy ranges from 40% to 70%. A study in Austria demonstrated that despite the recent advancements made in renal

replacement therapies and ICU care, the mortality rate of patients was still 62.8%.[2] Severe malnutrition has been documented in 42% of patients with AKI and is an independent predictor of in-hospital mortality and increased morbidity from sepsis, shock, dysrhythmias, and acute respiratory failure.[3] Because malnutrition is an apparently independent contributor to mortality in patients with AKI, nutrition support remains a cornerstone in the treatment of these patients, despite a lack of evidence demonstrating improvement in patient survival.[1,4]

Pathophysiology

Energy Requirements AKI does not itself change patient energy requirements. Energy requirements in AKI are greatly influenced by comorbid critical illness and the types of renal replacement therapies used.[4,5] In this patient population, they ideally should be measured by indirect calorimetry (see Chapter 149) because energy expenditures of patients with AKI are highly variable. Energy expenditure is close to normal in patients with uncomplicated AKI, but resting energy expenditure (REE) increases of up to 30% have been reported in the presence of sepsis and AKI.[6] Typically, patients with AKI and without underlying hypermetabolic conditions should receive 20 to 30 kcal/kg (84–126 kJ/kg) per day. Those with underlying hypermetabolic conditions, such as thermal injury or head injury, usually need even greater caloric intake, up to 35 kcal/kg (147 kJ/kg) per day, unless indirect calorimetry indicates otherwise.[7,8] Patients with stage 4 or 5 CKD and acute metabolic illness or injury should receive similar energy provisions.[5] Increasing energy provision beyond this to 40 kcal/kg/day (167 kJ/kg/day) is not associated with better nutritional outcomes but has been associated with more frequent metabolic complications.[9]

Carbohydrates Hyperglycemia and peripheral insulin resistance are common in AKI. Patients usually have a superimposed illness that exacerbates glucose intolerance. The etiology of glucose intolerance in AKI is thought to be a result of increased levels of glucagon, growth hormone, and catecholamines—all known antagonists of insulin. Other proposed mechanisms are an elevated glucagon-to-insulin ratio secondary to impaired degradation of these hormones and elevated secretion of inflammatory cytokines.

Fat Intolerance to IV lipid emulsion (IVLE), evidenced by increased serum triglyceride concentrations, is common in AKI. Hypertriglyceridemia is thought to be caused by decreased catabolism of triglycerides and increased triglyceride synthesis from free fatty acids.[1] Hepatic triglyceride lipase and peripheral lipoprotein lipase activity may be reduced significantly in AKI patients.[6] Insulin resistance and metabolic acidosis may contribute to this process by inhibiting lipoprotein lipase.[9] Triglyceride concentrations therefore should be measured before administering IVLE to patients with AKI.

Protein AKI is associated with marked protein catabolism and urea accumulation. Most patients with AKI have a primary stressful illness that results in ureagenesis; thus, protein breakdown is accelerated. Protein catabolism in AKI may be stimulated as the result of insulin resistance, metabolic acidosis, circulating proteases and inflammatory mediators, and the effects of uremic toxins.[1] The mechanism may be direct, via modulation of protein synthesis, or indirect, by inhibiting the action of anabolic hormones. Unlike healthy patients or those with CKD, protein catabolism in the presence of AKI is not significantly attenuated by the administration of exogenous nutrition support.[4]

Significant amounts of protein and amino acids are also removed by dialysis. Amino acid losses of 5.2 g per conventional hemodialysis (HD) treatment, 7.3 g per high-flux HD session, and up to 13 to 16 g/day during continuous renal replacement therapy (CRRT) have been reported.[10,11] The clearance of histidine and tryptophan are enhanced, whereas the clearance of phenylalanine and valine is reduced in nondialyzed patients with AKI.[12] In patients undergoing CRRT, glutamine represents roughly one-third of all amino acid dialysate losses. Serum glutamine concentrations decrease significantly early during CRRT but may return to baseline subsequently, suggesting altered glutamine metabolism early in the course of CRRT.[13]

Fluid, Electrolyte, And Acid–Base Disorders The volume status of patients with AKI depends primarily on residual urine output and the type of dialysis received, if any. The patient with oliguric AKI will have impaired excretion of sodium and water. In nonoliguric AKI, considerable sodium may be lost in the urine, necessitating replacement to maintain sodium balance. This also applies to the patient who is losing considerable gastric fluids. Patients on CRRT will lose sodium via hemofiltration or dialysis and should be given sodium as part of their CRRT replacement fluid regimen. To maintain sodium balance, most replacement fluids contain between 140 and 154 mEq/L (140 and 154 mmol/L) of sodium. The rate of administration of these fluids varies based on the type of CRRT, the rate of ultrafiltration, and the patient's clinical condition.[14]

Hyperkalemia is observed frequently in AKI secondary to protein catabolism and intracellular potassium release, as discussed in Chapter 60. Hyperkalemia also results from the impaired secretion and excretion of potassium by the kidney and the endogenous release secondary to tissue breakdown. If this is severe, emergent dialysis may be indicated. Patients on CRRT, however, usually require potassium replacement to avoid hypokalemia as a consequence of the significant dialytic potassium losses.

Because phosphorus is excreted renally, hyperphosphatemia is commonly observed in patients with AKI. Like potassium, large amounts of phosphorus are released into the circulation secondary to tissue breakdown. Control of hyperphosphatemia is important because as the calcium–phosphorus product (serum calcium in milligrams per deciliter multiplied by serum phosphorus in milligrams per deciliter) exceeds 55, the risk of developing metastatic calcification increases (see Chapter 58). Conversely, with initiation of dialysis, particularly CRRT, patients must be monitored for hypophosphatemia due to the enhanced clearance by the CRRT procedure. Hypophosphatemia may also be observed in patients with AKI or CKD who continue to receive oral phosphate binders despite decreased oral phosphorus intake.

The net removal of calcium during the continuous dialysis modalities depends on the calcium concentration of the dialysate fluid. Severe hypocalcemia has been reported when regional citrate anticoagulation has been used for CRRT in AKI and hepatic failure patients.[14]

Hypermagnesemia is less common than other electrolyte abnormalities, but it has been noted in those with AKI as the result of impaired excretion and endogenous release from tissues. Both magnesium and calcium losses via CRRT have been quantified: average daily losses were 24 mmol and 70 mmol of magnesium and calcium, respectively.[11]

Patients with AKI usually have metabolic acidosis because of impaired excretion of organic acids. If potassium and sodium are needed in the parenteral nutrition (PN) regimen, they should be added as acetate salts, which are converted to bicarbonate in the liver. This increase in bicarbonate partially compensates the patient's metabolic acidosis. Intermittent and continuous dialytic therapies also may help improve the metabolic acidosis because they increase the removal of endogenously generated acids and serum bicarbonate levels as the result of diffusion of bicarbonate from the dialysate into the blood. Correction of acidosis may be best managed with the use of lactate buffers (lactate > bicarbonate > acetate).[15]

Trace Elements The requirements for trace elements during nutritional support of AKI patients are not well established because

trace element accumulation or losses during AKI have not been characterized. Additionally, many of the trace element alterations in AKI may represent an "acute-phase reaction."[7] Zinc and chromium are excreted by the kidney and theoretically can accumulate because of reduced excretion and increased intake secondary to impurities in dialysate or IV fluids. In patients with AKI undergoing CRRT, zinc intake via nutrition support exceeds losses.[11] Selenium concentrations are reduced in AKI and may result in a decrease in thyroxine concentrations.[16,17] Because manganese and copper are excreted in bile, and zinc and copper are removed by peritoneal dialysis (PD) and HD, most patients receiving PN should also receive standard daily trace element supplementation; in addition, some experts recommend that selenium supplementation may be necessary.[4,17] Supplemental doses of 50 to 70 mcg/day may be necessary to maintain selenium balance.[7]

Vitamins The little available information available indicates that AKI-associated alterations in vitamin requirements are minimal; thus, there is no need to alter patient treatment.[18] Losses of vitamins via dialysis also must be considered. Traditional HD enhances the clearance of several water-soluble vitamins, such as folic acid, vitamins C and B_{12}, and pyridoxine, but not the highly protein-bound, fat-soluble vitamins A and D.[19] Significant reductions in the plasma concentrations of water-soluble vitamins have also been observed in patients receiving CRRT.[13,17] Currently, it seems prudent to administer vitamins at least daily in doses recommended by the Nutrition Advisory Group of the American Medical Association for patients receiving PN (see Chapter 149).[7] Administration of ascorbic acid should be restricted to 30 to 50 mg/day to offset losses caused by renal replacement therapies but to avoid secondary oxalosis, which may worsen renal function.[8,20] If the enteral route is used for nutritional support, vitamin administration should at least meet the recommended daily allowances.

TREATMENT

DESIRED OUTCOME

The maintenance of lean muscle mass and the prevention of disorders of macro- and micronutrient excess or deficiency are the primary goals in the nutritional management of the patient with AKI. Although it has yet to be proven that nutrition support is associated with a reduction in mortality, the secondary goals of nutrition therapy are to optimize immunocompetence and promote wound healing. Additionally, the attenuation of the inflammatory state, metabolic derangements, and alterations of the patient's antioxidant capacity should be considered in the design of specialized nutrition support for patients with AKI.[4]

GENERALIZED APPROACH TO TREATMENT

Enteral nutrition (EN) is the preferred route of nutrient delivery in patients with AKI.[4,5] Calorically dense, electrolyte-free or -reduced formulas are preferred.[21] These formulas are useful in patients with fluid overload, hyperkalemia, hypermagnesemia, and hyperphosphatemia. EN is well tolerated by many patients with AKI[22] and is associated with improved maintenance of GI tract function and survival in nonrandomized studies of patients with AKI.[2,23] It is recommended that EN be used for all patients to the degree tolerated, even if PN must be used as a supplement to meet the patient's nutritional needs. Unfortunately, because of the high incidence of GI complications, many patients may not tolerate EN to meet their nutritional goals and thus require PN support.[2]

PHARMACOLOGIC THERAPIES

Drug Treatments of First Choice

Patients with AKI and comorbid hypermetabolism typically require 20 to 30 kcal/kg (84–126 kJ/kg) per day.[8] Increasing energy provision beyond this does not improve nutritional outcomes and is associated with metabolic complications and a greater net fluid imbalance.[24] A relatively conservative initial estimate of patient energy needs is appropriate because the results of slightly underfeeding the patient are far less serious than those associated with overfeeding.[4,25]

1 In the absence of dialysis, the nutritional formula should be concentrated in a small volume and contain minimal sodium (Table 153–1). In the oliguric patient who is receiving renal replacement therapy, these restrictions may be less rigorous, but the formula generally will need to be concentrated.[5] When using these high-dextrose-concentration formulas, careful monitoring of

TABLE 153-1 Empiric Parenteral Nutrition Formulas for Patients with Organ Failure

	Acute Renal Failure	Chronic Renal Failure	Hepatic Failure	Short Bowel	Pulmonary Failure
Dextrose (%)[a]	40	30	25	20	20

[b]Hepatamine 4% when criteria for use are met.
[c]Does not include 0.45% Na chloride injection or lipid.
[d]The continuous renal replacement therapies frequently require variable additions of electrolytes and trace elements.

glucose homeostasis (every 6 hours) is important because the maintenance of glycemic control in a range of 110 to 150 mg/dL (6.1–8.3 mmol/L) has been associated with improved clinical outcomes of critically ill adults.[25,26] Additionally, CRRT, which is increasingly popular in the treatment of AKI (see Chapter 50), contributes significant calories to a nutritional regimen. This is a direct result of the absorption of glucose from the dialysate or ultrafiltrate replacement fluids: net uptakes of up to 355 g/day have been reported.[13] Total glucose intake should range from 3 to 7 g/kg/day.[5]

CLINICAL CONTROVERSY

There is debate as to the most appropriate protein provision for patients with ARF who are receiving CRRT. Although initial data has shown an association between higher protein intake (up to 2.5 g/kg/day) and improved survival, many express concern about the effectiveness and safety of this practice.

AKI is not a contraindication to IVLE use, despite the changes in lipid metabolism. When the serum triglyceride concentration is less than 300 mg/dL (3.39 mmol/L), IVLE is recommended to prevent essential fatty acid deficiency and to provide a balanced caloric intake. Current recommendations call for patients to receive between 0.8 and 1.2 g/kg/day, but no more than 1.5 g/kg/day.[5]

Although individual patient assessment for the presence of hypercatabolism and dialytic losses is necessary, it is not uncommon for patients to require 2.5 g/kg/day of protein or more to achieve a positive nitrogen balance.[27] Protein restriction, to reduce the urea nitrogen appearance rate from exogenous protein intake in an effort to avoid dialysis, should not be used unless the AKI is thought to be temporary (e.g., expected to resolve in 7 to 10 days), and hypercatabolism is not present.[5,7,28] Once dialysis therapy is instituted, protein intake should be liberalized to 1 to 1.5 g/kg/day for noncatabolic patients and at least 1.5 g/kg/day for hypercatabolic patients.[28] Patients undergoing CRRT with hypermetabolism may need to receive 1.5 to 2 g/kg/day[26] or more (up to 2.5 g/kg/day) to achieve positive nitrogen balance.[23] The safety and efficacy of this aggressive strategy remain to be confirmed before it can be routinely recommended.[8,26,29]

2 Several electrolytes (i.e., phosphorus, magnesium, and potassium) warrant special attention in patients with AKI.[5] During early AKI, PN solutions should not contain potassium unless the patient is hypokalemic or undergoing CRRT. After several days, the serum potassium concentrations tend to decrease, often necessitating cautious addition of potassium to the PN solution. If the enteral route is used, formulas with minimal potassium may be needed. Serum potassium concentrations may decrease more rapidly in patients receiving CRRT. Potassium losses during CRRT are proportional to the potassium gradient between blood and dialysate. Therefore, cautious additions of potassium may be considered early in the course of AKI for those patients treated with CRRT. Serum magnesium concentrations do not decrease as quickly as potassium concentrations in patients receiving electrolyte-free nutrition regimens. As serum concentrations decrease toward normal and/or renal function returns, magnesium should be added to the PN solution in small amounts (4–6 mEq/L [2–3 mmol/L]).

Phosphorus can be omitted from the nutritional formula of AKI patients receiving PN until the phosphorus level approaches normal (<5 mg/dL [<1.62 mmol/L]). It is prudent to monitor phosphorus concentrations daily and to add phosphorus in small doses once the serum concentration is <4 mg/dL (1.29 mmol/L). Failure to do so can lead to severe hypophosphatemia (see Chapter 59), especially in patients treated with CRRT. Patients with persistently high serum phosphorus concentrations who have a functional GI tract can be prescribed phosphate-binding therapy (see Chapter 53) and enteral feedings low in phosphorus to minimize the absorption of exogenous phosphorus.

Alternative Drug Treatments

Standard mixed amino acids rather than essential amino acid solutions should be used.[5,28] Early studies assessing essential amino acid products were promising. Subsequently, several prospective, double-blind studies have indicated no significant reduction in mortality when the essential amino acid formulations were used.[1,5,28]

PHARMACOECONOMIC CONSIDERATIONS

Although analyses of total costs of AKI care have been published,[30] no specific research has yet been published assessing the cost-effectiveness of nutrition support in patients with AKI.

EVALUATION OF THERAPEUTIC OUTCOMES

Although the clinical and quality-of-life (QOL) outcomes for patients with AKI have been reported, data specifically analyzing the effects of nutrition support are limited.[30] To date, there is no clear consensus regarding the degree of benefit, if any, of nutrition support on the outcome parameters of renal recovery or mortality. Data suggest that malnourished AKI patients experience significantly higher mortality rates (odds ratio of in-hospital mortality of 7.21) than AKI patients without malnutrition.[3] In one retrospective analysis, EN was associated with a survival benefit, even when controlling for severity of illness.[2] No prospective studies to date show a survival benefit from aggressive nutritional support in patients with AKI. When nutrition support is used, the evaluation tools employed in monitoring patients with AKI are similar to those for other patients receiving PN and EN (see Chapters 151 and 152).

CHRONIC KIDNEY DISEASE

CKD is defined by either structural or functional damage to the kidneys that is present for at least 3 months (see Chapter 52). Malnutrition secondary to reduced oral nutrient intake frequently is evident when the glomerular filtration rate drops below 20 to 25 mL/min (0.33–0.42 mL/s). Stage 5 CKD has been associated with inflammatory and metabolic changes that increase the likelihood of malnutrition, and increased nutrient losses have been documented in those receiving hemodialysis and peritoneal dialysis. Because of its chronicity, malnutrition in these patients is treated most frequently in the ambulatory setting with oral nutritional supplements and EN.

Epidemiology

Protein-energy malnutrition is very common in patients with CKD and is a significant predictor of morbidity and mortality. Significant malnutrition, typically represented by deficiency of visceral proteins or being underweight, has been noted in 28% to 48% of predialysis patients, in 9% to 72% of patients undergoing HD, and in up to 45% of patients commencing PD.[31,32] In one of the larger studies to date (n = 1,397), mean dietary calorie and protein intake in those 50 years of age and older was 22 kcal/kg/day (92 kJ/kg/day) and 0.9 g/kg/day, respectively.[33] Both these values are lower than published recommendations for patients with CKD.[34] Protein-energy malnutrition and wasting at initiation of dialysis are significant predictors of morbidity and mortality in patients with stage 5 CKD.[31]

However, there appears to be a gender-confounding factor: women tend to have a higher prevalence of malnutrition[32] and poorer nutritional outcomes, yet a lower mortality rate.[35]

Pathophysiology

Carbohydrate In general, patients with stage 5 CKD are not as nutritionally stressed as those with AKI; however, more than half of patients with stage 5 CKD have insulin resistance and hyperglycemia. This is attributed to the increased glucagon-to-insulin ratio, resulting in protein breakdown and gluconeogenesis. In patients with normal peritoneal transport on PD, ~60% of glucose in the dialysate is absorbed. One method of estimating the quantity of glucose absorbed is as follows: glucose absorbed (g/day) = 0.89x (g/day) – 43, where x is the total amount of dialysate glucose instilled daily. This dialysate glucose absorption can worsen existing hyperglycemia and contribute significantly to the patient's energy intake, making kwashiorkor-type malnutrition common. Although glucose control is not problematic unless the patient is diabetic, infected, or subjected to operative stress, insulin can be added to chronic ambulatory PD bags to control hyperglycemia (see Chapter 54).

Fat Hypertriglyceridemia is common in patients with stage 5 CKD. This is mainly a result of decreased catabolism of triglycerides secondary to decreased hepatic lipoprotein lipase activity.[36] Most patients with stage 5 CKD receiving HD also receive heparin, which activates lipoprotein lipase and converts triglycerides to free fatty acids and glycerol. Carnitine, an amino acid necessary for the transport of long-chain fatty acids across mitochondria, is removed by HD and PD; therefore, serum carnitine concentrations typically are reduced in patients with stage 5 CKD.[37]

Current guidelines do not advocate carnitine administration for the treatment of hypertriglyceridemia.[38] Studies of carnitine for this indication have varied widely in duration and have used both oral and IV administration in varying doses (1–2 mg/kg/day IV to as much as 10 mg/kg/day to 3 g/day orally).

Leptin, which is produced and secreted by fat cells, regulates satiety and energy balance (see Chapter 154). Leptin concentrations often are elevated in patients with stage 5 CKD, particularly those undergoing PD probably as the result of decreased renal degradation of leptin and increased production as the result of chronic inflammation. Hyperleptinemia in CKD is associated with decreased protein intake and weight loss. Further study is required to better define the relationship between leptin concentrations and nutrition status in patients with CKD.[39,40]

Protein Secondary analysis of the Modification of Diet in Renal Disease Study indicated that in nondiabetics, a reduction of dietary protein intake may slow the rate of renal disease progression and ultimately delay the onset of dialysis (see Chapter 52).[41] The National Kidney Foundation Kidney Disease Outcomes Quality Initiative (NKF K/DOQI) guidelines for nutrition in patients with CKD recommend a diet providing 0.6 g/kg of protein per day for those with a glomerular filtration rate less than 25 mL/min (0.42 mL/s).[38] Although the safety of low-protein diets has been questioned, it has been suggested that for carefully selected and monitored patients, protein intakes of as low as 0.3 g/kg/day supplemented with essential amino acids can be used safely.[5,28]

Patients with stage 5 CKD receiving PD require special attention as a consequence of protein losses across the peritoneal membrane. Peritoneal protein losses typically range from 5 to 15 g/day for patients undergoing PD.[38] PD protein losses, however, do not predict the risk for malnutrition (as measured by serum albumin concentration) in all patients.[38] The American Society for Parenteral and Enteral Nutrition (ASPEN) and K/DOQI guidelines suggest that dietary protein intake of at least 1.2 to 1.3 g/kg/day (at least 50% of high biologic value) is needed to consistently achieve neutral or positive nitrogen balance in nonacutely ill peritoneal dialysis patients and clinically stable HD patients.[38] Dialysate protein losses also must be considered for the patient with stage 5 CKD undergoing HD. The amount of protein lost via HD depends on the dialysis membrane used and whether the dialyzer is being reused. Typical losses are 10 to 12 g per dialysis session, but this may be increased by up to 50% with dialyzer reuse.[38]

Fluid and Electrolytes Hyponatremia, often due to overhydration, is common in patients with CKD (see Chapter 58). Regular dialysis is the principal means for control of body water and serum sodium concentration in the stage 5 CKD. Patients with CKD who develop hyperkalemia generally have ingested excessive potassium relative to the potassium-removing capacity of the failing kidney (and dialysis, in the case of stage 5 CKD). The undernourished CKD patient receiving PN, however, may require considerable potassium as new body cell mass is synthesized.

Patients with CKD often are treated for hyperphosphatemia with phosphorus-restricted diets and phosphate-binding agents (see Chapters 52 and 53). When these patients receive aggressive nutritional support, the combination of refeeding (cellular uptake of phosphorus for synthesis of body cell mass) and vigorous phosphate-binding therapy can result in hypophosphatemia.

Metabolic acidosis, a common complication of stage 5 CKD, is associated with increased protein degradation and decreased synthesis of albumin.[38] Correction of acidosis in patients with stage 5 CKD may be associated with increases in serum albumin, body weight, and midarm muscle circumference, along with fewer hospitalizations.[42] Stabilization of serum bicarbonate concentrations (>22 mEq/L[>22 mmol/L]) via alteration of the dialysate bicarbonate concentration or administration of oral bicarbonate salts is a prudent nutritional intervention in these patients (see Chapters 53 and 61).

Trace Elements There are considerable data regarding trace element requirements in patients with stage 5 CKD.[19] Decreased zinc concentrations have been linked to taste disturbances and sexual dysfunction. Zinc supplementation, however, does not universally reverse these anomalies. Although serum concentrations of this trace element are decreased, total body stores of zinc in stage 5 CKD often are increased. This suggests a redistribution of zinc or increased need to maintain normal enzymatic function in patients with stage 5 CKD.

Serum chromium concentrations are elevated in patients on chronic HD and PD, perhaps because the needles used during HD and the peritoneal and hemodialysate fluids are sources of chromium. Such patients have decreased selenium concentrations that can be increased with oral selenium supplements of 135 to 140 mcg/day.[43] It appears that for patients undergoing HD, significant selenium losses occur during dialysis.[19]

Vitamins Patients with CKD are prone to develop water-soluble vitamin deficiencies because of decreased dietary intake secondary to anorexia and restriction of many foods because of their protein, potassium, or phosphorus content. Additionally, vitamin losses due to hemodialysis are similar to those mentioned for AKI. The decrease in ascorbic acid serum levels observed in patients with CKD was recently associated with increased cardiovascular morbidity and mortality. Plasma ascorbic acid concentrations are usually normal in patients on PD. The highly protein-bound vitamins (A, D, and B_{12}) are not removed significantly by HD.[19] Vitamin D deficiency is correlated with decreased serum albumin concentrations, and supplementation of vitamin D has increased serum albumin concentrations significantly in deficient patients.[44] Vitamin A concentrations often are elevated in CKD and can lead to hypervitaminosis A and its cirrhosis-like syndrome. Conversely, vitamin E supplementation may have a distinct benefit to patients

with stage 5 CKD. Increased oxidative stress in stage 5 CKD may contribute to the accelerated atherosclerosis. Vitamin E in doses of 800 international units (IU) per day decreases low-density lipoprotein oxidation in patients with stage 5 CKD, especially in those undergoing PD.[45] Thiamine concentrations decrease during dialysis; supplementation within the daily recommended intake norms is sufficient to keep concentrations in the normal range. Hyperhomocysteinemia is common in patients with stage 5 CKD. Folate doses from 2.5 mg three times weekly to 60 mg/day have lowered homocysteine concentrations in patients with stage 5 but have not completely reduced concentrations to normal. In patients with stage 3 or 4 CKD, elevated homocysteine concentrations are associated with increased cardiovascular risk. In those with stage 5 CKD, lower homocysteine concentrations are associated with an increased risk of cardiovascular events. It is thought that in these patients, ongoing malnutrition and inflammation suppress homocysteine concentrations while continuing to accelerate atherosclerosis.[46]

TREATMENT

DESIRED OUTCOMES

Goals of nutrition support in CKD are similar to those in other patient populations, with only a few additional considerations because of the metabolic derangements that are commonly observed. Prevention of undernutrition and maintenance of lean body mass are of primary importance. Other goals are correction and prevention of metabolic disorders, maintenance of electrolyte homeostasis, minimization of CKD progression, and preservation of optimal GI structure and function.[5] The ultimate goal of nutritional interventions, considering the strong relationship between malnutrition and morbidity and mortality in CKD, is to optimize patient survival.[31]

GENERAL APPROACH TO TREATMENT

Nutrition support for patients with CKD can usually be managed with oral supplementation or EN. These patients rarely need PN because their GI tract is usually functional. Guidelines for nutrition support have been developed by NKF K/DOQI, ASPEN, and the European Society for Parenteral and Enteral Nutrition (ESPEN) (Fig. 153–1).[5,8,28,38] The calorically dense low-electrolyte (potassium, phosphorus, and magnesium) enteral formulas are particularly useful. For protein-restricted predialysis patients with CKD, Suplena and Renalcal, which have relatively low protein content, should be used. Even though patients with stage 5 CKD receive regular dialysis, many are anuric between dialysis sessions, so excess fluid intake is a potential problem. Nepro and Novasource Renal are marketed specifically (because of their high caloric density and low electrolyte content) for the dialysis-dependent patient with stage 5 CKD.[21] If there is superimposed illness that precludes EN, balanced amino acid products should be used as the protein component of PN formulations. There are no data supporting the use of essential amino acid parenteral formulations.

NONPHARMACOLOGIC THERAPIES

Nutritional interviews, diaries, and counseling are essential parts of the nutrition support plan for patients with CKD. The NKF K/DOQI guidelines stress the importance of renal dietetic interventions and recommend that patients maintain 3-day dietary diaries intermittently and discuss the results with their dietary

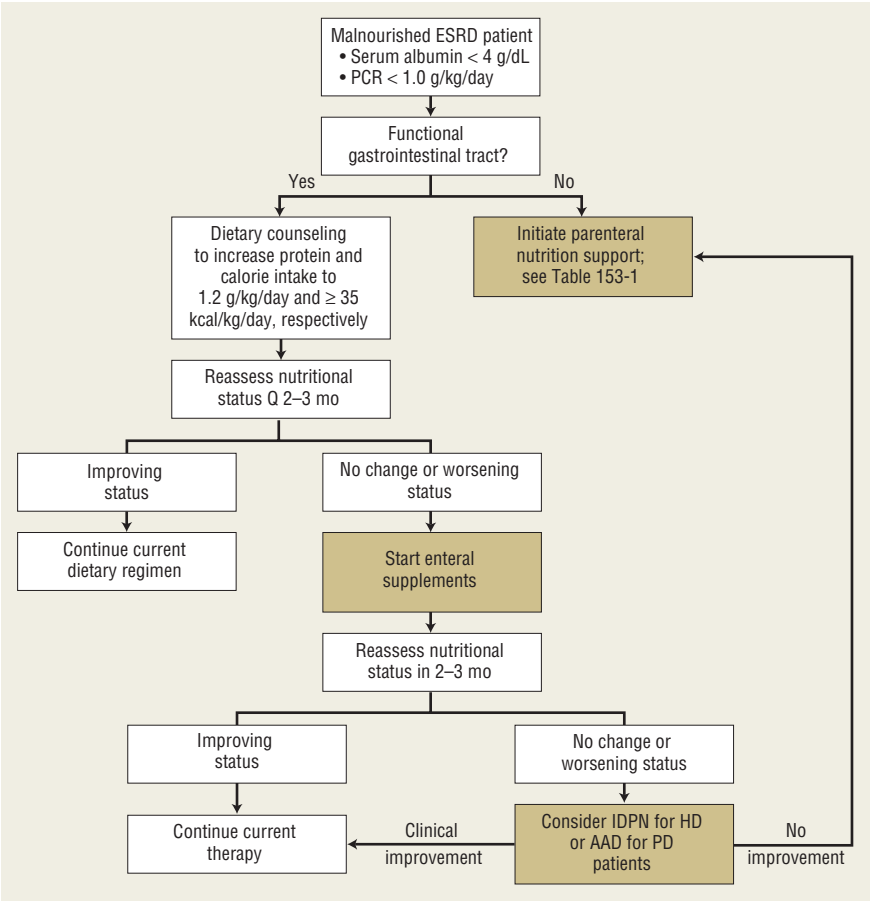

FIGURE 153-1. An algorithmic approach to nutritional support in the patient with end-stage renal disease. Serum albumin <4 g/dL is equivalent to <40 g/L. care provider. These interventions are conducted to optimize the quantity and quality of patient energy and protein intake. In other populations, such interventions with frequent nutritional counseling have resulted in increased adherence to the recommended dietary intake.[38]

PHARMACOLOGIC THERAPIES

Drug Treatments of First Choice

Current recommendations from NKF K/DOQI that factor in concurrent illnesses and the likelihood of preexisting malnutrition advocate 35 kcal/kg/day (147 kJ/kg/day) and 1.2 g/kg/day of protein for patients on chronic HD who are younger than 65 years and 1.2 to 1.3 g/kg/day of protein for patients on chronic PD.[38] This is higher than the spontaneous dietary intake in most dialysis patients. This emphasizes the importance of dietary counseling to encourage compliance with current dietary recommendations, especially for patients with concurrent hypercatabolic illnesses.

For patients who cannot achieve recommended dietary intake goals, several studies have examined the effect of EN on nutritional outcomes. A systematic review of these studies across all stages of CKD reveals that EN is associated with significant increases in energy and protein intake and serum albumin concentration.[31] No significant increases in metabolic or electrolyte imbalances were noted. However, no significant differences in CKD patient morbidity or survival were noted.

Several electrolytes warrant special attention for patients with CKD. Generally, sodium should be administered only to replace losses to avoid overhydration. Examples of initial daily supplementation can be found in Tables 153–1 and 153–2, and supplementation may be adjusted based on the patient's serum sodium concentration and fluid balance. Although these patients also are predisposed to hyperkalemia, once anabolism is attained, potassium requirements may be as high as 40 to 80 mEq/day (40–80 mmol/L/day). This dose needs to be given carefully and requires serum potassium concentration monitoring. Clinically significant hypermagnesemia is less common in patients with CKD than those with AKI. It is usually added to the PN solution in reduced doses (4 mEq/L [4 mmol/L]).

Patients with end-stage renal disease (ESRD) or stage 5 CKD often are treated for hyperphosphatemia. With aggressive nutritional support, the combination of refeeding and compliance with phosphate-binding therapy can result in hypophosphatemia within a matter of days. Decreasing or temporarily discontinuing the phosphate-binding therapy is appropriate if this occurs. Thereafter conservative amounts of phosphorus may need to be administered.

Some practitioners advocate withholding trace elements from patients with CKD who are receiving PN. Others recommend the administration of standard dietary intake of trace elements, because in stage 5 CKD, serum concentrations of certain trace elements are normal (e.g., manganese), and others are decreased (e.g., zinc and selenium).[19] Additional zinc and selenium supplementation may be considered in documented cases of deficiency.[5]

During PN, avoidance of vitamin A is recommended. Dialytic losses of ascorbic acid, folic acid, and pyridoxine are common. Thus, patients with stage 5 CKD should receive ascorbic acid 50 to 100 mg/day, pyridoxine 5 to 10 mg/day, and at least 1 mg/day folic acid in addition to the other essential vitamins.[19] Typical PN and EN prescriptions for a patient with stage 5 CKD are presented in Tables 153–1 and 153–2, respectively.[34] Figure 153–1 is an algorithmic approach to improve nutritional status and ensure optimal outcomes integrating recommendations from NKF K/DOQI, ASPEN, and ESPEN.[5,8,28,38]

TABLE 153-2 Initial Enteral Nutrition Prescription for Patients with End-Stage Renal Disease

Nutrient	Recommendation
Nonprotein calories	35 kcal/kg (147 kJ/kg) per day for HD 35 kcal/kg (147 kJ/kg) per day PD (including calories from glucose absorption from dialysate)
Protein	1.2 g/kg IBW for HD 1.2–1.3 g/kg IBW for PD
Sodium	2–3 g/day for HD[a] 2 g/day for PD[a]
Potassium	2,000–2,500 mg/day[a]
Phosphorus	800–1,000 mg/day[a]
Calcium	<2,500 mg/day total intake[a]
Fluid	1,000 mL + daily urine output for HD To maintain appropriate fluid balance for PD

[a]Individualized based on patient's laboratory values.
CAPD = continuous ambulatory peritoneal dialysis HD = hemodialysis, IBW = ideal body weight, PD = peritoneal dialysis.
Data from references 5, 9, and 41.

Alternative Drug Treatments

Poor nutritional intake due to anorexia and impaired GI motility have led to research assessing the impact of appetite stimulants and prokinetic agents on nutritional outcomes in patients with CKD. The use of the appetite stimulant megestrol acetate and prokinetic agent metoclopramide are associated with increases in serum albumin in patients with CKD.[42] Further research is needed to better define the effect and optimal dosing if their use is to be applied more widely for nutritional intervention in CKD. The association of poor nutritional status and increased morbidity and mortality in stage 5 CKD has led to the development of alternative nutritional delivery systems. One such approach is intradialytic parenteral nutrition (IDPN), or the provision of glucose–amino acid–lipid admixture during HD. IDPN typically allows for the infusion of 650 to 1,100 kcal (2,721–4,604 kJ) per session (250 mL of 50–70% dextrose and 250 mL of 10–20% lipids) and 50 to 90 g of protein (500 mL of 10–15% amino acids).[47] An evidence-based evaluation of 24 studies employing IDPN found that the use of IDPN was associated with decreased mortality, but only 3 of the 24 studies were randomized. Because of the limitations of presently available data, IDPN should be reserved for malnourished patients who have serum albumin <3.4 g/dL (<34 g/L), weight loss >10% of ideal body weight, dietary history of intake of <25 kcal/kg/day (<105 kJ/kg/day), and who failed attempts at oral supplements and enteral tube feedings or who are not appropriate for such attempts.[28,48]

Amino acid dialysate is the IDPN counterpart for the patient on PD. This technique entails using a 1.1% amino acid solution in place of one or two of the dextrose-containing PD exchanges per day. Improvements in serum transferrin and total protein concentrations have been observed in malnourished patients on PD; however, no beneficial effect has been noted on patient mortality. Adverse effects of this therapy have included exacerbations of uremic symptoms (because of increases in blood urea nitrogen) and metabolic acidosis. In the longest study to date, amino acid dialysate was associated with improved maintenance of albumin and cholesterol concentrations but no significant difference in morbidity or mortality.[49] In summary, amino acid dialysate may be useful in the treatment of malnourished patients on PD, but better-designed studies are needed.

Recombinant human growth hormone (rhGH) in doses of 0.2 IU/kg/day subcutaneously has been used experimentally in adults with stage 5 CKD to enhance anabolism; weight gain and increased transferrin concentrations have been reported after

TABLE 153-3 Routine Nutritional Monitoring in Patients with End-Stage Renal Disease

Parameter	Frequency
Predialysis serum albumin1	Monthly
Percentage of usual postdialysis or postdrain body weight	Monthly
Subjective global assessment	Every 6 months
Protein equivalent of total nitrogen appearance(PNA)[a]	Monthly for HD, every 3–4 months for PD
Dietary interview and/or diary	Every 6 months
Predialysis prealbumin	As needed
Anthropometry	As needed
Dual-energy X-ray absorptiometry	As needed

[a]Beginning of week PNA = $Co/[36.3 + (5.48)\ (spKt/V) + (53.5/spKt/V)] = 0.168$, where *Co* is predialysis BUN, and *spKt/V*, the single-pool index of hemodialysis adequacy = $\text{Ln}(R - 0.08 \times t) + [4 - (3.5 \times R)] \times UF/W$, where *R* is postdialysis:predialysis BUN ratio, *t* is dialysis session in hours, *UF* is ultrafiltration in liters, and *W* is postdialysis weight in kilograms. (See Chapter 48.)
BUN = blood urea nitrogen, PD = peritoneal dialysis, HD = hemodialysis.

4 weeks.[50] Despite these gains, rhGH is associated with sodium and water retention, and the fact that its effects may be lessened by catabolic illness or decreased dietary intake limits its utility. In the future, there may be a role for rhGH or other anabolic agents in the treatment of patients with stage 5 CKD who have inadequate oral intake despite appropriate dietary counseling and oral supplements.[42]

PHARMACOECONOMIC CONSIDERATIONS

There are no data demonstrating the economic value of nutrition support in patients with CKD.

EVALUATION OF THERAPEUTIC OUTCOMES

The short- and long-term monitoring plan for patient with stage 5 CKD receiving PN or EN needs to be carefully tailored. This can be achieved via frequent (daily) monitoring of serum electrolyte concentrations (e.g., sodium, potassium, phosphorus, magnesium, and calcium) and fluid balance. Serum glucose concentrations should be followed frequently (four times daily) in those who develop persistent hyperglycemia.

Because protein-energy malnutrition is a significant predictor of morbidity and mortality in patients with stage 5 CKD, monitoring to ensure the effectiveness of the long-term nutritional plan becomes critical. Increased serum albumin concentrations are correlated with increased survival; thus, monitoring of serum albumin concentrations is recommended for all patients undergoing HD and PD (Table 153–3).

HEPATIC FAILURE

The liver is the primary organ involved in the digestion, metabolism, and storage of nutrients. When functional capacity is depressed, profound nutrient intolerance (hyper- or hypoglycemia, hypertriglyceridemia, and hepatic encephalopathy) may result. Other sequelae that accompany the failing liver are fluid and electrolyte imbalances, vitamin deficiencies, and malnutrition. It is estimated that 65% to 90% of patients with advanced liver disease and almost 100% of patients awaiting liver transplantation have some degree of malnutrition, which increases morbidity and mortality. Nutritional support is an important component of the overall care of the patient with liver disease that may decrease complications and extend survival.[51]

EPIDEMIOLOGY

It is estimated that 30% of cirrhotic patients have protein-energy malnutrition, 40% have protein malnutrition, and 10% have energy malnutrition.[52] Changes in body composition such as decreases in body cell mass may be seen in early phases of the disease and become more severe as cirrhosis progresses. In general, there is no significant difference in the incidence of malnutrition between those with cirrhosis caused by alcoholism and those with postviral cirrhosis. One study, however, found that abstinent patients with alcoholic cirrhosis had lower average measures of nutritional adequacy than those with cirrhosis caused by chronic hepatitis C.[53]

PATHOPHYSIOLOGY

Energy

A decrease in spontaneous oral intake is quite common in patients with cirrhosis and appears to be multifactorial in nature. Potential causes of decreased oral intake include altered taste, early satiety as a result of ascites and/or hyperleptinemia, impaired GI motility, bacterial overgrowth in the small intestine, malabsorption as a consequence of GI dysfunction and treatment with neomycin or lactulose, nausea, and chronic encephalopathy.[28,51]

Resting energy requirements in stable cirrhotics can appear to be normal, but approximately one-third are hypometabolic, and one-third are hypermetabolic when energy expenditure is corrected for alterations in lean body mass.[51] The Harris-Benedict equation for estimating caloric needs usually underestimates their needs by 15% to 20%.[54] The marked variability in energy expenditure underscores the need for patient-specific regimen design and monitoring and may suggest the need for indirect calorimetry measurement.[51] An initial energy provision of 35 to 40 kcal/kg/day (147–167 kJ/kg/day) is recommended by ESPEN for patients with alcoholic steatohepatitis and liver cirrhosis.[55]

Carbohydrates

3 In healthy adults, ~60% of absorbed glucose is taken up by the liver and used for glycogen synthesis, triglyceride synthesis, and glycolysis. In general, glycogen synthesis and glycolysis are enhanced by insulin, whereas gluconeogenesis and glycogen breakdown are controlled by glucagon. Hyperglycemia is common in cirrhosis as a result of peripheral insulin resistance, which is mediated by a decreased binding to insulin receptors and defective postreceptor signal handling in peripheral tissues. Plasma concentrations of insulin are elevated with or without a glucose stimulus. This makes administration of large doses of glucose problematic because administration of insulin to control hyperglycemia may not improve its utilization substantially.

Patients with fulminant hepatitis are prone to hypoglycemia because hepatic glucose production is depressed secondary to decreased glycogen stores, diminished gluconeogenesis, and impaired degradation of insulin. A continuous IV infusion of 5% dextrose usually prevents hypoglycemia in acute hepatitis, but concentrations greater than 10% dextrose may be needed in more severe cases.

Fat

The liver is responsible for synthesis of cholesterol, high-density lipoproteins, and very low density lipoproteins. The enzymes lipoprotein lipase and lecithin-cholesterol acyltransferase are synthesized in the liver. Increased serum triglyceride and free fatty acid concentrations are thus encountered in patients with hepatic failure,

primarily as a result of the increased lipolysis. The significant insulin resistance that can be seen in those with cirrhosis causes a shift to lipids as a primary fuel source.[51] Whereas only 35% of total calories are derived from fat in normal patients, this can increase to 75% in patients with cirrhosis.[54] Incorporation of late-evening snacks may correct abnormal substrate metabolism, increase carbohydrate metabolism, and decrease fat oxidation rates.[56,57]

Patients with severe liver failure may be at increased risk for essential fatty acid deficiency; the ratio of nonessential to essential fatty acids was found to be increased in patients with acute and chronic liver failure. Poor oral intake of fat and dietary fat malabsorption in patients with cirrhosis both contribute to essential fatty acid deficiency.[58] The concentrations of linoleic acid can be increased with administration of an average of 33 g/day of IVLE supplementation.[59] Despite concerns of impaired clearance of long-chain triglycerides in IVLE as a consequence of impaired synthesis of apoprotein CII in cirrhotic patents, IVLE solutions have been given safely to patients with fulminant hepatic failure.[60]

Diarrhea and steatorrhea are common in patients with hepatic cholestasis because of intestinal malabsorption (partly as a result of mucosal edema from hypoalbuminemia), inadequate bile acid delivery to the duodenum, and pancreatic dysfunction with decreased secretion of lipase.[54] Because the micelle formation is impeded, the long-chain fatty acids pass through the colon, resulting in a foul-smelling, soapy diarrhea.

Protein

Nitrogen requirements for the patient with liver failure are similar to those of normal subjects, but intolerance to protein may limit the achievement of this goal. Thus, some experts have advocated restriction of dietary protein intake. Recent research indicates, however, that protein restriction is not beneficial for patients with cirrhosis even in the midst of episodic hepatic encephalopathy.[61]

Because the liver metabolizes the aromatic amino acids (i.e., phenylalanine, tyrosine, and tryptophan), methionine, and glutamine, the plasma concentrations of these amino acids are elevated in cirrhotic patients. Plasma concentrations of the branched-chain amino acids (i.e., valine, leucine, and isoleucine) often are depressed because these amino acids are metabolized by skeletal muscle. This altered plasma aminogram most likely contributes to the development of hepatic encephalopathy.

Fluid and Electrolytes

Patients with severe cirrhosis often have ascites and peripheral edema. The excess of total body sodium in the presence of an even greater excess of total body water results in hyponatremia. Salt and fluid restrictions are required to avoid exacerbating this overhydrated state (see Chapter 58).

Hypokalemia is common in patients with liver failure who have normal renal function. Poor nutritional intake and vomiting may initiate this disorder. Severe vomiting may also lead to volume contraction metabolic alkalosis, with increased renal excretion of potassium (see Chapter 61). Secondary hyperaldosteronism, a common finding in patients with liver failure and intravascular volume depletion, also increases renal excretion of potassium. Loop diuretic therapy causes increased renal excretion of potassium, whereas diarrhea from lactulose therapy increases fecal excretion of potassium. All these conditions can lead to profound hypokalemia. Therefore, potassium requirements in patients with liver failure who are receiving specialized nutritional support may be substantially larger than those in otherwise healthy adults.

Poor nutritional intake secondary to alcohol abuse and increased excretion of magnesium secondary to diuretic therapy contribute to hypomagnesemia. Even in cirrhotic patients with normal serum magnesium concentrations, muscle magnesium is depleted; this has been independently associated with the development of hepatic encephalopathy.[62] During nutrition support, requirements for phosphorus are also substantially elevated because synthesis of body cell mass occurs, placing this population at risk for developing hypophosphatemia during refeeding.

Trace Elements

Zinc deficiency is seen in many patients with liver failure because of malabsorption, chronic diarrhea, or elevated cytokine concentrations. Thus, patients with chronic diarrhea should be suspected of having zinc deficiency; the measurement of serum concentrations, however, is rarely used to confirm such deficiencies. Tumor necrosis factor, interleukin-1, and interleukin-6 may stimulate metallothionein, an intestinal zinc-binding protein, thereby inhibiting zinc absorption. Finally, patients receiving a protein-restricted diet may be at additional risk because substantial amounts of zinc are found in red meat.

Because copper and manganese are excreted in the bile, it has been recommended that these two trace elements not be administered or be administered in reduced doses to patients with serious cholestasis. Direct measurements of manganese in the globus pallidus of cirrhotic patients who died in hepatic coma were two- to sevenfold higher than expected.[63] These findings suggest that reduced quantities of manganese should be provided in the nutritional formulation to avoid exacerbating encephalopathy in the patient with chronic liver disease. There are no prospective evaluations, however, demonstrating the benefits of low copper or manganese diets.

An association between alcoholism and low serum selenium concentrations has been reported.[64] Because selenium is important in maintaining the enzyme glutathione peroxidase, a deficiency of this trace element has been implicated as a cause of hepatic injury in the alcoholic patient. However, because human serum contains at least three fractions of selenium, the use of serum selenium concentrations as a marker for selenium deficiency is controversial. At this time, maintaining a daily selenium intake of 40 mcg is the most appropriate approach in patients with chronic liver disease.

Vitamins

4 Folic acid deficiency may lead to megaloblastic anemia, whereas thiamine deficiency may result in Wernicke encephalopathy after rehydration with IV glucose. Depletion of hepatic stores of vitamin A, pyridoxine, folic acid, riboflavin, pantothenic acid, vitamin B_{12}, and thiamine has been reported in patients with hepatic failure. Poor intake and malabsorption are the principal causes of vitamin deficiencies in patients with chronic liver disease.

Because vitamin D is metabolized to 25-hydroxyvitamin D in the liver, low concentrations of this vitamin are seen in patients with biliary cirrhosis. Impaired absorption of dietary vitamin D as a consequence of decreased bile production may also contribute to these low serum concentrations and ultimately lead to the development of osteoporosis. The most appropriate approach at this time is to provide the daily recommended intake of these vitamins and consider additional supplementation when a deficiency is documented.

TREATMENT

DESIRED OUTCOMES

The primary objective of nutrition support in patients with cirrhosis is the provision of the recommended amounts of energy and protein. Adequate nutrition support may slow disease progression, prevent morbidity, enhance the structure and function of the GI tract, and decrease mortality.[51,55]

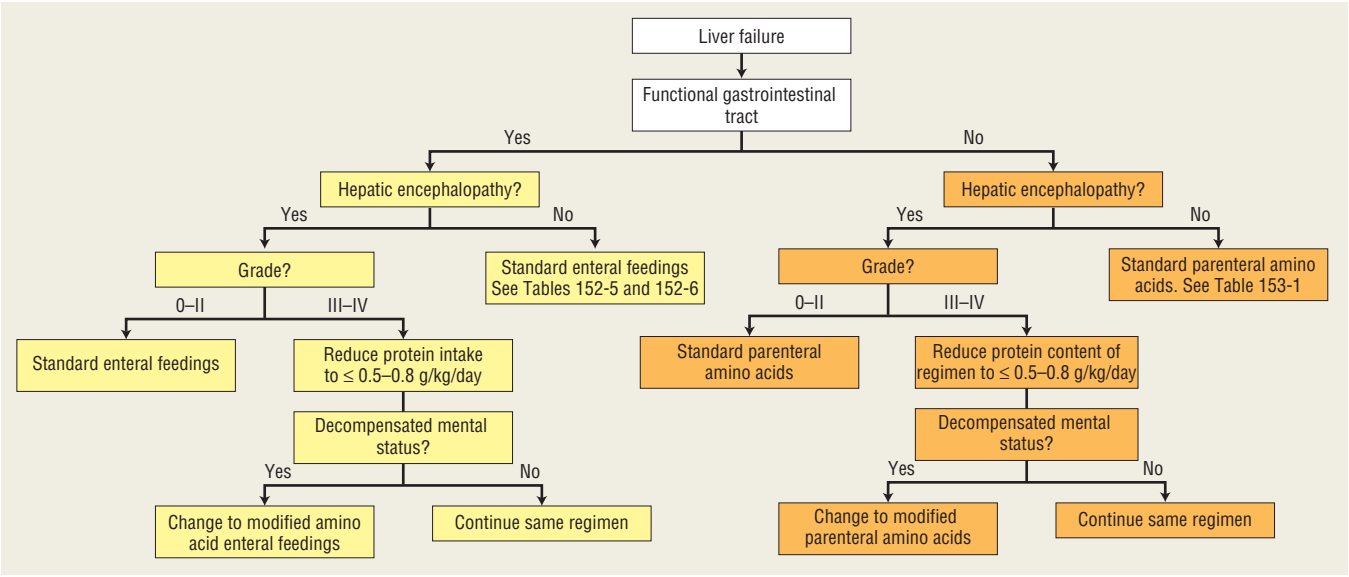

FIGURE 153-2. An algorithmic approach to nutritional support for the patient with hepatic failure. *Adapted from references 28 and 55.*

GENERAL APPROACH TO TREATMENT

Enteral nutrition is preferred in patients with cirrhosis when the GI tract is functional and accessible (Fig. 153–2).[28,55] The indications for PN in the patient with liver failure are similar to those for general hospitalized patients. Because EN can contribute to hyperammonemia in cirrhotic patients with transjugular intrahepatic portosystemic shunts,[65] the use of PN in such patients might be preferable. In most cases, PN in the patient with liver failure can be accomplished via the administration of standard mixed amino acids (Fig. 153–2).[66]

NONPHARMACOLOGIC THERAPIES

Dietary counseling makes patients aware of the risks that malnutrition poses for the progression of their disease and can provide strategies for patients to attain goal intakes, while being mindful of dietary restrictions. Many patients will have a higher likelihood of maintaining normal substrate utilization if they eat four or five small meals a day and a snack at bedtime. At least one study has found that intensive counseling is equivalent to providing oral nutritional supplements in increasing patient intake.[51] Cirrhotic patients may also derive up to a 26% increase in energy intake and a significant increase in lean body mass after the insertion of a transjugular intrahepatic portosystemic shunt.[67]

There is considerable interest in the use of vegetable-protein diets in the chronic management of patients with cirrhosis and hepatic encephalopathy. Enthusiasm for this therapy is based on the reduced amounts of aromatic amino acids and methionine in vegetable protein and a decrease in nitrogen absorption as the result of a decreased GI transit time and an increase in fecal nitrogen excretion by colonic bacterial flora. However, compliance is more difficult to achieve with vegetable-based than animal-based protein diets. ASPEN recommends that a diet with vegetable-based protein be considered for those patients who do not tolerate at least 1 g/kg/day of protein from their normal diet.[28]

PHARMACOLOGIC THERAPIES

Drug Treatments of First Choice

In patients with liver disease who are unable to meet their nutritional needs despite dietary counseling, ESPEN guidelines recommend that EN be initiated with a goal of providing 35 to 40 kcal/kg/day (147–167 kJ/kg/day) and protein intake of 1.2 to 1.5 g/kg/day.[55] Indirect calorimetry quantification may be preferred to empiric estimates of caloric requirements in this setting. Excessive calorie provision actually may promote liver dysfunction and increased production of carbon dioxide with an associated increased work of breathing. Standard whole-protein formulas are recommended, but more concentrated formulations are appropriate to avoid excessive fluid overload in patients with ascites.[55]

When dextrose-based PN is started in those who cannot tolerate EN, additional thiamine may be needed to prevent Wernicke encephalopathy. Standard mixed amino acids are appropriate for most patients. IVLE should be used in patients with liver failure only to prevent essential fatty acid deficiency when initial serum triglyceride concentrations exceed 300 mg/dL (3.39 mmol/L). If serum triglyceride concentrations are low or normal, IVLE may be used as a calorie source. Monitoring serum triglyceride concentration and free fatty acid oxidation (not available in all facilities) to ensure that lipid is both cleared and oxidized appropriately has been suggested. Oral medium-chain triglycerides have been used occasionally with success because they do not require pancreatic enzymes or micelle formation before absorption. However, these products do not provide essential fatty acids.

The electrolytes that warrant the most careful monitoring in those with liver disease are sodium, potassium, phosphorus, and magnesium. During fluid and salt restriction, patients (especially those receiving concurrent lactulose therapy for encephalopathy) should be observed for symptoms of volume depletion (e.g., increased pulse rate, decreased blood pressure, or dry mucous membranes). Magnesium concentrations as high as 24 mEq/L (12 mmol/L) in the PN solution, which is two to three times the standard daily dose, may be required to maintain plasma concentrations in the normal range.

Trace elements that warrant individual attention include zinc, copper, and manganese. For patients receiving PN, withholding copper from the solution until a copper serum concentration in the normal range is documented or the cholestasis resolves are appropriate. Patients who have chronic cholestasis may require copper in reduced doses (e.g., 0.6 mg/day); however, they should have serum copper concentrations checked regularly (once per month in the acute care setting and every 6 months in the ambulatory setting). Manganese restriction also may be required in these patients.

TABLE 153-4 Nutrition Recommendations for Patients with Liver Disease

Patient Type	Calorie Energy (kcal/kg/day)[b]	Protein (g/kg/day)	Comments
Compensated cirrhosis	25–35	1–1.2	Use a bedtime snack and frequent small meals
Decompensated cirrhosis[a]	25–35	0.5–1.5 for mild; 0.5 for severe	Use branched-chain amino acids for refractory cases of encephalopathy unresponsive to protein restriction
Decompenstated cirrhosis[a] with malnutrition	35–40	1.5	May have to temporarily decrease protein for encephalopathy worsening

[a]Decompensated cirrhosis: cirrhosis accompanied by significant ascites or encephalopathy.
[b]One kcal/kg/day is equivalent to 4.2 kJ/kg/day.
Adapted from reference 51 and 55.

Table 153–4 lists the nutritional requirements of patients with liver failure secondary to cirrhosis, and Table 153–1 presents an empiric PN formula for the patient with hepatic failure.[54,60,66]

Alternative Drug Treatments

The major controversy in nutritional support of the patient with liver failure has centered on the selection of the optimal protein product. Modified amino acid solutions for PN (e.g., HepatAmine) are marketed for patients with liver failure and hepatic encephalopathy. They are enriched with branched-chain amino acids and have reduced amounts of aromatic amino acids and methionine. These products are formulated on the basis of the false neurotransmitter hypothesis, which postulates that hepatic encephalopathy may be a result of increased aromatic amino acid concentrations in the central nervous system.

NutriHep, a supplement for patients with hepatic encephalopathy, usually provides adequate amounts of vitamins and minerals, contains a high percentage of medium-chain triglycerides, and is supplemented with carnitine. Clinical trials using this and other branched-chain amino acid products have yielded promising outcomes, including decreases in morbidity and mortality. These results, however, have not been consistent. Enteral products with branched-chain amino acids are associated with significant nonadherence because of poor taste.[51] This, coupled with the increased cost of these products, has led ASPEN and ESPEN to recommend reserving these products for patients with severe encephalopathy who decompensate on standard protein formulations despite continued lactulose–neomycin therapy.[28,55]

PHARMACOECONOMIC CONSIDERATIONS

Nutritional supplementation in patients with alcoholic cirrhosis reduces the frequency of hospitalizations.[68] Intuitively, this should be a cost-saving intervention, but without formal analysis, the degree of benefit cannot be quantified.

EVALUATION OF THERAPEUTIC OUTCOMES

Weight, albumin concentration, and prealbumin concentration are commonly used markers of nutrition status that may not be as reliable in patients with hepatic failure. Ascites, edema, and impaired hepatic protein synthesis make nutritional evaluation difficult in this patient population. Indeed, many of the commonly used markers of nutritional status correlate poorly with body cell mass in those with ESLD. Subjective global assessment, prognostic nutritional index, bioelectrical impedance, midarm muscle circumference, and hand grip strength have been tested as predictors of body cell mass.[51] Hand grip strength best correlates with malnutrition and is a better predictor of major complications in patients with cirrhosis.[69]

SHORT BOWEL SYNDROME

Short bowel syndrome (SBS) is generally a consequence of significant surgical resection of the small bowel that results in the malabsorption of nutrients and fluids. Morbidity and mortality caused by GI failure in SBS patients have been improved with the provision of PN and EN. The goal of nutritional support with EN and PN is to maintain nutritional status, prevent or correct nutritional deficiencies, and enhance quality of life.[70]

EPIDEMIOLOGY

There are at least 10,000 patients who have SBS in the United States.[71] The most common etiologies in adults are surgical resections because of Crohn disease, mesenteric vascular disease, and cancer. In infants, necrotizing enterocolitis, midgut volvulus, and intestinal atresia are the most common etiologies for resection leading to SBS.[71] SBS occurs more commonly in women than in men, most likely as a consequence of women having less small intestine length to begin with. This condition also may be functional as opposed to anatomic and occurs in individuals who have not had resections, but who have a decreased small bowel absorptive capacity as a result of radiation enteritis or severe inflammatory bowel disease.[70] Symptoms of SBS generally include diarrhea, dehydration, electrolyte disturbances, and progressive malnutrition.[71]

PATHOPHYSIOLOGY

The average length of the small intestine, where the majority of nutrients are absorbed, in adults is 400 to 600 cm (157–236 inches). The American Gastroenterological Association considers a patient to have SBS when the patient has 200 cm (79 inches)or less of functional small intestine.[72] Losing this absorptive capacity leads to deficiencies in multiple nutrients, requiring the initiation of interventional nutrition.

5 PN must be used at least immediately following resection of the small intestine while the GI tract is healing and adapting. Enteral nutrition may be used later during the transition to oral feedings, as the GI tract is able to adapt with time, by increasing absorptive capacity, in ~50% of patients with SBS.[71] The length and type of nutritional support a patient may require are based on such factors as the length of remaining small intestine and the presence or absence of a functional colon. Adult patients have the highest likelihood of transitioning off PN if the residual jejunum–ileum length is greater than 100 cm (40 inches) for individuals without a colon, or greater than 60 cm (24 inches) if a portion of the colon is in continuity with the remaining small intestine.[73] Factors that are predictive of a poor outcome include older age, disease in the residual bowel, and removal of the ileocecal valve, the physiologic sphincter that controls the rate of passage of intestinal contents from the small to large bowel and prevents small bowel bacterial overgrowth.[74]

Intestinal Adaptation

The adaptation process of the residual small intestine to compensate for the loss of the resected area begins 24 to 48 hours after bowel resection and may continue to occur for 1 to 2 years.[75] Several factors act as stimuli for adaptation, including enteral nutrients, pancreatic biliary secretions, and intestinal hormones.[28] The ability of the remaining intestine to adjust after resection is also influenced by the area of bowel loss. The jejunum is the primary site for absorption of most nutrients, but if it is removed, the ileum usually can accommodate and take on the structural characteristics and functional roles. Even with this compensation, patients with less than 50 to 60 cm (<20–24 inches) of jejunum typically need indefinite PN. With ileal resection, the jejunum has a decreased capacity to adapt and perform the functions of the ileum.[75]

Energy Requirements

Caloric intake and energy needs of SBS patients are highly variable. Individuals who have lost >50% of their small intestine typically require 25 to 30 kcal/kg (105–126 kJ/kg) of ideal body weight when receiving PN, but they may need to ingest 50 to 60 kcal/kg (209–251 kJ/kg) of ideal body weight when receiving enteral feedings to compensate for malabsorption.[72,76] This condition is referred to as *adaptive hyperphagia*.[77]

Carbohydrates

Carbohydrate malabsorption plays a major role in diarrhea associated with SBS. Unabsorbed carbohydrates, especially simple carbohydrates, represent a substantial osmotic load in patients with SBS and are associated with an increased output. In patients with an intact colon, however, soluble fiber and complex carbohydrates are broken down by colonic bacteria to short-chain fatty acids, hydrogen, and methane. This fermentation causes flatulence; however, the colon is able to use the short-chain fatty acids as a source of energy. Thus, complex carbohydrates may provide a significant caloric source for patients with a massive resection and a preserved colon.[73]

Fat

Fat malabsorption also is common in SBS. The pathophysiology of this problem is complex and related to alterations in pancreatic enzyme secretion and bile salt absorption. The ileum is the major site of the latter process, and with its removal, bile salt malabsorption is common. Eventually, the total bile salt pool may be depleted, resulting in increased fat malabsorption and steatorrhea.[71] There has been much debate regarding the restriction of oral fats, which may decrease steatorrhea, number of stools, and stool weight in some patients. Fats have the highest number of kilocalories per gram and make the diet more palatable; thus, patients with SBS without a colon should not be restricted in the amount of fats they take in. For patients with SBS but with a healthy colon, a diet higher in complex carbohydrates and lower in fat may result in lower stool volume and electrolyte loss, so this type of diet may be more beneficial.[73] Medium-chain triglycerides have also been suggested for patients with SBS and an intact colon, as MCTs are better absorbed than long-chain triglycerides. MCTs may be especially useful in decreasing steatorrhea in patients with bile acid or pancreatic insufficiency. Care must be taken, however, because medium-chain triglycerides do not contain essential fatty acids.[71,73]

Protein

Protein typically is well tolerated as a caloric source in patients with SBS. The optimal form for the delivery of protein to patients with SBS is the subject of much study and debate.[73] In the past, EN was often initiated with elemental formulas that contain free amino acids as the protein source because the efficiency of protein uptake was perceived to be better. However, total protein absorption is faster and more complete with dipeptide and tripeptide formulations. Absorption of free amino acids by the enteral route is a saturable process, whereas the absorption of small peptides is not. These more complex protein sources also may stimulate intestinal adaptation.[75] The American Gastroenterological Association now recommends that standard enteral formulas be used preferentially in SBS.[72]

Fluid, Electrolyte, and Acid–Base Disorders

6 After substantial resections of the small bowel, the postoperative course is complicated by fluid and electrolyte imbalances that typically last 1 to 3 months.[75] Patients may have high-volume gastric fluid loss from nasogastric tubes and small intestine fluid loss from ostomies. Sodium content usually is elevated in these secretions, with concentrations reaching 80 to 100 mEq/L (80–100 mmol/L).[71] Acute gastric hypersecretion may occur after massive resection and contribute significantly to these deficits.[75] Secretory diarrhea (see Chapter 43) also results in fluid and electrolyte losses that may be difficult to quantify.

Patients with end jejunostomies or proximal ileostomies (surgically created openings into the jejunum and ileum, respectively, that divert the intestinal contents externally through a stoma) can have recurrent dehydration and electrolyte deficiencies. A high jejunostomy can produce fluid output of 3 to 4 L/day, with sodium loss of 90 mEq/L (90 mmol/L). To overcome the net secretion of sodium and water into the jejunum, the sodium content of fluids ingested by the patient needs to be ~90 mEq/L (90 mmol/L). In patients who have a small intestine in continuity with the colon, the malabsorbed bile and fatty acids stimulate sodium and water excretion into the large bowel, but in general, these patients are at less risk for sodium and water depletion.[71]

Patients with a jejunostomy and individuals with long-term sodium depletion, magnesium deficiency, or excessive loss from diarrhea are at risk for hypokalemia.[70] Metabolic alkalosis, which may occur when a patient becomes dehydrated, accelerates the renal excretion of potassium, as all hydrogen ions are conserved in an attempt to correct the acid–base disorder. As bicarbonate ions are excreted renally, potassium is taken with them to maintain osmotic balance.

The unusually large amount of unabsorbed fatty acids within the remaining small intestine and colon of the patient with SBS will cause increased binding to calcium, resulting in a deficiency. This also may result in hyperoxaluria because dietary oxalate usually complexes with the intraluminal calcium and is excreted in the stool. As a result of decreased calcium available for binding, more oxalate is absorbed and available for renal excretion; thus, the risk of calcium oxalate renal stone formation is increased.[73] Because vitamin D deficiency results in insufficient calcium absorption, patients with SBS requiring long-term PN are at risk for metabolic bone disease. Magnesium deficiency is common in patients with large ostomy or diarrheal losses. This deficiency should be corrected aggressively because of the correlation between low magnesium and potassium concentrations with the development of calcium oxalate stones. Serum concentrations are commonly monitored, but urinary magnesium concentrations may decrease earlier with deficiency and be a better estimate of total body stores than serum levels. Oral supplementation may be difficult because it can contribute to increased diarrhea or ostomy output. However, repletion is necessary to prevent complications and to effectively correct potassium deficits.[70]

Patients with SBS can lose substantial amounts of chloride (60–140 mEq/L [60–140 mmol/L]) in addition to sodium from ostomy output. These individuals have a high risk of developing hypochloremic metabolic alkalosis. Patients who have SBS complicated by a pancreatic fistula and severe diarrhea lose considerable potassium and bicarbonate and may develop metabolic acidosis. Patients with severe diarrhea who have an intact colon will conserve sodium and chloride, resulting in considerable loss of potassium and bicarbonate and the development of metabolic acidosis. Quantifying fluid losses with particular attention to the sources of loss will aid in the acid–base management of these patients (see Chapter 61).

Lactic acidosis can occur in patients with SBS who have an intact colon and may result in symptoms of ataxia and delirium.[75] D-lactic acid is produced by the fermentation of malabsorbed carbohydrates by colonic bacteria, and increased concentrations are associated with small bowel bacterial overgrowth. The diagnosis of D-lactic acidosis should be considered in patients with a functional colon who have an unexplained metabolic acidosis and an elevated anion gap.[75]

Trace Elements

Patients with SBS are particularly prone to zinc deficiency as a result of excessive losses from stool, ostomy outputs, and fistula drainage. Although serum zinc concentrations are not always reflective of body zinc status, a low serum zinc concentration requires an adjustment in the replacement amount.[71] Significant bowel resection, GI losses, and impaired intestinal absorption also contribute to imbalances of other trace elements, such as copper, selenium, and manganese. Because trace element deficiencies are common, the need for supplementation of these micronutrients is essential for SBS patients, including those receiving PN, EN, or an adequate diet.[75]

Vitamins

7 Patients with ileal resection commonly develop vitamin B_{12} deficiency, necessitating therapy with parenteral or intranasal cyanocobalamin. Most other water-soluble vitamins are absorbed in the proximal jejunum, and deficits of these vitamins are less common. There are reports, however, of SBS patients with symptomatic thiamine, folate, and biotin deficiencies.[71] Small bowel bacterial overgrowth can contribute to diminished vitamin B_{12} because bacteria may metabolize the nutrient within the intestine, decreasing its availability for absorption. Patients with SBS with fat malabsorption can acquire deficiencies in vitamins A, D, E, and K.[71]

TREATMENT

DESIRED OUTCOMES

The desired outcomes of the nutritional management of patients with SBS are to provide effective energy, protein, micronutrients, and fluids in amounts adequate to maintain patient health and normal growth, avoid complications of SBS or the nutrition support regimen, and optimize quality of life.[70] Finally, one wants to maximize the use of the GI tract for nutrient provision to maintain GI tract function.

GENERAL APPROACH TO TREATMENT

After intestinal resection, the clinical course and nutritional management of patients with SBS may be described in three stages (Fig. 152–3).[72,74] The first stage typically covers the initial postoperative week; however, it may continue for up to 3 months. It is complicated by major fluid and electrolyte losses (up to 5 L/day).

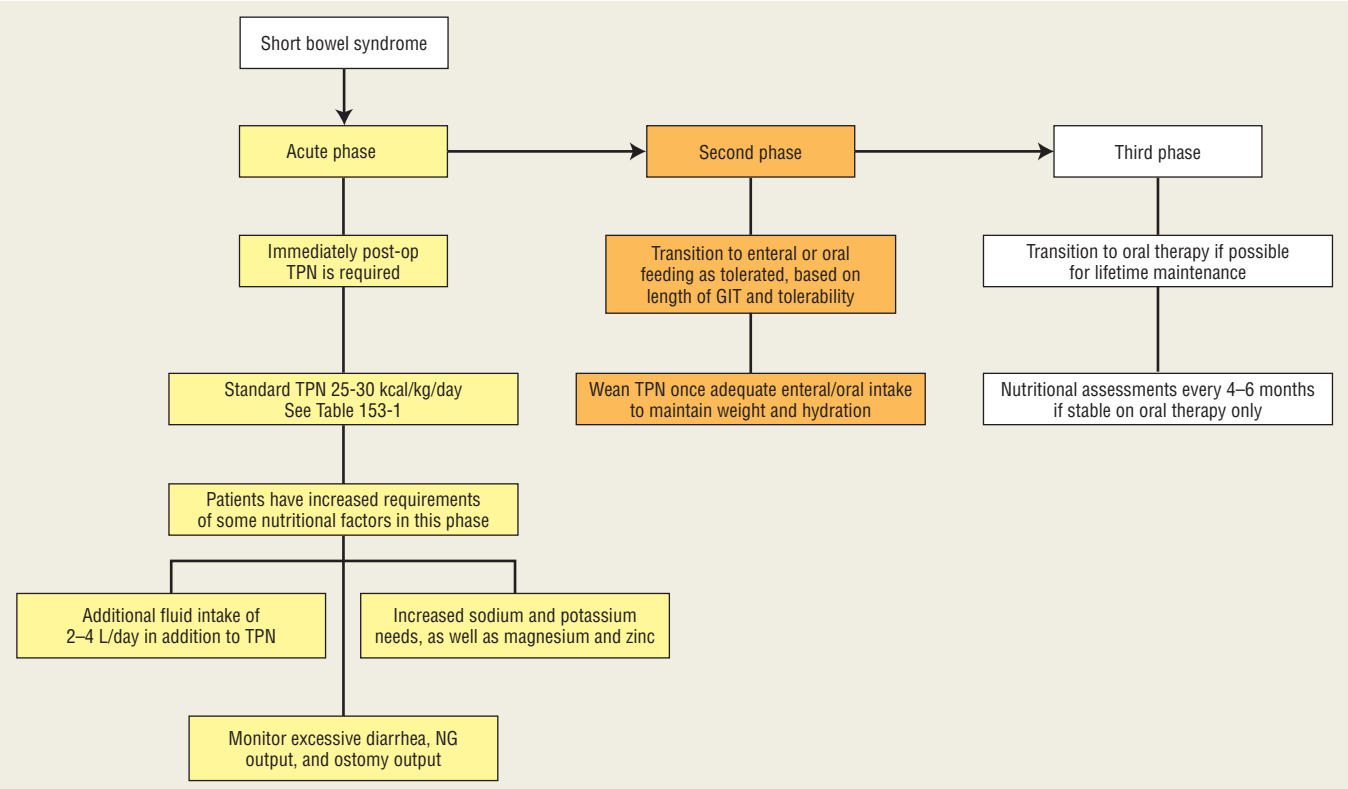

FIGURE 153-3. An algorithmic approach to nutritional support for the patient with short bowel syndrome. Energy intake of 25 to 30 kcal/kg/day is equivalent to 105 to 126 kJ/kg/day. GIT, gastrointestinal tract; NG, nasogastric; TPN, total parenteral nutrition. *Adapted from data in reference 70 and 72.*

The parenteral route should be used to supply nutritional needs during this stage of recovery.

8 The second stage lasts from a few months to longer than a year, and institution of enteral or oral intake early during this stage is important because intraluminal nutrients are essential stimuli for intestinal adaptation. The amount of enteral/oral nutrition can be advanced as the patient tolerates; concomitantly, the duration and/or rate of PN may be decreased. If a PN regimen is to be reduced or discontinued, it should be done slowly; initially, 1 or 2 nights of PN may be eliminated each week. In the third and final stage, adaptation is maximized, and many patients can be maintained with oral nutrition alone. However, PN may not be required on a daily basis for some. Eventually, some patients may be able to tolerate administration on an every-other-night or every-third-night basis.[74,75]

NONPHARMACOLOGIC THERAPY

Initially, surgical management focuses on preserving as much GI tract as possible. Intestinal transplantation is a surgical treatment option for some patients with SBS, and ~1,200 such procedures have been performed worldwide as of 2006.[70] With refinement of patient selection and surgical techniques, the 1-year survival rate after small bowel transplantation is 88% to 92%, which is similar to that of those receiving home PN. Five-year survival, however, is still poorer than that reported in patients receiving home PN.[78] After transplantation, the majority of survivors are able to completely discontinue PN.[70] Small bowel transplantation is currently reserved for those patients with SBS who fail PN therapy because of recurrent line sepsis, loss of vascular access, PN-induced liver failure, or frequent severe dehydration.[72] As patient selection and immunosuppressive regimens continue to evolve, the indications for small bowel transplantation will likely expand.

PHARMACOLOGIC THERAPY

Drug Treatments of First Choice

The early stage of SBS is associated with large day-to-day variations in fluid and electrolyte losses. Strict input and output records should be assessed, including IV medications. Initially, it is recommended to start a standard PN solution that meets the patient's maintenance metabolic, fluid, and electrolyte needs, and a separate IV replacement solution is typically necessary to keep the patient euvolemic. Insensible losses should be estimated between 300 and 800 mL/day above measured output, and daily urine output should be kept at least at 0.5 mL/kg/hour. As fluid and electrolyte losses stabilize over time, it becomes possible to incorporate these replacement requirements into the PN solution. The American Gastroenterological Association recommends that the PN solution typically be composed of standard crystalline amino acids, glucose, and IV lipids. Energy provision of 25 to 30 kcal/kg (105–126 kJ/kg) of ideal body weight per day is recommended and may be administered as 1 to 1.5 g/kg of protein per day, ~20% to 30% of calories from IV lipids, and the remainder of calories from carbohydrates.[72] Table 153–1 gives an example of a PN formula for the patient with SBS.

The amounts of chloride versus acetate salt forms chosen for cation delivery should be based on assessment of the acid–base balance of the patient and sources of GI losses. More proximal GI losses generally are associated with increased chloride needs and more distal outputs with increased bicarbonate (i.e., acetate) requirements. Sodium losses may be extreme in patients with SBS as already mentioned, requiring supplementation above what a typical patient on PN requires. In addition, supplementation of potassium, calcium, magnesium, zinc, or other micronutrients over their maintenance amounts may be necessary to meet replacement needs.[75]

The transition from PN to enteral feedings is desirable because EN serves as a stimulus for intestinal adaptation. Thus, EN should be instituted as the patient progresses throughout the postoperative period.[71] Enteral nutrition, given as a continuous infusion through a nasogastric or gastric feeding tube, may be advantageous over bolus feedings because it can maximize absorptive capacity, decrease recovery time, and minimize diarrhea.[75] Although specialized and elemental formulas have been studied, standard EN formulations are preferred in SBS.[72] Avoiding lactose-containing foods and enteral formulations is also appropriate in patients who have extensive jejunal resection or who demonstrate lactose intolerance.[71]

Small volumes (600–1,000 mL/day) of oral electrolyte solutions, such as low-carbohydrate sports drinks and sugar- and caffeine-free beverages, are optimal for patients with a colon, and oral rehydration solutions (with ~90 mEq/L [90 mmol/L] of sodium) for those without a colon. Frequent, small amounts of solid food composed primarily of complex carbohydrates and proteins (600–1,000 kcal/day [2,511–4,186 kJ/day]) have been recommended, with avoidance of concentrated sweets and dairy products.[73] When a patient is able to maintain hydration and weight via EN and/or eating, PN may be tapered.[74] Many factors must be considered once a patient with SBS begins to transition off interventional nutrition when determining the content of a long-term oral diet. Factors such as the site and length of remaining intestine, tolerance, and patient acceptance must be considered. Fat generally is not restricted in patients without a colon. However, patients with a colon may experience more diarrhea with a high-fat diet and may benefit from oral intake that has more calories from carbohydrates and less fat content.[73] The oral diet for patients with remaining functional colon also must account for oxalate content, and patients should avoid foods with high amounts of oxalate (e.g., spinach, parsley, rhubarb, cocoa, and tea) to decrease formation of calcium oxalate renal stones.[73] Finally, oral diets in patients with SBS often need to be supplemented to maintain electrolyte, mineral, vitamin, and trace element balance.

The delivery of medications to patients with SBS may present many challenges, not the least of which is the questionable absorption of oral therapies. Oral products that contain sorbitol or mannitol should be avoided to minimize medication-related diarrhea. Loperamide and octreotide may be used to control diarrhea (see Chapter 43), and proton-pump inhibitors and H_2-receptor antagonists are frequently required to reduce gastric hypersecretion (see Chapter 39). Because of erratic absorption, the dose of oral or enteral medications may need to be greater than recommended for patients with an intact GI tract.

Alternative Drug Treatments

The use of specialized nutrients and growth factors to enhance small bowel adaptation is a focus of intensive research. The amino acid glutamine is a fuel for intestinal cells and may be necessary for maintaining intestinal structure in normal and physiologically stressed states. Initial uncontrolled research findings suggested that those who received glutamine in combination with rhGH and a high-carbohydrate/low-fat diet may have a reduced PN dependence and increased nutrient absorption.[79] Recombinant growth hormone was added to the regimen because of its stimulant properties on bowel adaptation. Subsequent double-blind, placebo-controlled crossover studies, which were done in small numbers of patients, were unable to duplicate the beneficial results of glutamine and rhGH.[80]

However, the most recent double-blind, placebo-controlled trial showed that glutamine, rhGH, and a high-carbohydrate/low-fat diet (optimized for 2 weeks prior to the treatment phase) resulted in a significant reduction in PN volume and caloric requirements.[76] Patients in the group receiving glutamine and rhGH were able to

maintain their nutritional status while decreasing their average PN requirements from 5 to 6 days per week down to 2 days per week.[76] In the wake of this study, the FDA approved one form of rhGH for use in patients with SBS who are receiving specialized nutrition support.

A consensus panel convened by a manufacturer of rhGH recommended the FDA-labeled dose of 0.1 mg/kg subcutaneously daily for 4 weeks be considered a reasonable therapeutic intervention. The panel suggested that appropriate patients are PN-dependent patients who are nutritionally stable and on an optimized diet and medication regimen, and that treatment be given 6 to 24 months after bowel resection.[80] This treatment, however, is not recommended by the American Gastroenterological Association.[72] Other experts question the benefit of rhGH and suggested that before incorporating it into SBS treatment, it should be studied during the adaptive phase of SBS.[71] The safety of prolonged use of rhGH is also unknown.

CLINICAL CONTROVERSY

Although there are some data indicating that rhGH in combination with dietary optimization and glutamine may decrease PN dependence in patients with SBS, the role of these therapies is still not well defined. There are conflicting data as to whether this therapy enhances nutrient absorption. The timing of therapy and the identification of appropriate patient populations are also still areas of active research.

PHARMACOECONOMIC CONSIDERATIONS

Nutritional management of SBS is quite costly, especially in patients who require home PN. One year of home PN therapy is estimated to cost $100,000.[78] This figure does not include home nursing, equipment, and the costs of intermittent hospitalizations. Significant savings may be realized in patients who are able to transition from PN, but this is unlikely to occur in patients who are still PN dependent after 2 years. A study in pediatric patients found the average total cost of care for the first year following SBS was $505, 250 and over the first 5 years was $619,851.[81]

No analyses have yet been published that describe the economic consequences of the potential PN-reducing effect of rhGH.[80] It has been reported that intestinal transplantation is a cost-effective intervention relative to the cost of home parenteral nutrition in patients who survive for 2 years postoperatively.[82]

EVALUATION OF THERAPEUTIC OUTCOMES

Therapeutic monitoring of patients with SBS who are receiving PN for metabolic complications should follow the guidelines outlined in Chapter 151. This patient population differs in that serum electrolytes should be obtained daily until the patient has stabilized postoperatively. Special consideration should also be given to the fluid status of patients with SBS, especially in the period immediately following surgery, when fluid losses are extreme. Monitoring of stool output is such a large factor that it must be taken into consideration for all such patients. Because many patients with SBS remain on PN for extended periods of time, clinicians must be careful to monitor for elevations in liver enzymes, and cycling PN for 12 to 14 hours daily should be considered in those patients to minimize these complications. Obtaining a serum fatty acid profile may be judicious in those patients on long-term PN without oral intake to ensure they do not have essential fatty acid deficiency.[83]

The most comprehensive and thorough analysis of the clinical outcomes of patients receiving home PN or EN comes from Medicare and the North American Home Parenteral and Enteral Patient Registry.[84] It was estimated that 40,000 and 152,000 patients in the United States were receiving home PN and EN support, respectively as of 1995. Patients with GI failure, which included those with Crohn disease, ischemic bowel disease, motility disorders, and congenital bowel defects, had relatively good clinical outcomes, especially when compared with the groups with cancer or acquired immune deficiency syndrome. The patients with GI failure had an 87% annual survival rate and a 50% to 75% likelihood of complete rehabilitation. Sepsis, metabolic disorders, and mechanical problems with catheters resulted in one or two hospitalizations per year for all patients.[84]

QUALITY-OF-LIFE ISSUES

Initially, those patients on extended PN therapy have a significant gain in QOL when transitioning from the hospital to their home setting. This is often followed by the reality of restrictions in daily living, dehydration and malnutrition despite PN, and complications such as sepsis and liver dysfunction. Patients with SBS on home PN have reported that their QOL is significantly reduced in comparison to those with anatomic or functional SBS not on home PN.[80] There are currently no data assessing the effect of treatment with growth factors such as rhGH on QOL, although one might expect to see an improvement. Valid comparisons of home PN and intestinal transplantation are not available, as a consequence of the limited indications for transplantation.[82] Preparing patients and their caregivers for the possible stresses associated with this therapy (e.g., financial challenges, fatigue, depression, complications, and social or emotional problems) through education and referral to support groups, such as the Oley Foundation, may help to increase QOL.[85]

PULMONARY FAILURE

Nutrition support is an important aspect of preventing and treating both acute and chronic pulmonary failure. Malnourished patients are at increased risk of acute respiratory distress syndrome (ARDS), and malnutrition in patients with chronic obstructive pulmonary disease (COPD) is well documented. There is also a correlation between the outcomes of patients with alterations in nutritional status and concurrent pulmonary diseases.[86] Loss of lean muscle mass is detrimental because the depletion of diaphragm and intercostal muscles makes the effort of breathing harder, and progression of weight loss leads to muscle fatigue and respiratory failure. The ventilatory drive, as well as compensation to hypoxia, is depressed in patients with COPD who are malnourished, and nutritional support plays a key role in optimizing respiratory muscle function in patients with pulmonary disease.[87]

EPIDEMIOLOGY

More than 10% of the U.S. population over 45 years of age have COPD, resulting in significant cost to the healthcare system.[87] Weight loss and protein–calorie malnutrition may occur in up to half of these patients, and weight loss often coincides with disease progression.[28,87] In those with acute respiratory failure, nutritional abnormalities have been reported in up to 70%.[86] Engelen et al evaluated the body composition of patients with COPD, specifically those with emphysema and chronic bronchitis. They found a higher incidence of lean mass depletion in patients with emphysema than in those with chronic bronchitis. Body weight and body mass index (BMI) were also lower in the group with emphysema.[88] In a

subsequent evaluation, the same investigators reported that skeletal muscle weakness was associated with wasting of extremity fat-free mass that was independent of COPD subtype.[89] Finally, malnutrition is associated with an increased mortality rate in patients with COPD with low BMI.[90]

PATHOPHYSIOLOGY

Energy Requirements

9 Patients with COPD have highly variable REE, and commonly used predictive measures may underestimate their energy needs.[91] Those who are losing weight tend to have significantly higher REE adjusted for fat-free mass compared with weight-stable patients. Total daily energy expenditure also was found to be elevated in clinically stable COPD patients with both normal and increased REE. The cause of elevated total daily energy expenditure despite a normal REE is still unknown, although the oxygen cost of breathing, acute or chronic systemic inflammation, and medications may contribute.[86] Although the optimal approach to energy needs in COPD has not been identified, it is evident that there is no advantage to providing 1.7 × REE compared with 1.3 × REE.[92] Hypermetabolism likely contributes to the decreased body weight and fat-free mass, although it has been shown that in this patient population, intake may be suboptimal. During meals hypoxic patients tend to experience decreases in oxygen saturation and increased dyspnea. Gastric filling may also be impaired because of diaphragmatic expansion and a false feeling of fullness.[86] These problems, combined with increased daily requirements, may result in the negative energy balance seen in many patients with COPD. Several specialized equations have been developed to estimate energy requirements in this patient population, and indirect calorimetry may be used, but clinical benefit is questionable. Patients with acute respiratory failure also may have alterations in energy expenditure, but the situation is similar in that predictive formulas for energy needs exist, and indirect calorimetry may be used. Providing excess calories to the acutely ill patient in respiratory failure should be avoided because this may increase CO_2 production and the associated work of breathing.[28,87]

Carbohydrates

Malnutrition in patients with pulmonary disease has been consistently identified in the literature, and nutrition support should be considered as part of the overall treatment plan. However, increasing nutritional intake can be complicated because it may elevate the respiratory quotient, which may lead to a corresponding increase in the work of breathing and resulting hypercapnia. The respiratory quotient is the ratio of the amount of CO_2 produced divided by the amount of O_2 consumed. When a subject is overfed, the amount of CO_2 produced markedly exceeds the amount of O_2 consumed, which can result in increased ventilatory demand.[93] Ventilatory drive may be improved in some patients with moderate infusions of carbohydrates; however, administration of glucose formulas at a rate greater than 5 mg/kg/min has been shown to increase production of CO_2 and is associated with the inability to wean from mechanical ventilation.[87]

Fat

Fats have the lowest respiratory quotient, but administration of IV fat emulsions to mechanically ventilated patients has the potential to adversely affect pulmonary gas exchange in some clinical conditions.[94]

The administration of lipid emulsions to patients with ARDS may decrease oxygenation. A trial assessing both long-chain triglyceride and combination long-chain triglyceride/medium-chain triglyceride administration showed that there was no deleterious effect on oxygenation. Discrepancies in trial data may be a result of differing lipid infusion rates and duration, as well as preexisting lung status.[95] Rapid administration of IV lipids should be avoided; a rate of 3 mg/kg/min increases pulmonary vascular resistance in patients with ARDS.[95] A review of nutritional intervention in ambulatory patients with COPD revealed that diets high in fat placed a lower demand on the respiratory system in comparison to diets with a higher carbohydrate content. In addition to an improvement in forced expiratory volume, the number of breaths needed per minute decreased within 3 weeks in patients with COPD who switched to a high-fat/low-carbohydrate diet.[93] Although these effects are important, the most critical element in managing patients with pulmonary compromise is avoiding overfeeding.[28]

Protein

Undernourished patients demonstrate a blunted response to hypercapnia that improves after as little as 1 week of adequate nutritional support. This response is thought to result from protein administration, as evidenced by decreased partial CO_2 pressure, increased minute ventilation, and improved breathing patterns after the start of PN. Protein administration also may influence ventilatory demand by increasing ventilatory response to hypoxia and hypercapnia. This stimulation may be altered by the amino acid composition of the protein source, with increased amounts of branched-chain amino acids having a greater effect compared with standard amino acids. Although this protein effect is potentially beneficial in some patients, excessive protein administration could theoretically lead to increased work of breathing and fatigue.[87]

Fluid, Electrolyte, and Acid–Base Disorders

10 In patients with ARDS or pulmonary edema, excessive fluid intake should be avoided, as fluid accumulation is associated with a poor outcome. Patients in the ICU often receive substantial fluid loads from medication administration… When possible, it is important to limit intake by concentrating these sources.[28,87]

Alteration of micronutrient requirements in respiratory failure is commonly focused on phosphorus replacement. Phosphorus has an essential role in the synthesis of adenosine triphosphate (ATP) and 2,3-diphosphoglycerate (2,3-DPG). Inadequate stores of ATP can lead to respiratory muscle weakness, and normal contractility of the diaphragm muscles is dependent on phosphate.[87] Finally, a significant percentage of critically ill patients experience hypophosphatemia from refeeding. Most patients with moderate to severe hypophosphatemia and respiratory failure should be treated with IV sodium or potassium phosphate (see Chapter 59). Correction of hypophosphatemia in patients in the ICU receiving nutritional support with a graduated weight-based dosing scheme of phosphorus replacement has been reported.[96]

Ventilator-dependent patients and those with stable COPD often have respiratory acidosis. A balanced mixture of chloride and acetate salts often is appropriate in these patients. The acid–base status of the patient in the ICU with pulmonary compromise should be monitored daily, whereas every 2 to 3 days may be adequate for the stable hospitalized patient with COPD.

Vitamins and Trace Elements

Patients with pulmonary disease usually do not have significant alterations in vitamin and trace element requirements, and they can receive standard doses of these micronutrients. There are some data that support the supplementation of vitamin C, vitamin E, and β-carotene because of a correlation with moderately improved pulmonary function. Patients with COPD may have an increased

burden of oxidants from cigarette smoke or release of oxygen free radicals from inflammatory leukocytes in the lungs, and deficiencies of antioxidants may contribute to oxidant/antioxidant imbalances in these individuals.[97]

TREATMENT

DESIRED OUTCOMES

In patients with pulmonary failure, nutritional support should be given to meet energy and protein requirements and to limit wasting of respiratory muscles. In stable patients with COPD, this may be done in addition to exercise rehabilitation programs to optimize weight and fat-free body mass. To date, nutrition support has not been shown to affect long-term survival in these patients.[98]

GENERAL APPROACH TO TREATMENT

When oral feedings are inadequate, ASPEN recommends that EN be used in those who have a functional gut and can meet their needs through this route.[28] PN is recommended when the GI tract is not usable or as a supplement to EN if sufficient energy intake is otherwise not possible.[28,87]

Most general EN formulas contain an equal balance of nonprotein energy between carbohydrates and fat. Elemental or chemically defined products are the exception because they are intended to be high-carbohydrate, low-fat formulas to enhance absorption and digestion. In pulmonary patients, administration of a high-carbohydrate formula may result in a significant increase in minute ventilation, heat production, and CO_2 production when compared with a high-fat formula. Because most general formulas contain balanced nonprotein calories, moderate doses of these products may be appropriate in most patients with pulmonary disease.[26,90] Patients who are fluid restricted should be given a higher energy formulation so as to maintain an appropriate fluid balance.[28]

NONPHARMACOLOGIC THERAPY

Patient education and nutritional counseling are essential to maximizing the health of patients with COPD. Education about appropriate energy and caloric intake and the proper use of oral nutritional supplements may enhance patient adherence to these practices. Ambulatory patients with COPD may also benefit from a pulmonary rehabilitation program that integrates diet, supplements, and exercise.[90]

PHARMACOLOGIC THERAPY

Drug Treatment of First Choice

Moderate doses of carbohydrate, fat, and protein given enterally are appropriate in most conditions. Total calorie provision 30% above basal energy expenditure does not have any untoward effects on pulmonary status. However, patients who are overfed, that is, those who are receiving twice the basal energy expenditure, often produce excessive CO_2. Critically ill patients with respiratory failure can be fed 25 to 30 kcal/kg/day (105–126 kJ/kg/day) as they recover.[28,99] In patients with borderline ventilatory status, the nutritional regimen should be monitored closely to prevent excessive CO_2 production, and increasing the proportion of nonprotein calories as fat relative to the amount of carbohydrates may be beneficial.[87]

A concentrated enteral formula (Oxepa) has been marketed specifically for critically ill patients on mechanical ventilation and studied in patients with acute lung injury and ARDS. The macronutrient composition of Oxepa is similar to that of the other specialized pulmonary enteral formulas, with 55% of the nonprotein caloric content being from fat. However, the lipid blend in the formula was altered to decrease the production of proinflammatory cytokines by including eicosapentaenoic acid from fish oil and γ-linolenic acid from borage oil. Nutrients with antioxidant properties (i.e., vitamin C, vitamin E, and β-carotene) also are included in this product.[100,101] This formulation is associated with improved respiratory mechanics, decreased ventilatory dependence, and an attenuation of the inflammatory state in those with acute lung injury/ARDS. In one study of patients with a diagnosis of ARDS, as well as severe sepsis/septic shock, the use of this formulation resulted in a statistically significant decrease in 28-day mortality. These results have led ASPEN and the Society of Critical Care Medicine to recommend the preferential use of this product in critically ill patients with severe acute lung injury or ARDS.[28,26,99]

In general, patients with ARDS who need PN may receive nonprotein calories administered within the following ranges: 60% to 70% carbohydrate and 30% to 40% lipid. A reasonable protein dose is 1 to 1.5 g/kg/day for the patient with stable COPD. Patients who are mechanically ventilated with superimposed illness may require higher doses of protein (1.5–2.5 g/kg/day). Figure 153–4 illustrates an approach to the patient with acute respiratory failure requiring PN or EN support based on recommendations from ASPEN and ESPEN.[28,99] Table 153–1 includes an empirical PN formula for the patient with respiratory failure.

CLINICAL CONTROVERSY

There are conflicting data on the safety of administration of lipid emulsions to patients with ARDS. Discrepancies in trial data may be due to the use of differing lipid infusion rates and duration, as well as preexisting lung function.

Alternative Drug Therapies

Enteral formulas (e.g., Pulmocare) marketed for use specifically in patients with pulmonary disease are commercially available. These products contain a higher percentage of nonprotein calories as fat (>50%). Several studies evaluated the use of these high-fat/low-carbohydrate products in patients with COPD and acute respiratory failure, and generally the outcomes were favorable.[93] These specialized pulmonary EN products are calorically dense (1.5 kcal/mL [6.3 kJ/mL]), which may be helpful for patients with severe ARDS or pulmonary edema, as well as others who may require fluid restriction. There are no data, however, indicating that these formulas result in improved clinical outcomes in patients with pulmonary failure. Nonspecialty formulations and high-concentration formulations for those requiring fluid restriction are still preferred for routine use.[28,90]

Recombinant human growth hormone is known to induce general muscle growth, lipolysis, and protein anabolism. When used as adjunctive therapy to EN support, patients with COPD have shown improvements in lean body mass, maximal inspiratory pressure, and exercise capacity. The benefit of rhGH is debatable, with trials having differing results, but body mass and fat-free mass typically increase in patients after use of this product. The benefit in pulmonary patients as shown by improvements in respiratory muscle function and pulmonary function testing is questionable. The effects of anabolic steroids also have been evaluated for use in COPD as an adjunct to nutritional intervention. Patients on anabolic steroids tend to have larger increases in fat-free mass and

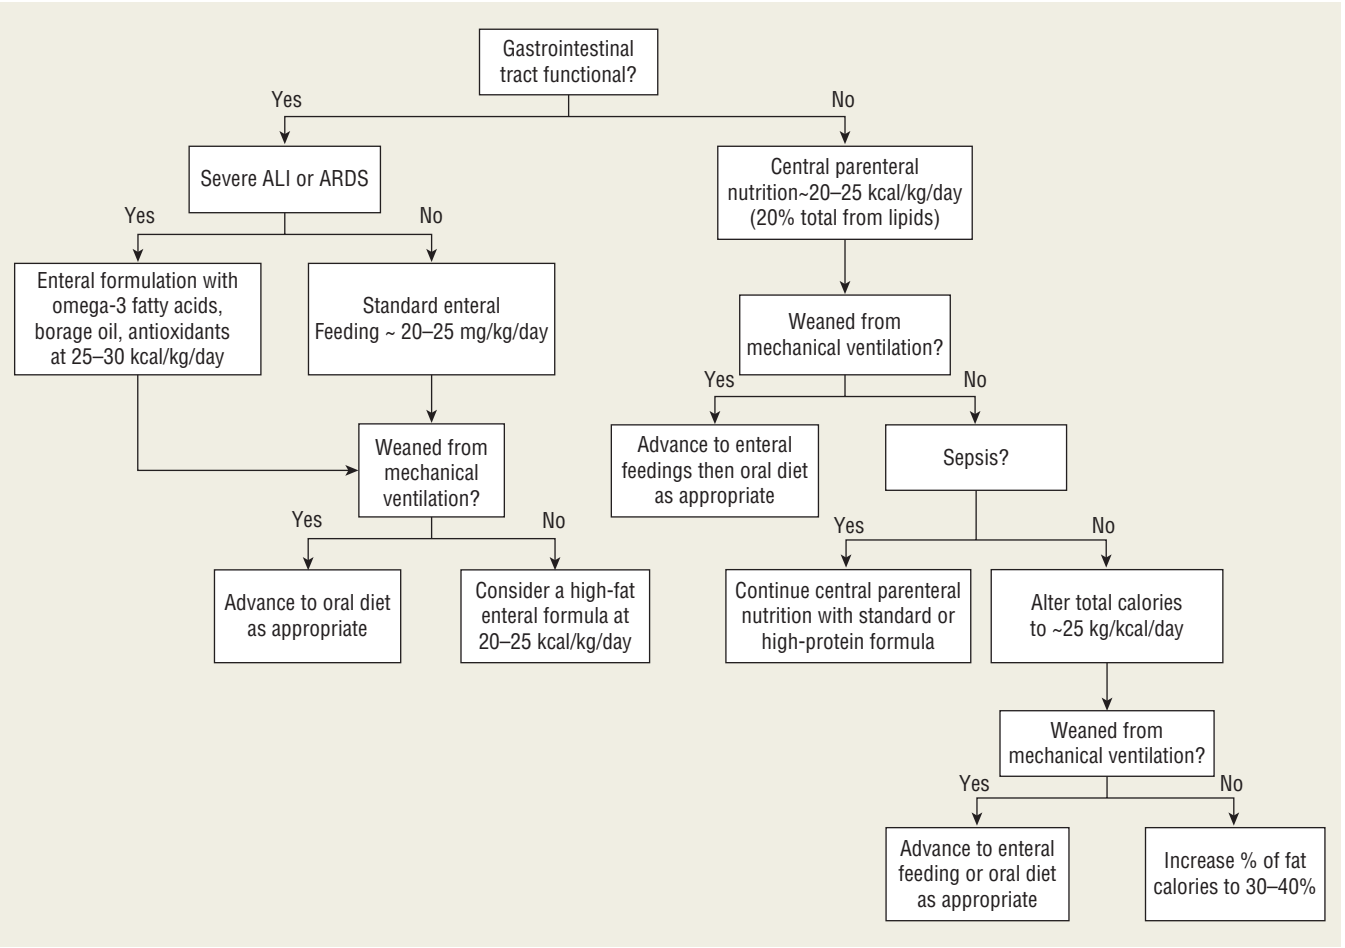

FIGURE 153-4. An algorithmic approach to nutritional support for the patient with acute respiratory failure. Energy intake of 20 to 25 kcal/kg/day is equivalent to 84 to 105 kJ/kg/day. Energy intake of 25 to 30 kcal/kg/day is equivalent to 105 to 126 kJ/kg/day.

more favorable distributions in weight gain in comparison to interventional nutrition alone.[102] More studies are needed to characterize the benefits of rhGH, as well as anabolic steroids, and to determine the risk-to-benefit ratio.

PHARMACOECONOMIC CONSIDERATIONS

There are no data available that establish the pharmacoeconomic value of nutrition support in patients with respiratory failure.

EVALUATION OF THERAPEUTIC OUTCOMES

Because pulmonary patients are at extreme risk of malnutrition, monitoring the progression of the patient on interventional nutrition is extremely important. Therapeutic monitoring of pulmonary patients on PN for metabolic complications should follow the guidelines presented in Chapter 151. Patients on EN should be monitored as described in Chapter 152. Pulmonary status must be assessed for any changes, especially with the initiation of higher carbohydrate formulas of PN or EN. Weights should be charted frequently, and it is important that prealbumin concentrations are assessed weekly for hospitalized patients. It is important to remember that patients with ARDS in critical care units are prone to fluid overload from medication administration, so careful monitoring of intake and output is necessary to avoid pulmonary edema. Nutritional status should be monitored every 4 to 6 months for those patients with stable pulmonary disease and COPD.

QUALITY-OF-LIFE ISSUES

Patients with COPD who have fat-free mass depletion experience decreased disease-specific QOL when compared with control patients.[103] Decreased activity and exercise capacity are associated with low fat-free mass, which appears to be related to decreasing patient satisfaction.[86] Dyspnea also has been shown to be correlated strongly with health-related QOL in patients with decreased fat-free mass and may be the strongest predictor of patient satisfaction. Nutrition support supplementation has not been shown to definitively improve QOL in COPD. In one study, however, patients who received a diet of 1.3 × REE stated that they had an improved feeling of control over their COPD, whereas those fed 1.7 × REE did not report any improvement in QOL.[92]

CHAPTER 154

Obesity

JUDY T. CHEN, AMY HECK SHEEHAN, JACK A. YANOVSKI, AND KARIM ANTON CALIS

KEY CONCEPTS

1. Two clinical measures of excess body fat, regardless of sex, are the body mass index (BMI) and the waist circumference (WC). BMI and WC provide a better assessment of total body fat than weight alone and are independent predictors of obesity-related disease risk.
2. Excessive central adiposity increases risk for development of type 2 diabetes, hypertension, and dyslipidemia.
3. Weight loss of as little as 5% of total body weight can significantly improve blood pressure, lipid levels, and glucose tolerance in overweight and obese patients. Sustained, large weight losses (i.e., after bariatric surgery) are associated with long-term improvements in many of the complications associated with obesity and a lower risk of both myocardial infarction and death.
4. Pharmacotherapy may be considered in patients with a BMI ≥30 kg/m^2 and/or a WC ≥40 inches (≥ 102 cm) for men or 35 inches (89 cm) for women, or BMI of 27 to 30 kg/m^2 with concurrent risk factors if 6 months of diet, exercise, and behavioral modification fail to achieve weight loss.
5. There is a high probability of weight regain when obesity pharmacotherapy is discontinued.
6. The FDA does not regulate labeling of herbal and food supplement diet agents, and content is not guaranteed.

It is now estimated that more than 140 million or approximately two out of every three adults are overweight or obese in the United States.[1] Additionally, the number of children and adolescents who are overweight has been increasing at an alarming rate in the last 40 years,[2] with one out of every three adolescents currently considered overweight or obese.[3] Based on the national trend, this epidemic is projected to affect ~80% of the U.S. adults by 2020, and the prevalence of overweight among children is expected to double by 2030.[4] The presence of obesity and overweight is associated with a significantly increased risk for the development of many diseases (Table 154–1),[5–18] poorer outcomes of comorbid disease states, and increased healthcare costs. Prospective cohort studies show that overall mortality parallels increases in adiposity.[19,20] The evidence is strongest for middle-aged adults. In older individuals, excess body weight and adiposity increase the risk of death, but the degree of impact diminishes with age.[19,20] Annually, up to 35% of Americans have actively resolved to lose weight, spending between $30 billion and $50 billion on such attempts.[21] As of 2003, it was estimated that overweight and obesity account for 5% to 7% of total medical expenditures in the United States, and the sum of direct and indirect costs approaches $150 billion annually.[21] The inclusion of several aggressive Healthy People 2020 goals stimulated national initiatives to reverse the obesity epidemic through implementation of prevention strategies, consensus guidelines, and best practices.[22–26] This chapter reviews the epidemiology, pathophysiology, and therapeutic approaches for the management of obesity. Although nonpharmacologic treatment modalities are discussed, the pharmacotherapy of obesity is highlighted, and the role of pharmacotherapy relative to the other therapeutic options is critically reviewed.[27–30]

The complete chapter, learning objectives, and other resources can be found at **www.pharmacotherapyonline.com**.

EPIDEMIOLOGY

Obesity is increasing in prevalence in the United States. The National Health and Nutrition Examination Survey (NHANES) II data (1976–1980) estimated the prevalence of obese adults in the United States at 15%.[2] During NHANES 1999–2000, the prevalence had increased twofold to 30.9%,[2] and by 2006, obesity affected 35.1% of the adult population,[1] making the prevention of obesity a public health priority.[23] This is further emphasized by the continued pursuit of safe and effective long-term therapies for obesity. Existing evidence consistently reports children who are overweight are at least twice as likely to remain overweight as adults when compared with normal-weight children.[31] In particular, obese adolescents have a higher risk of obesity that persists into adulthood that is associated with significant affects on psychological and physical health. Therefore, childhood and early adulthood are critical intervention periods for prevention of obesity in the future. The prevalence of obesity varies by sex among racial and ethnic minorities within the United States.[2] The highest prevalence is observed among non-Hispanic black women (52.9% obese and 13.7% with extreme obesity) compared with values of 37.2% and 5.9% of non-Hispanic black men, respectively.[32] This gender disparity is also associated with the level of parental education. Young black women from the lowest-educated families are at greater risk of obesity compared with young black men.[33] The prevalence of obesity also increases with age, reaching a maximum by the eighth decade.[2] After the age of 80, the prevalence falls progressively for both genders. Socioeconomic status clearly affects the prevalence

TABLE 154-1 Conditions More Prevalent in Obese Populations[5–18]

Cancer
- Breast cancer (postmenopausal)
- Colorectal cancer
- Gallbladder cancer
- Endometrial cancer
- Esophageal carcinoma
- Hepatic cancer
- Kidney cancer
- Ovarian cancer
- Pancreatic cancer
- Prostate cancer
- Rectal cancer

Cardiovascular
- Atrial fibrillation
- Cerebral vascular accidents
- Congestive heart failure
- Coronary artery disease
- Cor pulmonale
- Hypertension
- Left ventricular hypertrophy
- Myocardial infarction
- Peripheral vascular disease
- Peripheral venous insufficiency
- Pulmonary embolism
- Thrombophlebitis
- Varicose veins

Dermatologic
- Acanthosis nigricans
- Cellulitis
- Intertrigo, carbuncles
- Lymphedema
- Skin tags
- Status pigmentation of legs
- Striae distensae (stretch marks)
- Psoriasis (women)

Endocrine/reproductive
- Amenorrhea/menstrual disorders
- Congenital anomalies
- Fetal abnormalities
- Hirsutism
- Hypogonadism (male)
- Infertility
- Polycystic ovarian syndrome/androgenicity
- Pregnancy complications
- Sexual dysfunction

Gastrointestinal
- Cholelithiasis
- Gastroesophageal reflux disease
- Hepatic cirrhosis
- Hernias
- Nonalcoholic fatty liver disease

Genitourinary
- Chronic kidney disease
- Increased serum urate
- End-stage renal disease
- Obesity-related glomerulopathy
- Urinary stress incontinence

Metabolic
- Diabetes mellitus
- Hyperlipidemia
- Hyperinsulinemia
- Hypertriglyceridemia
- Low high-density lipoprotein
- Impaired glucose tolerance
- Metabolic syndrome

Musculoskeletal
- Degenerative joint disease
- Diffuse idiopathic skeletal hyperostosis
- Disc disease
- Gait disturbance
- Gout and hyperuricemia
- Fibromyalgia
- Immobility
- Low back pain/back strain
- Osteoarthritis (knee, hips, ankles, feet)
- Plantar fasciitis

Neurologic
- Carpal tunnel syndrome
- Idiopathic intracranial hypertension
- Meralgia parethetica
- Pseudotumor cerebri
- Stroke

Oral health
- Dental caries
- Loss of teeth
- Periodontitis
- Xerostomia

Psychological
- Affective disorders
- Body image disturbance
- Depression
- Eating disorders
- Low self-esteem
- Social stigmatization

Respiratory
- Asthma
- Chronic obstructive pulmonary disease
- Dyspnea
- Hypoventilation syndrome
- Obstructive sleep apnea
- Pickwickian syndrome
- Pneumonia
- Pulmonary hypertension
- Venous thromboembolism

of obesity among non-Hispanic white adults; a strong inverse association is observed among non-Hispanic white women from lower socioeconomic classes.[2] Educational achievement, which is linked to socioeconomic status, is also correlated with the fraction of people who are overweight; the prevalence of overweight is greatest in those with less than a high school education.

ETIOLOGY

Obesity occurs when there is an imbalance between energy intake and energy expenditure over time, resulting in increased energy storage. The specific etiology for this imbalance in the vast majority of individuals is multifactorial, with genetic and environmental factors contributing to various degrees. In a small minority of individuals, excess weight may be attributed to an underlying medical condition or an unintended effect of a medication.

GENETIC INFLUENCES

Observational studies in humans and experimental studies in animal models have demonstrated the strong role of genetics in determining both obesity and distribution of body fat. In some individuals, genetic factors are the primary determinants of obesity, whereas in others, the obesity may be caused primarily by environmental factors. The genetic contribution to the actual variance in BMI and body fat distribution is estimated to be between 50% and 80%.[34] The increase in the prevalence of obesity that has taken place in the United States over the past 40 years is without doubt the result of alterations in our environment.

The role of genetic influences in the development of obesity is an area of extensive research. A number of single-gene mutations producing extreme obesity have been identified, but such mutations are rare and account for an extremely small number of the total cases of obesity.[35] Some common alleles, for instance, the rs9939609 obesity-risk allele in the *FTO* (fat mass and obesity associated) gene that is found in almost 70% of people, increases BMI by about 2 kg/m^2.[36] The total number and identity of contributing genes are still being determined, as is the means by which the many potential "obesity" genes interact with each other, and with the environment, to produce the obesity phenotype. The Human Obesity Gene Map Database provides a repository listing of candidate genes that may be associated with obesity.[37]

ENVIRONMENTAL FACTORS

Many of the societal changes associated with economic development over the past 30 years have been implicated as potential causes for the increase in the prevalence of obesity. The comforts of modern life in Western civilizations have ultimately resulted in reduced physical activity, in combination with an abundant food supply.[38] Advances in technology and automation have resulted in relatively sedentary lifestyles during both work and leisure time for most individuals. At the same time, there has been a significant increase in the availability and portion size of high-fat foods, which are aggressively marketed and are often more convenient and less expensive than healthier alternatives. This modern environment has been described by some as "obesogenic," as it is likely to result in a state of positive energy balance in many individuals (Fig. 154–1).[39] Obesity has also been reported more frequently among individuals within close social networks (e.g., siblings, spouses, and friends), with a person's risk of becoming obese increasing significantly if a friend in his or her social network is obese.[40] Finally, it should be noted that cultural factors, socioeconomic status, and religious beliefs may influence eating habits and body weights.

MEDICAL CONDITIONS

Occasionally, patients present with obesity secondary to an identifiable medical condition. Conditions associated with weight gain include iatrogenic and idiopathic Cushing disease, growth hormone deficiency, insulinoma, leptin deficiency, and various psychiatric disorders, such as depression, binge-eating disorder, and schizophrenia. Hypothyroidism is often included in this list, but it mostly causes fluid retention (myxedema) and is generally not a cause of significant obesity. Genetic syndromes that have obesity as a major component are extremely rare: Prader-Willi, WAGR (Wilms tumor, Aniridia, Genitourinary abnormalities or gonadoblastoma, and

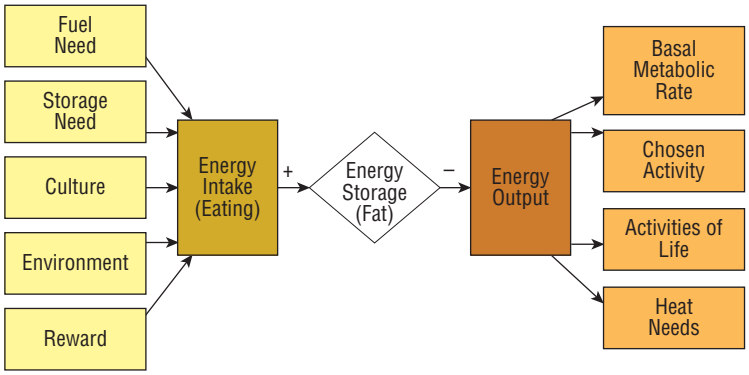

FIGURE 154-1. Net energy stores are determined by various inputs and outputs. Simply stated, obesity occurs when there is an imbalance between energy intake and expenditure.

mental Retardation), Simpson-Goabi-Behmel, Cohen, Bardet-Biedl, Carpenter, Börjeson, and Wilson-Turner. The clinician evaluating a patient for obesity needs to be aware of these potential conditions. The physical examination of obese patients always should include an assessment for secondary causes of obesity, including genetic syndromes.

MEDICATIONS

An increasing number of medications are associated with unintended weight gain.[41] These include several anticonvulsants (i.e., carbamazepine, gabapentin, pregabalin, and valproic acid), antidepressants (i.e., mirtazapine and tricyclic antidepressants), atypical antipsychotics (e.g., clozapine, olanzapine, quetiepine, and risperidone), conventional antipsychotics (e.g., haloperidol), and hormones (e.g., corticosteroids, insulin, and medroxyprogesterone). Although the pharmacologic mechanism responsible for weight gain is usually drug specific, in most cases the exact cause has not been determined.

PATHOPHYSIOLOGY

The pathophysiology of obesity involves numerous factors that regulate appetite, energy storage, and energy expenditure. Disturbance of these homeostatic functions results in an imbalance between energy intake and energy expenditure.

APPETITE

Human appetite is a complex process that is the net result of many inputs within a neural network involving principally the hypothalamus, limbic system, brainstem, hippocampus, and elements of the cortex.[42] Within this neural network, many neurotransmitters and neuropeptides have been identified that can stimulate or depress the brain's appetite network and thereby affect total caloric intake.

Biogenic Amines

The first receptor systems found to alter food intake in animals and humans were the biogenic amines. These neurotransmitters are the foundation from which the most robust pharmacologic interventions for obesity have been developed. Serotonin, also known as 5-hydroxytryptamine (5-HT), and cells known to respond to 5-HT are found throughout the central nervous system and the periphery. Currently, two major noradrenergic receptor subtypes are recognized (α and β), each with multiple subtypes. Histamine and dopamine also demonstrate multiple receptor subtypes, but their role in the regulation of human eating behaviors and food intake is less well documented. Direct stimulation of 5-HT_{1A} and noradrenergic α_2-receptors will increase food intake, whereas the opposite occurs with 5-HT_{2C} and noradrenergic α_1- or β_2-receptor activation. Table 154–2 summarizes the major effects of direct receptor stimulation, inhibition, or changes in synaptic cleft amine concentrations on food intake.

Neuropeptides

Many neuropeptides that influence appetite exert their effects within the hypothalamus. Thus, in the last several years research has focused on the neural projection between parts of the hypothalamus and the arcuate nucleus sending signals to the paraventricular nucleus. The key peptides in this projection are currently thought to be neuropeptide Y and α-melanocyte–stimulating hormone, which engages melanocortin receptors in the paraventricular nucleus. Neuropeptide Y is the most potent known stimulator of eating, and α-melanocyte–stimulating hormone action at the melanocortin 3 and 4 receptors is one of the crucial inhibitors of eating.[42,43]

TABLE 154-2 Effects of Various Neurotransmitters, Receptors, and Peptides on Food Intake

Anatomic Region	Increased Eating	Decreased Eating
Arcuate nucleus of hypothalamus	Ghrelin	Leptin Insulin Glucagon-like peptide-1 Peptide YY
Paraventricular nucleus of hypothalamus	Neuropeptide Y Agouti-related protein Opioids (especially mu) Galanin	Melanocyte stimulating hormone (melanocortin) Corticotropin-releasing hormone Cholecystokinin
Lateral hypothalamus	Orexin Melanocyte concentration hormone	
Hypothalamus	Norepinephrine α_2 Serotonin 5-HT_{1A}	Norepinephrine α_1 and β_2 Serotonin 5-HT_{1B} and 5-HT_{2C} Histamine H_1 and H_3
Nucleus accumbens	Dopamine	
Amygdala	Opioids (especially mu)	
Brainstem (Hindbrain)	Neuropeptide Y Agouti-related protein Opioids (especially mu)	Leptin Melanocyte stimulating hormone (melanocortin) Cholecystokinin (CCK)
Vagus nerve	Ghrelin	Leptin Cholecystokinin Glucagon-like peptide-1 Peptide YY
Various or undetermined	Cannabinoid CB_1	Dopamine D_1 and D_2

Adapted from Dhillo WS. Appetite regulation: An overview. Thyroid 2007;17(5):433–445; and Valassi E, Scacchi M, Cavagnini F. Neuroendocrine control of food intake. Nutr Metab Cardiovasc Dis 2008;18(2):158–168.

The lateral hypothalamus has been referred to as the "hunger" center within the brain. The most prominent of these lateral hypothalamic peptides, orexin, increases food intake stimuli within the lateral hypothalamus.[42] Another important neuropeptide stimulator of eating that principally originates in the lateral hypothalamus is melanocyte-concentrating hormone. Neurons in the lateral hypothalamus use orexin and melanocyte-concentrating hormone to communicate with other neurons throughout the brain and thereby affect a number of functions beyond appetite.[42,43] Table 154–2 summarizes the major effects of various neuropeptides on food intake. Although hunger and satiety functions are thought to be primarily regulated by the hypothalamus, humans eat in response to a broad set of stimuli, such as reward, pleasure, learning, and memory.

Peripheral Appetite–Related Signals to the Brain

Peripheral appetite signals also dramatically affect food intake. Leptin, a hormone that is secreted by adipose cells, acts on the arcuate nucleus of the hypothalamus and elsewhere in the brain to decrease appetite and increase energy expenditure.[44,45] Studies conducted in leptin-deficient mice and humans revealed that exogenous leptin administration produced significant weight loss. However, recombinant leptin replacement therapy in obese humans who are not leptin deficient has not proved successful, as obese humans appear to be leptin resistant. Figure 154–2 shows the peripheral link that leptin appears to provide in signaling the central nervous system about the status of fat cell mass. Leptin also has been found to regulate various functions outside the central nervous system, including insulin and glucocorticoid secretion, reproduction, and glucose transport within the small intestine.[44]

Other peripheral signals important to the brain's processing of appetite include several gut hormones, notably those released by the intestine in response to passage of digesting food such as glucagon-related peptide-1, oxyntomodulin, and peptide YY.[46] Each of these hormonal signals suppresses eating in animals and humans. Glucagon-related peptide-1 has other effects, most importantly as an incretin, which facilitates release of insulin by pancreatic β cells in response to meal-related glucose. Ghrelin, another important gut hormone that is released from the distal stomach and duodenum, stimulates appetite.

An understanding of the relationships between the brain, its many neurotransmitters and neuropeptides, environmental stimulation of brain activities, and other hormones is still evolving. Dysfunction in any of these factors can upset the homeostatic functions regulating energy balance. Exogenous manipulation of neural signals and associated peripheral hormones may provide future pharmacotherapeutic approaches to obesity management.

ENERGY BALANCE

The net balance of energy ingested relative to energy expended by an individual over time determines the degree of obesity (see Fig. 154–1). An individual's metabolic rate is the single largest determinant of energy expenditure. Resting energy expenditure (REE) is defined as the energy expended by a person at rest under conditions of thermal neutrality. Basal metabolic rate (BMR) is defined as the REE measured soon after awakening in the morning, at least 12 hours after the last meal. Metabolic rate increases after eating, based on the size and composition of the meal. It reaches a maximum approximately 1 hour after the meal is consumed and returns to basal levels 4 hours after the meal. This increase in metabolic rate is known as the *thermogenic effect of food*. The REE measures the energy costs of the wakeful state and may include the residual thermogenic effect of a previous meal; it is thus usually higher than metabolic rate measured during quiet sleep. Physical activity is the other major factor that affects total energy expenditure and is the most variable component.

PERIPHERAL STORAGE AND THERMOGENESIS

There are two major types of adipose tissue, white and brown. The primary function of white adipose tissue is lipid manufacture, storage, and release. Brown adipose tissue, once believed to be found only in infants, is now recognized to exist in most adults.[47] It is more commonly identified in lean than obese individuals, but its importance for human obesity remains unclear. Lipid storage occurs in response to insulin, whereas lipid release is seen during periods of calorie restriction. Brown adipose tissue is notable for its ability to dissipate energy via uncoupled mitochondrial respiration.[48]

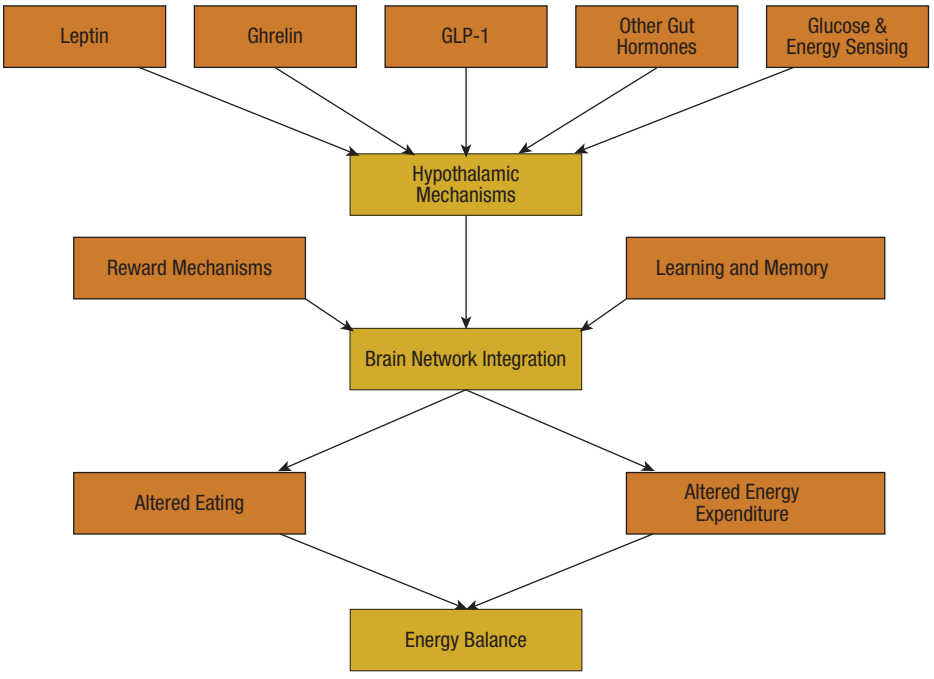

FIGURE 154-2. Intrinsic hypothalamic hunger and satiety mechanisms are modified by input from fat tissue via leptin, the gut via ghrelin, glucagon-like peptide-1 (GLP-1) and other hormones, and also by direct sensing of prevailing glucose and other energy signals. The hypothalamus generates signals that are integrated within brain networks, which are also receiving signals and food hedonics, learning and memory, and other motivations. The brain network effects change in energy balance by modifying food intake and energy expenditure.

Both white and brown adipose tissues are highly innervated by the sympathetic nervous system, and adrenergic stimulation via β-adrenergic receptors (β_1, β_2, and β_3) is known to activate lipolysis in fat cells as well as increase energy expenditure in adipose tissue and skeletal muscle. Genetic polymorphisms have been identified in both the β_2- and β_3-receptor systems that are associated with obesity or excess weight gain.[49] Thus, genetic susceptibility for excess weight status may in part be related to adrenergic dysfunction.

CLINICAL PRESENTATION

Although obesity is readily apparent, most obese patients seek healthcare only when obesity-associated comorbidities become problematic. A consistent and reproducible description of weight status is essential in the diagnosis and management of obesity. Evidence-based guidelines issued by many groups, notably the World Health Organization and the National Institutes of Health (NIH), have established a stratification of weight excess based on associated medical risks.[50] The first increment of excess weight is termed *overweight,* with the term *obesity* reserved for the higher levels of weight excess. These levels of excess weight are defined on the basis of body mass index (BMI), a measure of total body weight relative to height. Those with a BMI of 18.5 to 24.9 are considered to have "normal" weight; the terms *overweight, obese,* and *severely obese* are reserved for those with a BMI of 25 to 29.9, 30 to 39.9, and 40 and over, respectively. Using metric units, BMI (kg/m^2) is defined as weight in kilograms divided by height in meters squared (kg/m^2). Using pounds and inches, BMI (lb/inch^2) is estimated as (weight [lb]/height [inches^2]) × 703. Because BMI may overestimate the degree of excess body fat in some clinical situations (e.g., edematous states, extreme muscularity, muscle wasting, and short stature), the assessment of body composition in such cases often requires clinical judgment.

1 BMI is an acceptable measure of obesity and is the practical method of defining obesity in the clinic and epidemiologic studies; however, it does not always correspond to excess fat. There are well-established differences in the relationship between BMI and obesity-related risks among disparate racial and ethnic groups. For examples, BMI overestimates adiposity among non-Hispanic blacks and underestimates risk among Asians.[51–54] Ideally, obesity refers to a state of excess body fat as determined by measures of adiposity. Direct ways to assess fat-free body mass include skinfold thickness, body density using underwater body weight, bioelectric impedance and conductivity, dual-energy radiographic absorptiometry, computed tomography (CT), and magnetic resonance imaging (MRI).[55] These measurement techniques that determine body fat directly are currently too expensive and time-consuming to be used routinely in the clinical setting. Furthermore, all fat is not equal in its danger to health. Superficial subcutaneous fat has a weak association with metabolic markers of insulin production, release, and resistance, whereas deep subcutaneous fat demonstrates a strong relationship with insulin resistance.[48] Central obesity reflects high levels of intraabdominal or visceral fat, and this pattern of obesity is associated with an increased propensity for the development of hypertension, dyslipidemia, type 2 diabetes, and cardiovascular disease (sometimes referred to as the "metabolic syndrome"). Thus, in addition to the absolute excess fat mass, the distribution of this fat regionally in the body has important clinical effects. Intraabdominal fat is best estimated by imaging techniques such as CT and MRI but can be estimated through measurement of the waist circumference (WC). Clinically, WC is the narrowest circumference measured in the area between the last rib and the top of the iliac crest.[56] The current definition for high-risk WC is greater than 40 inches (102 cm) in men and greater than 35 inches (89 cm) in women.[56] Notably, epidemiologic studies demonstrate that WC adds little in terms of risk prediction once a patient's BMI reaches 35 kg/m^2. Thus, routine determination of WC should be implemented in those with BMIs between 25 and 34.9 kg/m^2.

2 Although BMI and WC are related, each measure independently predicts disease risk. Both measurements should be assessed and monitored during therapy for obesity.[57] The risks for development of type 2 diabetes, hypertension, or cardiovascular disease at various stages of obesity based on BMI or WC are outlined in Table 154–3. Note that increased WC confers increased risk even in normal-weight individuals.

TABLE 154-3 Classification of Overweight and Obesity by Body Mass Index (BMI), Waist Circumference, and Associated Disease Risk

			Disease Risk[a] (Relative to Normal Weight and Waist Circumference)	
	BMI (kg/m^2)	Obesity Class	Men ≤ 40 inches Women ≤ 35 inches	Men > 40 inches Women > 35 inches
Underweight	<18.5		–	–
Normal weight[b]	18.5–24.9		–	High
Overweight	25.0–29.9		Increased	High
Obesity	30.0–34.9	I	High	Very high
	35.0–39.9	II	Very high	Very high
Extreme obesity	≥40	III	Extremely high	Extremely high

[a]Disease risk for type 2 diabetes, hypertension, and cardiovascular disease.
[b]Increased waist circumference can also be a marker for increased risk even in persons of normal weight.

National Institutes of Health, National Heart, Lung and Blood Institute, http://www.nhlbi.nih.gov/guidelines/obesity/ob_home.htm.

COMORBIDITIES

Although overall mortality is not increased among those classified as overweight, those who are obese have serious health risks and increased mortality,[57] particularly adults with BMI greater than 35 kg/m^2.[58] Substantial reductions in life expectancy have been predicted in adults with BMI greater than 35 kg/m^2.[58] Further reduction in life span has been observed in obese individuals who are current or former smokers.[58] Several disease states and/or conditions are more prevalent in obese patients (see Table 154–1).[5–18] Increased body fat, increased total body weight, and a central distribution of body fat all are associated with an increased incidence of mortality, primarily as a result of cardiovascular disease. Hypertension, hyperlipidemia, insulin resistance, and glucose intolerance are all known cardiac risk factors that tend to cluster in obese individuals. Therefore, the obese individual is exposed to multiple risk factors. Some of the earliest studies from Framingham have confirmed the relationship between obesity and increased risk of stroke and coronary heart disease in both men and women.[59] Blood pressure frequently is elevated in obese individuals and may in part explain the increased incidence of stroke and cardiovascular disease observed with obesity. Hypertension in lean individuals is associated with concentric cardiac hypertrophy as a consequence of an increased afterload, which increases the risk of cardiac ischemia. In contrast, eccentric dilation is observed in obesity, leading to an increased volume load. This dilated cardiomyopathy is associated with a reduction in ventricular ejection fraction and a high-output cardiac state.

The combination of obesity and hypertension is associated with thickening of the ventricular wall, ischemia, and increased heart volume. This leads more rapidly to heart failure, an association that has been recognized for more than 2 decades.[60,61] Alterations in pulmonary function are common in patients with obesity. Sleep apnea, which is more common in men, is a significant and costly condition that is associated with increased morbidity and mortality in the obese.[60,61] The exact mechanism by which obesity leads to sleep apnea is unknown, but weight loss often results in significant and sometimes dramatic improvements in the condition.

Diabetes mellitus and impaired glucose tolerance are associated with insulin resistance and obesity. As insulin response becomes impaired, the pancreatic β cells respond by increasing insulin production and release, resulting in a state of relative hyperinsulinemia. Although hyperinsulinemia is known to be associated with an increased risk of cardiovascular disease, it is not known whether the increased insulin levels contribute directly to cardiac disease, or if they are a marker for the underlying defect of insulin resistance and glucose intolerance. Insulin resistance, in turn, also frequently leads to impaired lipid metabolism (increased cholesterol, increased triglycerides, and low circulating high-density lipoprotein) and hypertension. As with cardiovascular disease, central obesity is an important factor in determining the risk of developing type 2 diabetes.

Osteoarthritis in weight-bearing joints, such as the knees, may be related directly to the mechanical effects of excess body weight and the resulting forces exerted on these joint surfaces. The increase of osteoarthritis in non-weight-bearing joints, however, suggests that obesity may lead to altered cartilage, collagen, and even bone metabolism.[8] Increasing evidence has suggested proinflammatory adipocytokines, such as tumor necrosis factor-α and leptin, may play an important role in the metabolic influence of overweight on osteoarthritis. Osteoarthritis and its symptoms, such as pain, are a significant barrier to physical activity and a key impediment to sustained weight loss.

Obesity affects the human reproductive system in a number of ways. Obesity is associated with earlier menarche in girls and hyperandrogenism, hirsutism, and anovulatory menstrual cycles in women. In some women, this disorder manifests as overt polycystic ovary syndrome, a condition in which insulin resistance is common.[62] Weight loss therapy with insulin-sensitizing drugs, such as the thiazolidinediones and biguanides, has been shown to restore normal ovulation in some women.[62] These observations suggest that insulin resistance plays a part in the causation of polycystic ovary syndrome associated with obesity.

TREATMENT

DESIRED OUTCOME

Weight management is commonly considered successful when a predefined amount of weight has been lost such that a final goal is achieved. However, desired outcomes are fully dependent on the clinical situation. Success may also include end points of decreasing the rate of weight gain or maintaining a weight-neutral status. A significant number of web-based resources for supporting both patient and practitioner weight management activities are available.[23,24,56]

GENERAL APPROACH TO TREATMENT

The success of obesity therapy has been measured most often as weight loss over a defined study period of up to 4 years in duration. Successful obesity treatment plans have incorporated an integrated dietary intervention, exercise, behavior modification (with or without pharmacologic therapy), and/or surgical intervention. Specific weight goals should be established that are consistent with medical needs and the patient's personal desire. For most obese patients, a weight loss goal of 5% to 10% of initial weight is reasonable. Patients should not be allowed to attain abnormally low body weight (i.e., less than their estimated ideal body weight).

Patients seeking help for obesity do so for many reasons, including improvement in their quality of life, a reduction in associated morbidity, and increased life expectancy. Unfortunately, numerous individuals seek therapy for obesity primarily for cosmetic purposes and often have unrealistic goals and expectations. Aggressive marketing of weight loss programs, therapies, and diets—parallel to the fashion industry's standards of desirable body profiles—has led many individuals to set impossible goals and expectations. In some cases, these persons will go to extreme measures to achieve weight loss. Consequently, clinicians must be careful to fully discuss the risks of therapies and to clearly define the achievable benefits and magnitude of weight loss. Obese patients should be redirected away from trying to achieve an "ideal weight" to the more reasonable goals of modest (e.g., loss of 5–10% of body weight) but sustained, medically relevant weight loss. In practice, the goal has to be set based on many factors, including initial body weight, patient motivation and desire, presence of comorbid conditions, and age. For example, in patients with diabetes, even modest weight loss can improve glucose control and may reduce mortality,[63–66] yet in individuals with osteoarthritis, significantly more weight reduction may be required to improve symptoms. Indeed, dietary modification and exercise have been shown to ameliorate hyperglycemia, hyperlipidemia, and hypertension with weight loss of less than 5% of initial body weight. These data emphasize the importance of defining end points and measures of success in any weight loss plan.

3 Weight loss interventions must be founded on lifestyle changes, such as a modification in eating practices, complemented by drug therapy if indicated, and in some cases surgery (Fig. 154–3). Prior to recommending any therapy, the clinician must evaluate the patient for the presence of secondary causes of obesity. If a secondary cause is suspected, then a more complete diagnostic workup and the initiation of appropriate therapy may be warranted. The next step in patient evaluation is to determine the presence and severity of other medical conditions that are either directly associated with obesity (e.g., diabetes) or that have an impact on therapeutic decision making (e.g., history of liver disease or cardiac arrhythmia). Appropriate laboratory tests to exclude and/or quantify the degree of specific conditions such as diabetes, liver dysfunction, and nephropathy should be done as indicated by the history and physical examination. Based on the outcome of this medical evaluation, the patient should be counseled on treatment options, benefits, and risks. No matter what the treatment options are, they all require significant effort on the part of the patient to change lifestyle and comply with the management plan. If the patient is not yet ready to meet these expectations, then early counseling will reduce the chance of frustration for the patient, clinician, and in some cases other family members. Providing basic education can lead to a significant change in motivation and desire to lose weight and improved compliance.

The ultimate goals of treatment must be defined clearly. These goals may be absolute weight loss if obesity is present without other comorbid conditions. If improvement in blood glucose, blood cholesterol, and hypertension are primary goals, then these must be defined appropriately and may include setting target levels for low-density lipoprotein cholesterol, glycosylated hemoglobin, or blood pressure. Per current national guidelines, the recommended weight loss goal for adults is 10% of initial weight gradually over 6 months of therapy to achieve a reasonable rate of weight loss of ~1 to 2 lb (0.5–0.9 kg) per week.[6] All too often patients expect to lose

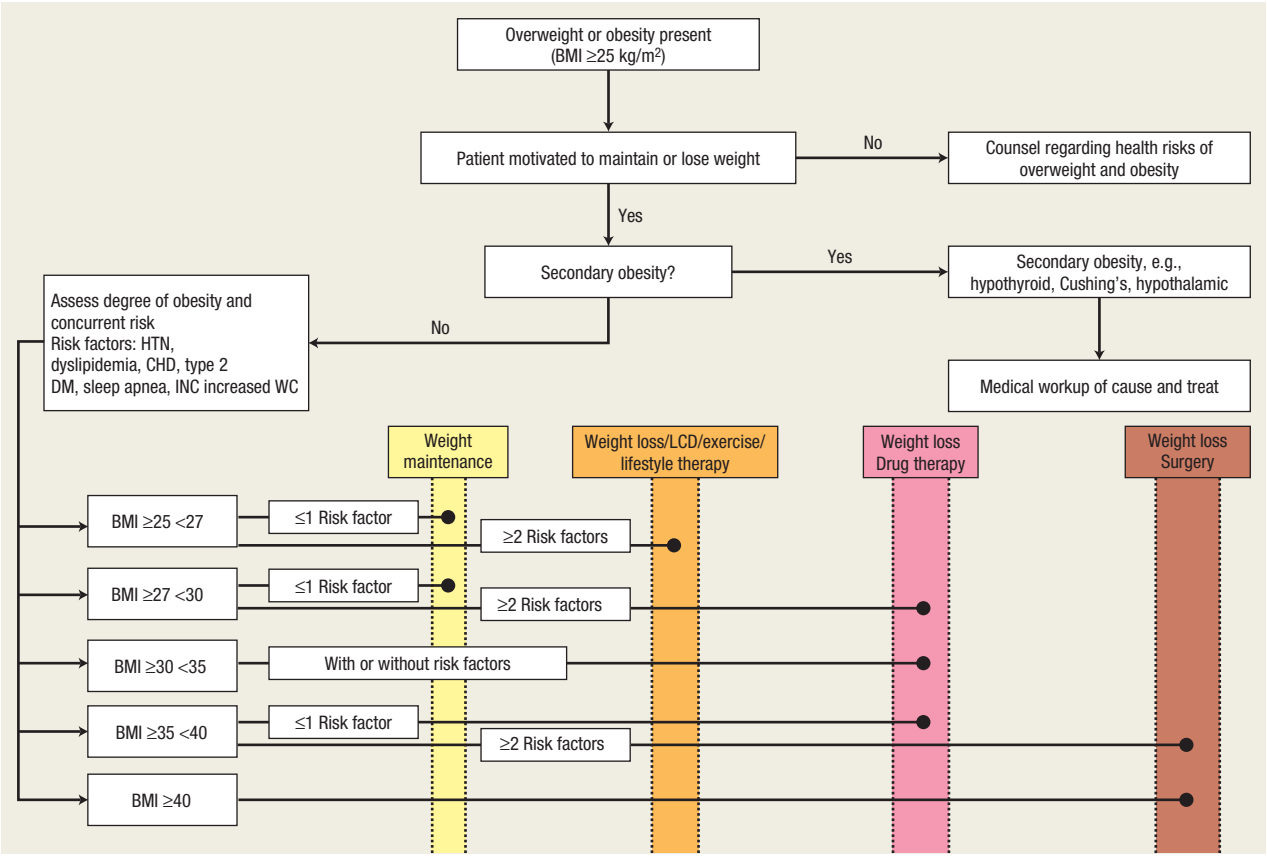

FIGURE 154-3. Pharmacotherapy treatment algorithm. Candidates for pharmacotherapy are selected on the basis of body mass index and waist circumference criteria, along with consideration of concurrent risk factors. Medication therapy is always used as an adjunct to a comprehensive weight-loss program that includes diet, exercise, and behavioral modification. CHD, coronary heart disease; DM, diabetes mellitus; HTN, hypertension; WC, waist circumference, ≥40 inches [≥102 cm] for men and ≥35 inches [≥89 cm] for women; LCD, low-calorie diet.

weight overnight, only to be disappointed. Thus, it is important to set a time course for the plan. Ultimately, lifelong therapeutic goals should consist of maintenance of reduced body weight and prevention of weight gain.

NONPHARMACOLOGIC THERAPY

Nonpharmacologic therapy including reduced caloric intake, increased physical activity, and behavioral modification is the mainstay of obesity management. This combination is recommended as first-line therapy in current evidence-based clinical guidelines for the treatment of overweight and obesity in adults set forth by the NIH.[6]

Reduced Caloric Intake

CLINICAL CONTROVERSY

Because of the popularity of diets such as Atkins's New Diet Revolution (high fat, low carbohydrate, high protein), there is extensive coverage in the media and ongoing debate in academic circles regarding the risks, benefits, and outcomes related to diets that preferentially employ macronutrient extremes (i.e., high protein vs high carbohydrate vs low fat). However, recent information suggests that macronutrient composition of the diet may not be as important as consistent adherence to reduced energy consumption.

Current adult guidelines recommend reduced caloric intake through adherence to a low-calorie diet (LCD).[6] The LCD should provide a daily caloric deficit of 500 to 1,000 (kcal) (2,093–4,486 kJ), which generally correlates to a total intake of 800 to 1,200 kcal/day (3,349–5,024 kJ/day). Severely obese individuals will require more energy, at least at the start of dietary restriction. The composition of the LCD is outlined in the Step I Diet recommended by the third report of the Expert Panel on the Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (ATP III), as shown in Table 154–4.[67] Adherence to the LCD has been shown to result in an average weight loss of 8% after 6 months.[6]

Numerous diet and nutrition plans are available to aid patients in their pursuit of weight loss. Popular diets include moderate energy-deficient plans (e.g., Weight Watchers, LEARN [Lifestyle, Exercise, Attitude, Relationships, Nutrition], and Jenny Craig), vegetarian-based plans (e.g., Ornish), and low carbohydrate plans (e.g., Zone and Atkins).[68] Short-term weight loss is significant for almost all diet plans. However, long-term weight loss and maintenance of weight loss is less promising, primarily because of difficulty with adherence. Low-carbohydrate diets have been found to achieve better weight loss than low-fat diets for the first 6 months of treatment, but similar efficacy is generally seen after 1 year.[69,70] More recently, a long-term trial reported no significant difference in the amount of weight loss achieved with adherence to various types of reduced-calorie diets.[71] Therefore, macronutrient composition of the diet may not be as important as consistent adherence to reduced energy consumption.

TABLE 154-4 Recommended Composition of the Step I Low-Calorie Diet

Nutrient	Recommended Intake
Total fat	25 to 35% or less of total calories
Saturated fat	<7% of total calories
Monounsaturated fat	≤20% of total calories
Polyunsaturated fat	≤10% of total calories
Cholesterol	<200 mg/day
Protein	~15% of total calories
Carbohydrates	50 to 60% or more of total calories
Fiber	20 to 30 g
Calories	Overall daily intake reduced by 500 to 1,000 kcal (2,094–4,186 kJ)
Total caloric intake	1,000 to 1,200 kcal/day (4,186–5,024 kJ/day) for most women; 1,200 to 1,600 kcal/day (5,024–6,698 kJ/day) for most men

Adapted from Third report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III). National Institutes of Health, National, Heart, Lung and Blood Institute, 2002.

Very low calorie diets, providing less than 800 kcal/day (3,349 kJ/day), are not recommended.[6] Although, very low calorie diets can often result in early weight loss, long-term results have been disappointing because it is difficult for individuals to maintain compliance.[72] Additionally, very low calorie diets require intensive medical monitoring and should only be used in certain situations under the supervision of an experienced clinician. Regardless of the diet program, it is clear that energy consumption must be less than energy expenditure to achieve weight loss (see Fig. 154–1). The challenge is to develop a diet plan that leads to consistent adherence by the patient and therefore sustained weight loss and/or maintenance.

Increased Physical Activity

Increased physical activity is an important component in achieving the state of greater energy expenditure than energy intake that is necessary to lose weight and maintain weight loss. When increased physical activity is attempted as monotherapy, only modest weight loss has been reported.[73] However, when it is combined with reduced calorie intake and behavior modification, it can augment weight loss and improve obesity-related comorbidities and cardiovascular risk factors.[6,73] Current recommendations suggest at least 30 minutes of moderate physical activity on most days of the week. However, 1 hour of moderate physical activity per day may be required to augment weight loss.[74] Patients should be advised to start slowly and gradually increase intensity. All obese patients should receive a medical examination prior to embarking on a physical activity program.

Behavioral Modification

Behavior modification is common to almost all weight loss interventions. The primary aim is to help patients choose lifestyles that are conducive to safe and sustained weight loss. Behavioral therapy is based on principles of human learning and thus attempts to substitute desirable behaviors for learned undesirable habits using a combination of stimulus control and reinforcement. Most such programs use self-monitoring of diet and exercise both to increase patient awareness of behavior and as a tool for the clinician to determine patient compliance as well as patient motivation.[75,76] Behavior is reinforced by techniques including behavioral contracting, social support, relapse prevention, and in some cases booster treatments. Behavioral contracts are written agreements jointly developed by the patient and ther clinician. Components of these agreements include goals of therapy, methods to achieve these goals, and rewards for achieving these goals. Social support requires the active participation of a close friend or relative who is involved in monitoring compliance and reinforcing behavior. Relapse prevention is geared to identifying high-risk situations for relapse, such as social events, and training the individual to avoid these circumstances. Eventually, the patient is trained to deal with these situations actively, such as refusing high-fat foods assertively rather than avoiding such social events.

Bariatric Surgery

Consistent with the growing obesity epidemic, the demand and popularity of bariatric surgery have increased drastically over the last 10 years. In 1998, 13,365 surgeries were performed in the United States; that number grew to approximately 200,000 in 2007.[77,78] The American Association of Clinical Endocrinologists, the Obesity Society, and the American Society for Metabolic and Bariatric Surgery issued clinical practice guidelines for the nonsurgical perioperative management of bariatric surgical patients.[78] Surgery remains the most effective intervention for the treatment of obesity. However, because of its related morbidity and mortality, this intervention is reserved for patients with extreme obesity (BMI greater than or equal to 40 kg/m^2) or BMI greater than 35 kg/m^2 with significant comorbidities.[6,78] Surgical weight loss options should only be considered in patients who have met the eligibility criteria and have failed other recommended methods for weight loss. It is critical for bariatric surgical candidates to fully understand the associated surgical risks and be able to adhere to the extensive postoperative care, follow-ups, and necessary lifelong dietary and lifestyle adjustments to ensure long-term success of the procedure. Careful patient selection and choice of procedure are critical to achieving a successful outcome. The input of an experienced surgeon working with a multidisciplinary team is invaluable in the care of these patients.

All bariatric surgical procedures achieve weight loss and maintenance through two principle mechanisms: 1) restriction or reduction of food intake by reducing stomach volume or 2) malabsorption by reducing the absorptive surface of the alimentary tract. Currently, the four major types of procedures are adjustable gastric banding, vertical banded gastroplasty, biliopancreatic diversion with duodenal switch, and conventional Roux-en-Y gastric bypass. Gastroplasty and adjustable gastric banding are designed to reduce the volume of the stomach and thus restrict the rate of nutrient intake. The biliopancreatic diversion with duodenal switch is primarily malabsorptive in nature, and the length of the diversion determines the extent of nutrient malabsorption. The conventional Roux-en-Y gastric bypass is the most common procedure currently performed in the United States. It combines a restrictive approach with a degree of malabsorption induced by excluding 90% to 95% of the stomach, the entire duodenum, and a portion of the proximal jejunum from the effective alimentary tract. Conventional Roux-en-Y gastric bypass yields greater and longer lasting weight loss than the other purely restrictive methods. Ultimately, reductions in excess body weight of ~48% to 85% can be achieved within the first 1 or 2 years, and weight loss maintenance of 25% to 68% of presurgery weight has been reported after 7 to 10 years with this procedure.[78]

Improvements in the peri- and postoperative care of gastric surgery patients have reduced morbidity and mortality associated with bariatric surgeries. The operative 30-day mortality rate is ~0.3% with conventional bypass or laparoscopic gastric banding[79] and 1.1% with malabsorptive procedures.[78] Some of the most common early complications of conventional gastric bypass are deep venous thrombosis, pulmonary emboli, anastomotic leaks, bleeding, and wound infections. Approximately one-third of patients who do not

receive vitamin supplementation will develop significant vitamin B_{12} and iron deficiency, with a large proportion demonstrating microcytic anemia.[78] Empiric supplementation with one or two tablets of daily multivitamin, 1,200 to 2,000 mg/day of calcium citrate with 400 to 800 IU/day of vitamin D, 400 mcg/day of folic acid, 40 to 65 mg/day of elemental iron, and at least 350 mcg/day of oral vitamin B_{12} (or 500 mcg intranasally once weekly) is essential to prevent nutritional deficiencies in bariatric recipients.[78] Dumping syndrome, characterized by abdominal pain and cramping, nausea, diarrhea, and bloating, tachycardia, and syncope can occur in 70% to 76% of patients after Roux-en-Y gastric bypass procedure[78] and may complicate provision of drug therapy in some cases. Dietary changes such as eating small, frequent meals, avoiding refined sugars, and increasing intake of fiber, complex carbohydrates, and protein can help alleviate the symptoms associated with dumping syndrome.

Weight losses resulting from bariatric surgery are often accompanied by dramatic improvements, and sometimes complete resolution, of many obesity-related complications. With improved glycemic control and reduced insulin resistance, remission rates for type 2 diabetes mellitus have been as high as 83% to 92% after Roux-en-Y gastric bypass and ~50% after gastric banding.[78] Other clinical benefits are improvements in hypertension, hypertriglyceridemia, high-density lipoprotein cholesterol, cardiomyopathy, cardiac function, degenerative joint diseases, mobility, nonalcoholic fatty liver disease, respiratory functions, obstructive sleep apnea, obesity–hypoventilation syndrome, polycystic ovary syndrome, infertility, pregnancy complications, and positive psychosocial changes, as well as enhanced quality of life.[78] Reduced risk of cancer-related mortality has also been documented after bariatric surgery. Furthermore, data from the prospective controlled Swedish Obese Subjects study have demonstrated a significant 29% reduction in overall mortality for patients who underwent bariatric surgery compared with those who received conventional treatments (ranging from lifestyle or behavioral medications to no interventions) after an average follow-up duration of 10.9 years.[80]

After experiencing weight loss, many gastric surgery patients are able to discontinue pharmacotherapy for glucose lowering, dyslipidemia, and hypertension. Frequently, however, antihypertensive medications must be restarted postsurgery, despite the fact that the patient has not experienced marked weight regain. It is imperative for clinicians to recognize that bariatric interventions not only alter nutrient absorption but also may impede drug absorption.[81] Achlorhydria and reduced surface area for intestinal and gastric absorption after bariatric surgery can lead to altered dissolution of certain pH-dependent medications, such as ketoconazole, enalapril, simvastatin, tacrolimus, sirolimus, and mycophenolic acid.[81,82] Data regarding absorption challenges associated with bariatric surgery remain scarce; thus, close therapeutic monitoring of any orally administered medication after surgery is highly recommended as dosage form selection, dose conversion, or therapeutic interchange may be necessary to avoid or minimize absorption problems and ensure bariatric surgery success.

PHARMACOLOGIC THERAPY

4 The debate regarding the appropriateness of obesity pharmacotherapy remains heated, fueled by the recognized national need to treat a growing epidemic and the medical and litigious fallout from the failed use of fenfluramine and dexfenfluramine (Redux).[83] Strategies for the pharmacologic management of obesity have historically focused on modulating central and/or peripheral sites that regulate energy balance. Figure 154–4 depicts the sites of action of these therapies within the energy intake, storage, and expenditure cycle. Short-term use of anorexic agents is difficult to justify because of the predictable weight regain that occurs with discontinuation of therapy. Long-term pharmacotherapy may have a place in the treatment of obesity for patients who have no obvious contraindications to approved drug therapy.[56,84] According to the NIH guidelines for treatment of overweight and obese patients, pharmacotherapy may be considered in adults with a BMI ≥30 kg/m^2 and/or a WC ≥40 inches (102 cm) for men or 35 inches (89 cm) for women, or

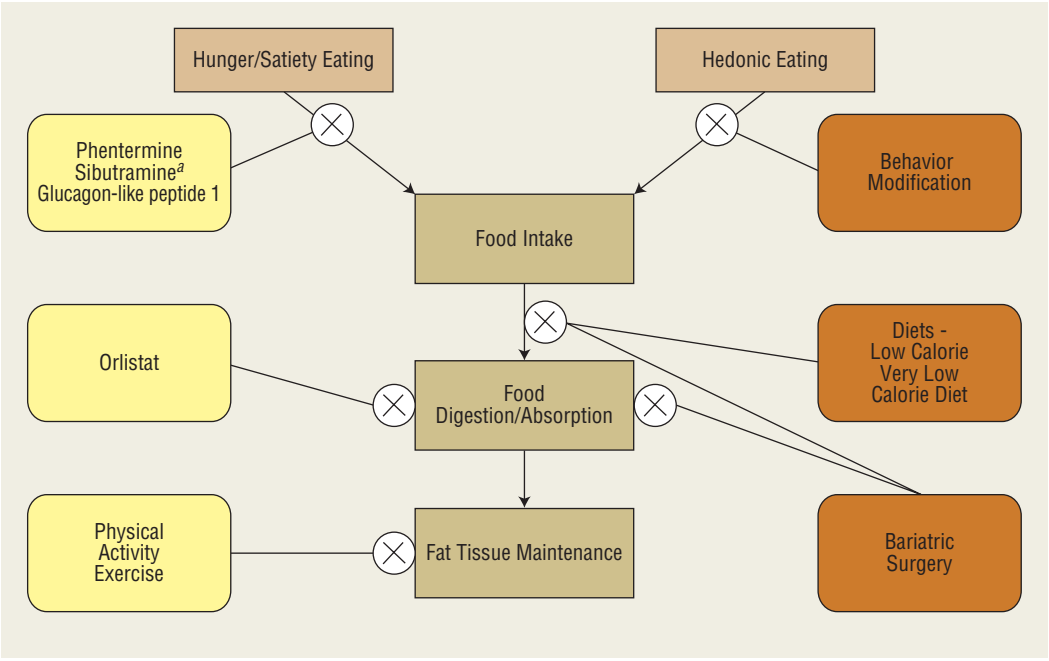

FIGURE 154-4. Sites of action for obesity treatments are represented by a circled X. Most appetite suppressants act on hunger and satiety mechanisms. Traditional diets and bariatric surgery act by limiting food intake. Orlistat interferes with fat absorption in the gut, whereas gastric bypass surgery interferes with absorption more generally. [a]*Sibutramine was withdrawn from the U.S. market in October of 2010.*

TABLE 154-5 Pharmacotherapeutic Agents for Weight Loss

Class	Availability	Status	Daily Dosages (mg)
Gastrointestinal lipase inhibitor			
Orlistat (Xenical)	Rx	Long-term use	360 (3 divided doses)
Orlistat (Alli)	OTC	Long-term use	180 (3 divided doses)
Noradrenergic/serotonergic agent			
Sibutramine (Meridia, Reductil)[a]	Rx	Long-term use	5–15
Noradrenergic agents			
Phendimetrazine (Prelu-2, Bontril, Plegine, Obezine, Statobex, X-trozine)	Rx	Short-term use	70–105
Phentermine (Fastin, Adipex-P, Ionamin)	Rx	Short-term use	15–37.5
Diethylpropion (Tenuate, Tenuate Dospan)	Rx	Short-term use	75

[a]Sibutramine was withdrawn from the U.S. market in October of 2010.

BMI of 27 to 30 kg/m^2 with at least two concurrent risk factors if 6 months of diet, exercise, and behavioral modification failed to achieve weight loss (Fig. 154–3).[6] Table 154–5 lists the status of the most common classes of agents currently available.

5 A multidisciplinary team approach to the management of obesity is necessary to ensure long-term success. The U.S. Preventive Services Task Force published an exhaustive summary of evidence related to screening and interventions for adult obesity that incorporates a graded assessment of obesity pharmacotherapy randomized controlled trials.[75] The discovery of cardiac valve disease in relation to serotonergic appetite suppressant use and its resulting multibillion-dollar class action litigation affirms the task force's call for further study of available therapies.[83,85] It is common for patients to use a combination of nonprescription, prescription, and other complementary and alternative therapies to attain the desired weight loss goal. Therefore, clinicians should maintain a high degree of sensitivity toward the potential polypharmacy practices of patients with obesity. Finally, is it prudent to consider specific patient characteristics, efficacy, and safety profile of each individual agent when use of a pharmacologic intervention is warranted.

CLINICAL CONTROVERSY

Current practice guidelines state that pharmacotherapy may be considered in patients with a BMI ≥30 kg/m^2 and/or a WC ≥40 inches (≥ 102 cm) for men or 35 inches (≥ 89 cm) for women, or BMI of 27 to 30 kg/m^2 with concurrent risk factors after 6 months of diet, exercise, and behavioral modification failed to achieve weight loss. In clinical practice, however, drug therapy is often initiated regardless of whether or not patients have previously failed to lose weight during a 6-month trial of diet exercise, and behavioral modification.

Agents Approved for Long-Term Use

Lipase Inhibitors

Orlistat Excessive intake of dietary fat is one of the contributing factors in the development of obesity. Gastrointestinal (gastric, pancreatic, and carboxyl ester) lipases are essential in the absorption of the long-chain triglycerides. Additionally, lipase is known to play a role in facilitating gastric emptying and secretion of other pancreaticobiliary substances. Orlistat (Xenical,) is a synthetic derivative of lipstatin, a natural lipase inhibitor produced by *Streptomyces toxytricini*. The drug is minimally absorbed and induces weight loss by persistent lowering of dietary fat absorption through selective inhibition of the gastrointestinal (GI) lipase. Furthermore, lower luminal free fatty acid concentrations result in malabsorption of cholesterol. Up to 30% reduction in fat absorption occurred with daily doses of 120 mg three times daily with meals.[86] A nonprescription formulation of orlistat (Alli) is approved in the United States at a reduced daily dose of 60 mg three times daily.[87] The drug must be taken within 1 hour of consuming foods that contain fat in order to exert its effect. If a meal is skipped or contains no fat, the dose of orlistat can be omitted.

Clinical studies employing orlistat as an adjunct to diet therapy demonstrate dose-dependent reductions in fat absorption. Overall, results from clinical trials demonstrate that orlistat effectively increases the amount of weight lost and decreases the amount of weight regained during medically supervised weight loss programs.[86,88] The longest trial that evaluated the safety and efficacy of orlistat is XENDOS (XENical in the prevention of Diabetes in Obese Subjects), a 4-year, double-blind, randomized, placebo-controlled prospective study.[89] Although weight regain was observed with continual therapy beyond the first year of orlistat therapy, results from this study show moderate weight loss sustained after 4 years of treatment compared with placebo, 12.8 lb (5.8 kg) and 6.6 lb (3.0 kg), respectively. Weight loss using orlistat also decreased the rate of development of type 2 diabetes by 37.3% in patients with impaired glucose tolerance. Improved glycemic control can be attained in patients with type 2 diabetes by inducing or increasing weight loss with orlistat in addition to diet management.[86,88] In some cases, dosages or the number of antidiabetic medications may be reduced or discontinued.[86] Significant improvements in lipid profile (reduction in total and low-density lipoprotein [LDL] cholesterol), glucose control, and other markers of metabolism are seen when using orlistat in addition to diet.[86,88] Orlistat is approved for the chronic treatment of obesity in adults and adolescents ages 12 to 16 years. The recommended dose is 120 mg three times daily taken within 1 hour of consuming a fat-containing meal.

At least one GI complaint (soft stools, abdominal pain/colic, flatulence, fecal urgency, or incontinence) has been reported in up to 80% of individuals using prescription strength orlistat. These complaints are most common in the first 1 to 2 months of therapy, are mild to moderate in severity and tend to improve with continued orlistat use. Limiting dietary fat prior to initiation of orlistat therapy may be beneficial in decreasing initial GI complaints. Severe diarrhea secondary to orlistat use can affect the absorption of orally administered drugs, such as oral contraceptives, fat-soluble vitamins (A, D, E, and K) and β–carotene.[86,89] Therefore, supplementation with a multivitamin should be considered during therapy. In presence of severe diarrhea women receiving oral contraceptives should be advised of the need to employ alternative backup methods as absorption of oral contraceptive may be reduced.[86] Although orlistat does not appear to alter the pharmacokinetic profiles of other agents, including digoxin, glyburide, metformin, phenytoin, fluoxetine, amitriptyline, phentermine, sibutramine, losartan, nifedipine, captopril, atenolol, furosemide, alcohol, or atorvastatin, reduced fat absorption can potentially affect the absorption of lipophilic drugs, such as lamotrigine, valproic acid, gabapentin, and amiodarone.[90] Decreased vitamin K absorption has also been noted and can alter the patients warfarin dosage needs.[90] Clinicians should also be aware that orlistat may directly interfere with the absorption of other narrow therapeutic range drugs, such as cyclosporine

and levothyroxine.[90] In patients requiring concomitant therapies with orlistat, close monitoring is warranted to ensure an adequate therapeutic response. Separation of the administration times of the medications may minimize these potential drug interactions.

The Food and Drug Administration (FDA) is reviewing safety information for the possible risk of liver damage with the use of orlistat. Between 1999 and October 2008, there were 32 reports of serious liver injury, including 27 hospitalizations and 6 reports of liver failure, in patients using orlistat.[91] Causality has not been definitively linked to orlistat, and those taking prescription and nonprescription orlistat are advised to continue using the product as directed by their healthcare providers.

Noradrenergic–Serotonergic Agents

Sibutramine Until recently sibutramine was available in the U.S. for long-term use. This drug induces weight loss by decreasing appetite and maintaining or increasing thermogenesis via increasing the synaptic concentration of serotonin, norepinephrine (NE), and dopamine through reuptake inhibition. Reuptake inhibition appears to be greatest for NE, followed by serotonin, with dopamine the least inhibited. In humans, the degree to which these effects can be attributed to central versus peripheral activity is currently unknown.

In adults, the recommended starting dose is 10 mg daily, with a recommended dose range of 5 to 15 mg daily. A meta-analysis of available randomized trials suggests after 1 year of therapy sibutramine-treated patients on average lost 9.2 lb (4.2 kg) more weight than placebo-treated patients.[88] After 12 months of therapy, sibutramine-treated patients had a 32% higher chance of achieving a 5% reduction in total body weight and an 18% higher chance of achieving a 10% reduction in body weight compared to those taking placebo. As with other centrally active appetite suppressants, weight regain occurs with cessation of therapy; patients can regain up to 55% of weight lost 18 months after treatment is discontinued. STORM (Sibutramine Trial of Obesity Reduction and Maintenance) was the longest randomized, double-blind study to evaluate the effectiveness of sibutramine, lasting up to 2 years.[92] The group receiving sibutramine achieved more weight loss than the placebo group (22.4 lb [10.2 kg] vs 10.3 lb [4.7 kg]), respectively] and had more subjects who retained at least 80% of the weight loss (43% and 16%, respectively). Sibutramine-related weight loss was associated with a decline in triglycerides, very low-density lipoprotein cholesterol, insulin C-peptides, and uric acid concentrations. The 20% improvement in high-density lipoprotein (HDL) cholesterol is comparable to the average effects of the ingestion of fibric acid derivatives or statins.[67] Few studies have evaluated the safety and efficacy of sibutramine in children and adolescents.

Dry mouth, anorexia, insomnia, constipation, dizziness, and nausea were noted two- to threefold more frequently in sibutramine-treated subjects than in placebo-treated subjects. Statistically significant increases in blood pressure (1.7 mm Hg systolic and 2.8 mm Hg diastolic pressure) and pulse rate (4.5 beats/min) have been reported with sibutramine use.[88] Baseline blood pressure should be established prior to beginning therapy, and close monitoring is required when using this agent. Sibutramine's product labeling has indicated that the drug should not be used in patients with hypertension. Interestingly, however, some evidence suggests that the central α-adrenergic (clonidine-like) effect of sibutramine may predominate in patients with elevated sympathetic activity resulting in decreased blood pressure in hypertensive patients.[93] Nonetheless, use of sibutramine has been contraindicated in all patients with a history of cardiovascular disease, including coronary artery disease, stroke or transient ischemic attack, heart arrhythmias, uncontrolled hypertension, congestive heart failure, and peripheral arterial disease. The SCOUT (Sibutramine Cardiovascular OUTcomes) study—a prospective trial that evaluated the potential benefits of sibutramine on cardiovascular outcomes in obese or overweight individuals with preexisting cardiovascular disease, type 2 diabetes mellitus, or both—failed to provide any reassurance regarding sibutramine's safety.[94] Although individuals taking sibutramine had modest weight loss, improvement in cardiovascular outcomes was not seen. Conversely, subjects with preexisting cardiovascular disease actually had an increased risk of nonfatal myocardial infarction and nonfatal stroke. Because of concerns that the effectiveness of sibutramine on weight loss is counterbalanced by increased rather than decreased cardiovascular risk, the drug was voluntarily withdrawn from the U.S. market in late 2010.[95]

Combination Therapy Theoretically, the combination of orlistat and sibutramine would produce a synergistic effect because they work through different mechanisms of action to induce weight loss. However, none of the few studies to look at this combination has shown that it would result in greater weight loss compared with sibutramine alone.[96–99] The concomitant use of these two drugs may lead to increased adverse effects without improved therapeutic outcomes. Therefore, the combination of orlistat and sibutramine is not recommended over the use of either product individually.

CLINICAL CONTROVERSY

Obesity is considered a chronic disease. Agents approved by the FDA for long-term management of obesity have limited long-term data regarding morbidity and mortality outcomes; therefore, the optimal duration of treatment beyond the studied treatment periods remains unknown. Although discontinuation of drug treatment tends to result in weight regain, continuation of an effective and well-tolerated drug regimen is the current practice until additional evidence is available.

Agents Approved for Short-Term Use

Noradrenergic Agents

Phentermine Phentermine is structurally similar to amphetamine, but it has less severe CNS stimulation and a lower abuse potential. Its mechanism of action centers on its ability to enhance NE and dopamine neurotransmission. Phentermine is available in both immediate-release and sustained-release formulations. However, the value of sustained-release formulations is questionable based on the reported phentermine plasma half-life of 12 to 24 hours.[100] Phentermine is an effective adjunct to diet, exercise, and behavior modification for producing weight loss in excess of that seen with placebo.[101] Intermittent phentermine therapy appears to elicit comparable weight loss as that seen with continuous use. However, most individuals experience weight regains during therapy and generally always after discontinuing use.[100] A single dose of 30 mg once daily in the morning provides effective appetite suppression throughout the day. Divided doses of 8 mg immediately before meals, however, are common. Doses >30 mg daily do not improve effectiveness.[101] Evening or nighttime dosing should be avoided because of insomnia. Significant increases in blood pressure, palpitations, and arrhythmias can occur with phentermine administration. Use is not advisable in hypertensive patients and those with underlying cardiac abnormalities.

The potential for hypertensive crisis with coadministration of phentermine and MAOIs is noted in the product labeling of each agent; therefore, patients should be off an MAOI for at least 14 days prior to use of any adrenergic agent to avoid excessive adrenergic

stimulation syndromes.[102] Phentermine use is contraindicated in patients with hyperthyroidism or agitated states and in those who are abusers of substances such as cocaine, phencyclidine, and methamphetamine, again because of the potential for excessive adrenergic stimulation syndromes and abuse potential. Mydriasis from adrenergic stimulation can worsen glaucoma, and patients diagnosed with glaucoma should not receive phentermine. Diabetic patients may experience altered insulin or oral hypoglycemic dosage requirements soon after beginning therapy and prior to any substantial weight loss. Phentermine remains the most widely prescribed weight management medication by obesity specialists in spite of product labeling that indicates short-term (a few weeks), monotherapy use only.[103] This usage pattern deviates from the current national recommendations that promote only long-term drug intervention when obesity pharmacotherapy is appropriate.[56]

Diethylpropion Diethylpropion stimulates NE release from presynaptic storage granules. Increased adrenergic neurotransmitter concentrations activate hypothalamic centers, which results in decreased appetite and food intake. This drug undergoes extensive first-pass hepatic metabolism. Active metabolites are eliminated renally and account for ~70% of the administered dose. The elimination half-life of these metabolites is about 8 hours.[101] Less than 10% of the parent compound is recovered in urine. No specific dosing recommendations exist for use in patients with renal or hepatic insufficiency. Diethylpropion can be taken in divided daily doses, generally 25 mg three times daily before meals. An extended-release formulation is also employed by some clinicians, usually as 75 mg taken once daily in the morning or midmorning. Both dosing regimens are effective in achieving short-term weight loss in excess of placebo.[29] Complaints of insomnia increase if late afternoon dosing is used. Diethylpropion causes less stimulation of the central nervous system than mazindol and generally causes less insomnia than phentermine. Patients with severe hypertension or significant cardiovascular disease should not receive diethylpropion. Diabetic patients may experience decreased insulin or oral hypoglycemic dosage requirements soon after beginning therapy and prior to any substantial weight loss. More frequent blood glucose self-monitoring and medical follow-up are warranted when treating diabetic patients with diethylpropion.

Amphetamines Appetite suppressant effects of the amphetamines were well recognized in the 1930s. Amphetamines activate central noradrenergic receptor systems as well as dopaminergic pathways at higher doses by stimulating neurotransmitter release. Increases in blood pressure and mild bronchodilation are attributed to peripheral α- and β-receptor activation. Amphetamines are no longer widely used for the treatment of obesity due to their powerful stimulant effects and addictive potential.

Mazindol Chemically distinct from amphetamines and phentermine, mazindol's tricyclic structure results in amphetamine-like appetite suppression.[29] Despite demonstrated efficacy as a short-term therapy for weight reduction, mazindol is no longer available in the United States.[86]

Other Agents Used for Weight Management

Serotonergic Agents Serotonin is an important neurotransmitter involved in many human physiologic systems such as sleep–wake cycles, sensitivity to pain, blood pressure, mood, and eating behaviors. Increasing central serotonin levels disrupts the body's natural development of satiety by decreasing the amount of food consumed and prolongs the time between food intake.[104] Some serotonergic agents increase central serotonin concentrations via stimulating release of presynaptic stores and/or inhibition of reuptake into storage granules. Additionally, either the parent compound or metabolites of these agents may stimulate postsynaptic 5-HT receptors directly. Peripheral serotonin effects that have an impact on appetite, such as slowing gastric motility, have been described. A major distinction between serotonergic and noradrenergic anorexiants is that serotonergic agents lack the central stimulant effects and thus the abuse potential seen with the noradrenergic compounds.[27,29] Conversely, decreased wakefulness, altered sleep patterns, and changes in affect can be seen.

Antidepressants: Selective Serotonin Reuptake Inhibitors Some of the serotonergic appetite-suppressing agents were first studied as antidepressants (see Chapter 77) and when weight loss was noted in some patients, they began to be used as weight management agents. These drugs are not approved by the FDA as weight management agents and currently not recommended for treatment of obesity. Nonetheless, some practitioners have prescribed these agents for the treatment of obesity "off-label" either alone or in combination with phentermine.

Fluoxetine is a serotonergic agent that has been prescribed as an appetite-suppressing agent. Higher doses of fluoxetine (60 mg) were generally employed for weight loss as opposed to the lower doses (20 mg) frequently used for the treatment of depression. A meta-analysis of six fluoxetine trials demonstrated a variable effect on weight loss, ranging from 14.5 kg (31.9 lb) lost to 0.4 kg (0.9 lb) gained, when compared with placebo over periods of up to 1 year.[29] Weight regain was noted to occur despite continued medication use.[105]

The safety and efficacy of phentermine–serotonin reuptake inhibitor combinations is limited. A case report of adverse experiences (e.g., impaired mentation, tremor, hyperreflexia, and GI symptoms) with unintentional concurrent use of phentermine and fluoxetine reinforces the need for caution by prescribers of this unapproved combination therapy.[106] Although cases of pulmonary hypertension have been reported in patients exposed to fluoxetine,[107] serious adverse effects such as cardiac valve abnormalities in excess of baseline prevalence have not been reported in relation to selective serotonin reuptake inhibitor use for obesity therapy.[108]

Endocannabinoid System Agents Over the past 20 years, arachidonic acid derivatives, known as endocannabinoids, were identified as endogenous substances that activate cannabinoid receptors.[109,110] A complex relationship exists between the endocannabinoid system, energy regulatory hormones, and neuropeptides.[110] The endocannabinoid system appears to be overactive in states of overweight and obesity. Additionally, the endocannabinoid system appears to be involved in the propagation of addictive behaviors related to ingestion of substances such as nicotine, alcohol, marijuana, opioid, and other psychostimulants.

Two distinct cannabinoid receptors are known and have been cloned, CB_1 and CB_2. The existence of a third, CB_3, has also been described.[111] These G-protein-coupled receptors have wide and differing tissue distribution. CB_1 receptors are found in high concentrations in brain and peripheral organs, including the liver, GI tract, adipocytes, and cardiac muscle.[109] Central and peripheral CB_1 receptors are involved in many aspects of energy balance, regulation of food intake, glucose and lipid metabolism, and body composition. CB_2 receptors are mainly expressed within immune system tissues and are not currently recognized as affecting energy balance.

Rimonabant Rimonabant (SR141716A), first described in 1994 as an inhibitor of brain CB_1 receptors, has potent central and peripheral effects on feeding, nutrient metabolism, and body composition.[27,109] However, the FDA's Endocrinologic and Metabolic Drugs Advisory Committee in 2007 unanimously agreed that rimonabant did not demonstrate a favorable risk-to-benefit profile to enable it to be approved for weight management.[112] The

committee's concerns centered on increased risk of serious neurologic side effects—seizures, depression, anxiety, aggressiveness, and suicidal thoughts among patients randomized to rimonabant. Following a safety review from the European Medicines Agency's Committee for Medicinal Products for Human Use, marketing of rimonabant was withdrawn across the European Union in 2008 due to its serious psychiatric concerns.[113] Sanofi-Aventis subsequently decided to discontinue clinical development of rimonabant.[114] Similarly, the development of other CB_1 receptor antagonists has been suspended.[115]

COMPLEMENTARY AND ALTERNATIVE THERAPIES

6 Many complementary and alternative therapy products are currently promoted for weight loss. A survey of consumers revealed that ~18% of Americans reported use of "natural products" (i.e., dietary supplements other than vitamins and minerals) within the past year.[116] It is important for clinicians to be aware that the regulation of dietary supplements is less rigorous than that of prescription and over-the-counter drug products. As such, a manufacturer of a dietary supplement does not have to prove the safety or effectiveness of the product before it is marketed. Of concern, some herbal and food supplement diet agents contain pharmacologically active substances that should be used with caution or avoided in obese patients with conditions such as diabetes, hypertension, and significant cardiovascular disease. In addition, many marketed products have been reported to lack consistency in labeling versus actual product content. More recently, a number of dietary supplements have been found to contain undeclared prescription drugs.[117] Clinicians may access the FDA Dietary Supplement Alerts and Safety Information website to keep informed of these issues.[118] Table 154–6 lists some of the common herbal/natural products used for weight loss and the constituents found in many of these products.

Bitter Orange

Bitter orange (*Citrus aurantium*) contains m-synephrine, a sympathomimetic amine with structural similarities to ephedrine.[119] After FDA banned the sale of ephedra-containing dietary supplements in 2004, several manufacturers replaced the ephedra constituents within their products with bitter orange. Bitter orange–containing products are commonly promoted as "ephedra-free." Although bitter orange has been shown to effectively promote weight loss, it may also increase heart rate and blood pressure, potentially causing the same adverse cardiovascular effects that were observed with ephedra.[119]

TABLE 154-6 Common Herbal/Natural Products and Food Supplements Used for Weight Loss[a]

Herbal/Natural/Food Supplements	Active Component	Proposed Mechanism
Bitter orange	M-synephrine	Noradrenergic
Calcium pyruvate	Pyruvate	Unknown
Chromium picolinate	Chromium	Unknown
Chitosan	Cationic polysaccharide	Block fat absorption
Garcinia gambogia extract (citrin)	Hydroxycitric acid	Unknown
Guarana extract	Caffeine	Noradrenergic
Hoodia	P57	Unknown
Various tea extracts	Caffeine	Noradrenergic

[a]Safety and efficacy are not documented.

Chromium

Chromium is considered an essential nutrient and experimentally in animals is an insulin cofactor active in carbohydrate, protein, and lipid metabolism. In humans, insulin resistance has been reported in a few cases of apparent severe chromium deficiency during long-term total parenteral nutrition (see Chapter 151). Currently, there is no reliable means of assessing total body chromium status, making diagnosis of deficiency difficult. The tryptophan metabolite, picolinic acid, forms a complex with trivalent chromium, which improves bioavailability. Food sources with highly available chromium include brewer's yeast, calves' liver, American cheese, and wheat germ. Clinical trials assessing chromium picolinate as a supplement to aerobic exercise in the treatment of obesity have failed to demonstrate any effectiveness.[120,121]

Chitosan

Chitosan is a cationic polysaccharide, specifically a partially *N*-deacetylated form of chitin. This nonhydrolyzable fiber exhibits properties similar to those of cellulose. In vitro and preclinical data indicate that chitosan may be effective in blocking absorption of fat from the gut. It has been suggested that orally administered chitosan may be an effective weight reduction agent by blocking calories ingested as fat. Chitosan is a major constituent in several heavily advertised weight management food supplements and nonprescription preparations. However, a small number of randomized and blinded or open-label investigations have demonstrated that orally administered chitosan is not an effective inhibitor of fat absorption in humans.[122] Although further research may be warranted with respect to the appropriate dose in humans needed to impair fat absorption, current claims of chitosan effectiveness are unsubstantiated.

Ephedra Alkaloids

Based on the known effects of ephedrine, dietary supplements claiming weight management effects have employed plant sources of ephedra alkaloids. Various parts of the Ephedraceae, ma huang, *Sida cordifolia,* and *Pinellia ternata* plants are known to produce ephedra alkaloids, including L-ephedrine, D-pseudoephedrine, L-norephedrine, D-norpseudoephedrine, L-*N*-methylephedrine, and D-*N*-methylpseudoephedrine.[123] Common names routinely included in dietary supplement labeling for these alkaloid sources include joint fir, popotillo, country mallow, sea grape, and yellow horse. From 1994 through July 1997, the FDA received more than 800 reports of serious adverse events; including seizures, stroke, and death, coincident with ephedrine alkaloid-containing dietary supplement use. An in-depth review of 140 reports of adverse events related to ephedrine alkaloid-containing dietary supplements demonstrated that approximately half the reports involved cardiovascular symptoms.[124] In 2004, the FDA determined that all sources of ephedra alkaloids must be excluded from dietary supplements because they present an unreasonably high health risk.[125]

Guarana Extract and Various Tea Extracts

Guarana and tea are sources of caffeine that have inherent adrenergic properties and increase the effects of stimulant substances, such as ephedrine and ephedra alkaloids. Guarana and various tea extracts are commonly found in energy drinks and combination weight loss products that contain other substances with stimulant properties.[126,127]

Hoodia

Hoodia is a desert cactus of the Apocynaceae plant family. Natives indigenous to the Kalahari Desert are purported to consume the stems and roots of this plant for their appetite suppressant effects.[128] Other names appearing on product labels are Kalahari cactus, Hoodia cactus or extract, *Hoodia gordonii* cactus, and Kalahari diet. Hoodia extract, sometimes referred to as P57, is rumored to elicit weight loss; however, no peer-reviewed reports of effectiveness are currently available.

Pyruvate

Pyruvate is a commonly listed ingredient in many herbal weight management preparations. Multiple salt forms are used, including sodium, magnesium, potassium, and calcium. Other names are α-ketopropionic acid, 2-oxypropanoic acid, and acetylformic acid. Pyruvate is a three-carbon intermediate formed during normal glucose metabolism and/or during glycolysis. It is advertised in the lay press for its ability to "increase metabolism" and thus promote weight loss. Objective data documenting these effects are lacking.[129,130] Although most pyruvate nutritional weight management supplements contain less than 2 g per dose, large exposures (>20 g) are known to cause noticeable GI side effects, including bloating and diarrhea.

AGENTS UNDER INVESTIGATION

Several investigational pharmacologic agents are currently being evaluated for weight management. Lorcaserin, a selective serotonin (5-HT_{2C}) receptor agonist, is one such agent currently in phase III development. Activation of central 5-HT_{2C} receptors results in appetite suppression. A clinical trial evaluating the efficacy and safety of lorcaserin in healthy obese men and women reported dose-dependent weight loss and a favorable safety profile.[131] Subjects who received 10 mg of lorcaserin twice daily for 12 weeks experienced an average weight loss of 3.6 kg (7.9 lb), compared with 0.3 kg (0.7 lb) in placebo-treated subjects. It is important to note that this trial did not include any modifications in dietary intake or physical activity. The most common adverse events reported in subjects receiving lorcaserin were headache, nausea, and dizziness.

Another agent in the final stages of testing for obesity treatment is cetilistat, a lipase inhibitor. A trial involving 371 obese subjects reported an average weight loss of 4.1 kg (9 lb) over 12 weeks in patients who received 240 mg of cetilistat three times daily in combination with a hypocaloric diet.[132] Cetilistat also improved total and LDL cholesterol. The safety profile of cetilistat is similar to that of orlistat and includes primarily GI adverse events. Other products currently being studied for weight management include the following drug combinations: bupropion and naltrexone (Contrave), phentermine and topiramate (Qnexa), and pramlintide and metreleptin.[133,134]

PHARMACOECONOMIC CONSIDERATIONS

The economic consequences of treating obesity and obesity-related comorbidities are significant. The annual cost of health care attributed to obesity was estimated to be at least $147 billion in 2008.[135] Weight reduction has been reported to reduce prescription costs. A study conducted by Collins and colleagues evaluated the savings in prescription costs following a 12-week weight reduction program in 40 type 2 diabetic patients. A cost analysis was completed on 32 of 40 patients who were taking antihypertensive and/or antidiabetic medications based on their out-of-pocket costs for these medications at the beginning of the study and after 1 year. The average cost of these prescriptions at the beginning as compared with the 1-year follow-up was $63.30 versus $32.50 per month. The estimated annual average saving in prescription costs per patient was $443.[136] Another study evaluating the economic impact of weight change in patients with type 2 diabetes examined total healthcare cost and diabetes-related costs in 458 patients.[137] Patients were classified as either weight gainers (n = 224; average weight gain 3.9% in 6 months) or non–weight gainers (n = 234; average weight loss 3.3%). The overall pharmacy cost after 1 year was significantly less for the non–weight gainers than the weight gainers ($1,703 vs $2,225; P = 0.044). The cost of antidiabetic agents was also significantly less in the non–weight gainer group ($499 vs $769; P = 0.001). This evidence suggests that weight reduction can lead to decreased prescription medication costs. A systematic review of published economic evaluations of orlistat, sibutramine, and rimonabant reported incremental cost-effectiveness ratios (ICERs).[138] The authors reported a median ICER of $23,364 per quality-adjusted life-year (QALY). It was determined that most of the ICERs were within the appropriate range to be considered cost-effective. However, the authors concluded uncertainty regarding the utility gain associated with weight loss and weight regain. Of note, adverse events were not explicitly taken into account in any study.

Martin and colleagues compared the costs associated with medical and surgical treatment of obesity.[139] Medical therapy groups received diet therapy only (no medications), and cost included weekly clinic visits for behavioral modification. A successful outcome was defined as loss of at least one-third of excess body weight above ideal body weight. The authors monitored all patients for 2 years and some for as long as 7 years so that long-term weight control could be addressed. As expected, the costs of surgery were much higher than medical therapy over the first 2 years ($24,000 vs $3,000). However, when costs were extrapolated out to 6 years, the cost per pound lost for medical therapy exceeded surgical therapy (about $313 vs $261 per pound lost).

Finally, third-party payer and insurance reimbursement for provision of obesity treatment services continue to be inconsistent. For example, a recent questionnaire administered to 25 health plans in Pennsylvania reported that less than 50% of payers reimbursed for lifestyle modification (other than dietary counseling) or weight loss medication. All of the health plans that responded to the questionnaire provided some coverage for bariatric surgery.[140]

It is clear from the preceding data that weight loss can be expensive. Prospectively designed cost–benefit or cost-effectiveness analyses are needed to determine if costs of weight loss therapy or surgery are balanced by lower costs of hospitalizations for other medical problems associated with obesity or the additional life-years gained. Quality-of-life measures also need to be taken into consideration when evaluating these types of data.

EVALUATION OF THERAPEUTIC OUTCOMES

Monitoring the Pharmaceutical Care Plan

Assessment of patient progress should be documented once or twice monthly for 1 to 2 months and then monthly thereafter.[6] Each encounter should document weight, WC, BMI, blood pressure, medical history, and patient assessment of obesity medication tolerability.[6] Chronic use of obesity medications should be consistent with the approved product labeling, and medication therapy should be discontinued after 3 to 4 months if the patient has failed to demonstrate weight loss or maintenance of prior weight. To achieve optimal weight loss, patients should be instructed about the importance of adherence to prescribed medication and lifestyle changes. Numerous tools for both patient and practitioner are

readily available through the Department of Human Services and NIH–National Heart Lung and Blood Institute (NHLBI) Obesity Education Initiative.[141] The Short Form 36 (SF-36) also has been used as a quality-of-life evaluation tool for obese patients undergoing programmatic weight loss. Quarterly assessments of well-being and quality of life using validated assessment tools can be helpful in objectively quantifying the effectiveness of therapy, as well as potential drug-induced side effects (e.g., depression).

Diabetic patients receiving weight loss medication require more intense medical monitoring and self-monitoring of blood glucose. Insulin therapy may need to be adjusted with the start of obesity medication therapy. Some diabetic patients may require daily telephone contact with a healthcare provider to assist in adjusting their hypoglycemic therapy. Weekly patient visits to a healthcare setting may be necessary for 1 to 2 months until the effects of diet, exercise, and weight loss medication become more predictable. As frequent as quarterly assessment of hemoglobin A_{1c} may be appropriate in type 2 diabetics who lose weight to aid in adjustment of hypoglycemic therapy. Lipid profiles can normalize or improve with weight loss. Lipid status should be assessed semiannually or annually in patients with hyperlipidemia to determine the need for continued hyperlipidemia therapies. Weight loss also can result in normalization of blood pressure in hypertensive obese patients. Assessment of appropriateness of antihypertensive therapy should occur with each follow-up visit.

The evaluation and management of a patient with obesity requires careful clinical, biochemical, and, if necessary, psychological evaluation. The evaluation must include an assessment of current medical conditions and medications the patient uses. Clearly, a multidisciplinary team including, but not limited to, a physician, nutritionist, psychologist, and pharmacist best achieves this.

CONCLUSION

Obesity is a chronic disease with a prevalence that has increased dramatically over the past 30 years. Increased body weight is a consequence of an imbalance between energy intake and energy expenditure over time, which is influenced by many factors, including genetic and environmental aspects. Nonpharmacologic therapy, including reduced caloric intake, increased physical activity, and behavioral modification, is currently the mainstay of obesity management. Drug therapy may be considered as an adjunct for those patients who fail to achieve adequate weight loss after 6 months of diet, exercise, and behavioral modification. Currently, only orlistat is available in the United States for the long-term treatment of overweight and obesity. Bariatric procedures have evidence for long-term efficacy for weight reduction, but they also introduce surgical comorbidities and, for the most efficacious procedures, may cause significant nutritional deficiencies. Treatment of obesity should be individualized, considering factors such as patient desires, age, degree and duration of obesity, and the presence or absence of medical conditions both directly related to obesity and those that may have an impact on the therapeutic decisions. Regardless of the chosen treatment plan, the management of obesity is a lifelong process requiring patient support and careful monitoring for safety and efficacy.

ABBREVIATIONS

ATP III: Third Report of the Expert Panel on the Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults

5-HT: 5-hydroxytryptamine (serotonin)

BMI: Body mass index

BMR: Basal metabolic rate

CT: Computed tomography

HDL: High-density lipoprotein

ICER: Incremental cost-effectiveness ratio

LCD: Low-calorie diet

LDL: Low-density lipoprotein

Kcal: Kilocalories

MAOI: Monoamine oxidase inhibitor

MRI: Magnetic resonance imaging

NE: Norepinephrine

NHANES: National Health and Nutrition Examination Survey

NIH: National Institutes of Health

QALY: Quality-adjusted life-year

REE: Resting energy expenditure

WC: Waist circumference

GLOSSARY

2,3-Bisphosphoglycerate: An intermediate in the Rapoport-Luebering shunt, formed between 1,3-bisphosphoglycerate and 3-phospho-glycerate; an important regulator of the affinity of hemoglobin for oxygen.

5-α-reductase: Enzyme responsible for conversion of testosterone to its active metabolite dihydrotesterone. Two types of this enzyme exist. Type 2 is predominant in prostate cells.

α-Amino-3-hydroxy-5-methyl-4 isoxazolepropionate (AMPA)/kainate receptors: Two of three types of ionotropic post-synaptic glutamate receptors. These receptors are similar and are often considered together. Upon binding glutamate, these receptors permit the influx of Na^+ ions and results in brain excitation. These are one of the two primary receptors for excitatory neurotransmission in the brain.

α-Amino-3-hydroxy-5-methylisoxazole-4-propionate: See *AMPA*.

α-Hydroxy acids: Exfoliating products such as lactic, glycolic, malic, mandelic, and tartaric acid used in cosmetics.

β-Hydroxy acid: Salicylic acid.

γ-Aminobutyric acid (GABA): The major inhibitory neurotransmitter in the central nervous system.

γ-Aminobutyric acid ($GABA_A$) receptors: Postsynaptic ionotropic receptors that bind to GABA and result in Cl^- influx and neuronal hyperpolarization. GABA is the main inhibitory neurotrasmitter in the brain and $GABA_A$ receptors mediate fast CNS inhibitory neurotransmission.

Abscess: A purulent collection of fluid separated from surrounding tissue by a wall comprised of inflammatory cells and adjacent organs. It usually contains necrotic debris, bacteria, and inflammatory cells.

Abstinence: Refraining from the indulgence in something, as sexual intercourse or substances, by one's own choice. The absence of genital contact that could permit a pregnancy (i.e., penile penetration into the vagina).

Acanthosis: Increased thickness of the prickle cell layer of the skin.

Acculturation: The process by which individuals from one cultural group adopt or change behaviors, attitudes and/or beliefs through contact with a different culture.

Acetabular: Relating to the acetabulum, the hollow, cuplike portion of the pelvis into which the head of the thigh bone (femur) fits.

Achalasia: Problem that occurs when a ring of muscle fibers, such as a sphincter of the esophagus, fail to relax.

Acne: Inflammatory eruption of the sebaceous gland.

Acnegenicity: Product effect that causes irritation of follicles resulting in papules and pustules.

Acquired resistance: See *Secondary resistance*.

Acromegaly: A pathologic condition characterized by excessive production of growth hormone.

Activities of daily living: Dressing, bathing, getting around inside the home, feeding, toileting, and grooming. See also *Instrumental activities of daily living*.

Acute bacterial pharyngitis: Acute bacterial infection of the oropharynx or nasopharynx.

Acute bacterial sinusitis: Acute bacterial infection of the paranasal sinuses lasting less than 30 days.

Acute coronary syndrome (ACS): Ischemic chest discomfort at rest most often accompanied by ST-segment elevation, ST-segment depression, or T-wave inversion on the 12-lead electrocardiogram and caused by plaque rupture and partial or complete occlusion of the coronary artery by thrombus. Acute coronary syndromes include infarction and unstable angina. Former terms used to describe types of ACS include *Q-wave myocardial infarction, non–Q-wave myocardial infarction,* and *unstable angina.*

Acute otitis media: Acute inflammation of the middle ear.

Acute pain: Can be a useful physiologic process warning individuals of disease states and potentially harmful situations. Severe, unremitting, undertreated, acute pain, when it outlives its biologic usefulness, can produce many deleterious effects (e.g., psychological problems). It usually subsides when the healing process decreases the pain-producing stimuli.

Acute pancreatitis: Acute inflammation of the pancreas that can be mild with minimal or no organ dysfunction or severe with organ failure and local complications.

Acute stress disorder: A disorder characterized by anxiety, dissociative, and other symptoms that occurs within 1 month after exposure to an extreme traumatic stressor.

Acute tubular necrosis: Acute renal failure as the result of renal tubular epithelial cell damage, which can be caused by either direct toxic or ischemic effects of drugs.

Adaptive functioning: Individual effectiveness coping with everyday stressors compared to a peer with similar background, and socioeconomic and psychosocial opportunities.

Adaptive inflammation: Inflammatory pain that promotes the shifting from prevention of tissue damage to promotion of healing.

Addiction: A primary, chronic, neurobiologic disease, with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behaviors that include one or more of the following five Cs: *c*hronicity, impaired *c*ontrol over drug use, *c*ompulsive use, *c*ontinued use despite harm, and *c*raving.

Adjuvant analgesics: Agents that are useful in the treatment of pain but are usually not classified as analgesics.

Administrative burden: The demands placed on those who administer an instrument.

Adolescents: Pediatric patients who are 12 to 16 years of age.

Adoptive immunotherapy: Administration of immune cells for the purpose of cancer treatment.

Adrenergic: Neuronal or neurologic activity caused by neurotransmitters such as epinephrine, norepinephrine, and dopamine.

Adrenocorticotropic hormone (ACTH): A polypeptide hormone secreted by the anterior pituitary that controls secretion of cortisol from the adrenal glands.

Adverse drug events: Injuries resulting from administration of a drug or other circumstances surrounding use of the drug but not necessarily caused by the drug itself. See also *Adverse drug reaction*.

Adverse drug reaction: Any noxious, unintended, and undesired effect of a drug that occurs at doses used in humans for prophylaxis, diagnosis, or therapy.

Affect: Pattern of behaviors that a clinician can observe that expresses a person's current state of emotion.

Afterload: The pressure or the "load" the heart must generate to eject blood into the systemic circulation. Although approximated by the systemic vascular resistance, it is a complex measure that includes blood viscosity, aortic impedance, and ventricular wall thickness. Along with preload, it is an important determinant of cardiac output.

Aganglionosis: The state of being without ganglia.

Agnosia: Cardinal symptom of Alzheimer's disease; inability to recognize or identify a familiar object in the absence of impaired sensory function.

Agoraphobia: Anxiety about, or avoidance of, places or situations from which escape might be difficult (or embarrassing) or in which help might not be available in the event of having a panic attack or panic-like symptoms.

Akathisia: The sensation of inner restlessness resulting in the need to make movements such as pacing or moving the legs. Akathisia has subjective and objective components.

Albumin: The major protein in plasma, with a molecular weight of 65 kDa.

Albuminuria: A condition where a large amount of albumin (>300 mg/day) is present in the urine, often indicating glomerular damage in the kidney.

Alcohol ablation: Alcohol ablation of the septum is a nonsurgical procedure to improve outflow tract obstruction. It is a percutaneous catheter-based method to decrease septal thickness by therapeutic myocardial infarction.

Alcoholism: A chronic, progressive, and potentially fatal biogenic and psychosocial disease characterized by tolerance and physical dependence and manifested by a total loss of control, as well as diverse personality changes and social consequences.

Algorithm (treatment algorithm): Identifies and specifies sequences for treatment alternatives, with specific options and tactics for care. Based on scientific data and on expert consensus in areas where there is little scientific data, algorithms are divided into stages so that the simplest, most efficacious, and best-tolerated treatments available are tried first. If results are not optimal, treatment advances to the next stage. Unless a patient's illness fails to improve sufficiently with early stage treatments, he or she is spared treatments that are more complex, that might be less well tolerated, or that have more potential for drug interactions or serious side effects. Algorithms recommend key decision points in treatment decision making.

Allergic interstitial nephritis: Inflammation of the interstitial region of the kidney often associated with acute onset of renal insufficiency.

Allergic salute: Constant upward rubbing of the nose as a result of allergies.

Allergic shiners: Dark circles under the eyes as a result of nasal congestion leading to venous pooling.

Allodynia: Painful response to normally non-noxious stimuli.

Allogeneic transplantation: Transfer of cells between different individuals.

Allograft: An organ or tissue transplant from one human to another.

Allokinesis: A phenomenon whereby pruritic skin affects the surrounding normally nonpruritic skin area, whether inflamed or noninflamed. The nonpruritic skin becomes very sensitive, reacts to light stimuli, and begins itching.

Alloimmunization: Rapid consumption of transfused platelets through an immune-mediated reaction.

Alternate forms: All modes of administration other than the mode for which the instrument was originally developed.

Amenorrhea: Lack of menstruation or the abnormal ending of the female menstrual cycle.

American Urological Association (AUA) Symptom Index: A validated questionnaire of seven questions that can be used by patients to assess the bothersomeness of their voiding symptoms. The total score range is 0 to 35. Higher scores are consistent with severely bothersome symptoms.

Amnesia: A pathologic impairment of memory.

AMPA/kainate receptors: Two of three types of ionotropic postsynaptic glutamate receptors. These receptors are similar and are often considered together. On binding glutamate, these receptors permit the influx of sodium ions (Na^+) and results in brain excitation. These are one of the two primary receptors for excitatory neurotransmission in the brain.

Amygdala: A small almond-shaped temporal lobe structure that plays a role in emotions and fear control.

Anaphylactoid: Anaphylaxis-like reactions that do not involve immunoglobulin E (IgE)-mediated mechanisms.

Anaphylaxis: Acute, life-threatening allergic reaction involving multiple organ systems.

Anastomosis: The surgical connection of two tubular structures, such as blood vessels, in a transplanted organ.

Andropause: Refers to a number of symptoms associated with decreased testosterone production by the testes in aging men. The symptoms include decreased libido, increased body fat, depressed

mood, and osteoporosis. The symptoms of andropause generally worsen as the patient ages. Andropause in men parallels menopause in women.

Anemia of chronic disease: Mild to moderate anemia not associated with blood loss or hemolysis. Usually with normal cell size. Can be seen with chronic inflammation (e.g., rheumatoid arthritis, chronic infection) or malignancy.

Anemia of chronic kidney disease: A decrease in red blood cell production caused by a deficiency in the hormone erythropoietin normally produced by progenitor cells of the kidney. As kidney function declines, less erythropoietin is available to stimulate red blood cell production (erythropoiesis) in the bone marrow. Contributing factors include iron deficiency and a shortened, red-blood-cell life span.

Aneuploid: Deviation by a whole number in the total number of chromosomes in a cell compared to normal (46 in humans).

Angioedema: An allergic reaction characterized by edema of a tissue such as the lips, eyes, mouth, joints, or other structures because of leak of fluid from blood vessels.

Anhedonia: A lack of pleasure or interest in usual activities.

Anisocytosis: Considerable variation in the size of cells that are normally uniform, especially with reference to red blood cells.

Ankylosis: Bony fusion resulting from chronic joint inflammation.

Anomia: Cardinal symptom of Alzheimer's disease; inability to name objects or to recognize names.

Anorexia nervosa: A psychiatric disorder in which patients present with a fear of being obese. These patients often express a dislike or lack of interest in food; it is most common in young females and can disrupt normal menstrual cycles. It is associated with poor medication treatment response and can result in fatal medical complications.

Antenatal: Time between conception and birth; same as prenatal.

Anterograde amnesia: Inability to remember events or actions that occur after taking a sedative hypnotic medication.

Antibiogram: A summary of antimicrobial susceptibilities.

Anticipatory anxiety: The fear of having an anxiety attack, which is often a trigger by itself; "fear of fear."

Anticoagulant: Any substance that inhibits, suppresses, or delays the formation of blood clots. These substances occur naturally and regulate the clotting cascade. Several anticoagulants have been identified in a variety of animal tissues and have been commercially developed for medicinal use.

Antigenic drift: The creation of antigenic variants by point mutations in the surface antigens, hemagglutinin and/or neuraminidase, of a particular subtype of influenza.

Antigenic shift: Occurs when an influenza virus acquires a new hemagglutinin and/or neuraminidase.

Antimicrobial cycling: A predetermined change in an antimicrobial recommendation for empiric therapy of a specific infection at a predetermined time.

Antimycotic: Inhibiting fungal growth.

Antithrombotic: A pharmacologic agent that prevents thrombus/clot formation. This category includes both antiplatelet agents and anticoagulants.

Anuria: Production of less than 50 mL of urine/day.

Anxiety: A state of apprehension, uncertainty, and fear resulting from the anticipation of a realistic or fantasized threatening event or situation that often impairs physical and psychological functioning.

Aortic stenosis: Aortic stenosis is the obstruction of blood flow across the aortic valve. This disorder has several etiologies: congenital unicuspid or bicuspid valve, rheumatic fever, and degenerative calcific changes of the valve.

Aphasia: Cardinal symptom of Alzheimer's disease; inability to generate or comprehend spoken language.

Aphthous ulcer: A small superficial area of ulceration within the gastrointestinal mucosa, typically found in the oral cavity.

Apical pulse: Point at the apex (bottom portion) of the heart impacts the chest wall.

Apoptosis: Programmed cell death.

Appendageal: Referring to hair, sweat glands, and nails.

Apraxia: Cardinal symptom of Alzheimer's disease; inability to carry out a motor task in the absence of impaired motor function.

Arteriovenous (AV) fistula: In hemodialysis, a vascular access surgically created by connection of an artery directly to a vein, usually in the forearm.

Arteriovenous (AV) graft: In hemodialysis, a vascular access surgically created using a synthetic tube to connect an artery to a vein.

Arteriovenous malformations: A tangle of blood vessels, both arterial and venous, that can rupture and cause hemorrhage in the brain.

Arthrodesis: The surgical immobilization of a joint (i.e., joint fusion).

Arthropathy: Disease of the joints.

Ascites: Accumulation of serous fluid in the peritoneal cavity.

Asherman's syndrome: A cause for menstrual flow obstruction; often resulting from infection or surgery affecting the endometrium.

Asperger's disorder: A type of pervasive developmental disorder characterized by severe and sustained impairment in social interaction, restricted and repetitive patterns of behavioral/interested activities—similar to autism but without clinically significant delays in language and cognitive development or age-appropriate self-help skills.

Aspiration pneumonitis: The inflammation of lung tissue caused by the aspiration of fluids and gastric contents that often leads to dyspnea, pulmonary edema, secondary infections, and adult respiratory distress syndrome. Hydrocarbon pneumonitis is caused by the pulmonary aspiration of hydrocarbons such as kerosene and gasoline.

Assertive community treatment: A treatment program for the care of individuals with schizophrenia in which teams provide comprehensive wraparound services for the patient, including going to the home to provide support for daily living skills, housing, and supported employment. Team members are available 24 hours daily if needed to meet the patient's comprehensive care needs.

Asystole: The presence of a flat line on the electrocardiogram monitor.

Ataxia: Loss of the ability to coordinate muscular movement.

Atelectasis: Pulmonary parenchymal collapse caused by alveolar or bronchial obstruction.

Atopic dermatitis: Skin inflammation that causes itching, scales, and erythema.

Atopic pleat (Dennie–Morgan fold): An extra fold of skin that develops under the eye, characteristic of atopic dermatitis.

Atopy: An allergic syndrome characterized by asthma, hay fever, and urticaria or eczema.

Atrial fibrillation: Rapid beating of the atria that results in variable ventricular rates.

Atropinism: Symptoms of poisoning by atropine or belladonna.

Aura: Sensory or somatosensory alteration without loss of consciousness.

Augmentation: Addition of a medication not usually used as monotherapy for a disorder to a core medication for a disorder in an attempt to enhance the patient's clinical response.

Auscultation: Listening to the heart or other organs with a stethoscope.

Autism/Autistic disorder: A type of pervasive developmental disorder with a neurobiologic etiology, characterized by impaired reciprocal social interaction, impaired communication skills, and a limited range of activities and interests; frequently associated with mental retardation; sometimes referred to as early infantile autism, childhood autism, or Kanner autism.

Autologous transplantation: Readministration of the same person's cells that were previously collected.

Autosomal: Pertaining to a chromosome.

Axonal transaction: Destroying or severing the axon so that electrical impulses are impeded along the nerve sheath or across the nerve synapse. Axonal damage is not reversible and leads to long-term disability and the formation of black holes.

Azotemia: Term referring to elevated levels of urea in the serum or blood.

Azotorrhea: An excessive loss of protein in the feces.

Bacteremia: Presence of viable bacteria (fungi) in the bloodstream.

Bacterial prostatitis: An inflammation of the prostate gland and surrounding tissue as a result of infection.

Bacteriuria: The presence of bacteria in the urine.

Barrett esophagus: Inflammatory changes in the esophagus resulting in replacement of epithelial lining by columnar-type cells that can lead to stricture or adenocarcinoma.

Basal ganglia and striatum: Parts of the brain regulating movements.

Behavioral phenotype: The actions or reactions of a person to internal or external environmental influences.

Benign prostatic hyperplasia: Nonmalignant enlargement of the prostate gland in elderly men.

Bilateral salpingo-oophorectomy: Surgical excision (removal) of both ovaries.

Biliverdin: A green bile pigment formed from the oxidation of heme.

Binge eating: Excessive intake of calorie-laden food over a short period of time.

Bioavailability: The fraction of drug absorbed into the systemic circulation after extravascular administration.

Biochemical markers: Intracellular macromolecules released into the peripheral circulation from necrotic myocytes as a result of myocardial cell death (infarction). These laboratory tests are used in the diagnosis of myocardial infarction. Examples include troponin I, troponin T, creatinine kinase myocardial band (MB), and myoglobin.

Biofilm: A population or community of microorganisms adhering to a surface by a secreted coating. This coating also reduces microorganism vulnerability to antibiotics.

Biopsy: A procedure in which a tiny piece of a body part, such as the kidney or bladder, is removed for examination under a microscope.

Bioterrorism agents: Organisms or toxins that can cause disease and death in humans, animals, or plants for the purpose of eliciting terror.

Bipolar I disorder: Characterized by one or more manic or mixed episodes, and is usually accompanied by major depressive episodes.

Bipolar II disorder: Characterized by one or more major depressive episodes and accompanied by at least one hypomanic episode.

Bleeding diathesis: A condition in which there is an unusual susceptibility or predisposition to bleeding.

Blood urea nitrogen (BUN): A waste product in the blood that comes from the breakdown of food protein. The kidneys filter blood to remove urea and thus maintain homeostasis. As kidney function decreases, the BUN level increases.

Blood–brain barrier: The relative lack of permeability of large molecules (and those molecules lacking lipid solubility) into the central nervous system because of the nonfenestrated capillary beds of the cerebral vasculature.

Borborygmi: Rumbling or gurgling noises produced by movement of gas, fluid, or both in the alimentary canal and audible at a distance.

Brachytherapy: A procedure in which radioactive material sealed in needles, seeds, wires, or catheters is placed directly into or near a tumor. Also called internal radiation, implant radiation, or interstitial radiation therapy.

Bradykinesia: Delay or slowness in initiating and performing purposeful, voluntary movement as seen in Parkinsonism.

Breakthrough bleeding: The unpredictable and irregular bleeding associated with hormone therapy.

Bronchiectasis: Dilation of a bronchus or bronchi, usually related to excessive secretions.

Bronchioles: A subdivision of bronchi; smaller in diameter and without cartilage.

Bronchiolitis: Inflammation of the bronchioles.

Bronchoalveolar lavage: Instilling and then removing a lavage fluid to reveal the secretory and/or cellular contents from deep in the lung.

Bronchorrhea: Excessive bronchial secretions that can impair pulmonary ventilation.

Bruit: An abnormal and often harsh sound heard over a blood vessel, usually an artery, on examination with a stethoscope caused by turbulent blood flow.

B-type natriuretic peptide: B-type natriuretic peptide is a 32-amino-acid polypeptide secreted by the ventricles in response to excessive myocyte stretching. Elevated levels are typically seen in patients with left ventricular dysfunction and can correlate with both the heart failure severity and the prognosis.

Bulimia nervosa: A psychiatric disorder manifested by episodes of consuming a large caloric load over a short period of time (binge eating), with subsequent self-induced vomiting, use of cathartics or diuretics, fasting, or excessive exercise to prevent weight gain.

BUN (blood urea nitrogen): A waste product in the blood that comes from the breakdown of food protein. The kidneys filter blood to remove urea. As kidney function decreases, the BUN level increases.

Bursitis: Inflammation of the bursa, a fluid-filled soft tissue structure that usually results in pain and swelling.

Caffeinism: A clinical syndrome produced by acute or chronic overuse of caffeine characterized by anxiety, psychomotor alterations, sleep disturbances, mood changes, and psychophysiologic complaints.

Calcimimetic: A class of agents that stimulate calcium-sensing receptors on the parathyroid gland and *mimic* the effects of extracellular calcium. They suppress parathyroid hormone (PTH) release and increase the sensitivity of the receptor to extracellular calcium.

Calcium-sensing receptor: The calcium receptor on the chief cells of the parathyroid gland, activation of which leads to suppression of PTH release.

Candidiasis: Fungal infection involving *Candida* species.

Carbuncles: Broad, swollen, erythematous, deep, and painful, follicular masses commonly associated with fever, chills, and malaise.

Carcinoid: A carcinoid is a slow-growing tumor usually located in the gastrointestinal system and sometimes in the lungs or other sites. Carcinoids can spread to the liver and can secrete serotonin or prostaglandins.

Cardiac arrest: The cessation of cardiac mechanical activity as confirmed by the absence of signs of circulation.

Cardiac index: Cardiac output standardized for body surface area. Mathematically, cardiac index = cardiac output/body surface area.

Cardiac output: The volume of blood pumped by the heart per unit of time. Cardiac output is the product of heart rate and stroke volume.

Cardioembolic stroke: An ischemic stroke thought to be caused by an embolism arising from the heart. Cardioembolic stroke can be assumed in patients with significant cardiovascular disease including atrial fibrillation, dilated cardiomyopathy, prosthetic valves, recent myocardial infarction (MI), and patent foramen ovale.

Cardiopulmonary arrest: The abrupt cessation of spontaneous and effective ventilation and circulation following a cardiac or respiratory event.

Cardiopulmonary bypass: The use of extracorporeal devices to pump blood and oxygenate the blood while the heart or lungs are not functional. Extracorporeal membrane oxygenation (ECMO) is a form of long-term cardiopulmonary bypass that is typically used for days to weeks.

Cardiopulmonary resuscitation: The attempt to restore spontaneous circulation by performing chest compressions with or without ventilations.

Carotid Doppler: A technique that provides information about the presence and severity of atherosclerosis of the carotid artery using noninvasive sound wave technology.

Carotid endarterectomy: Removal of the atherosclerotic plaque from the inside of a stenotic carotid artery by a surgical technique. The vessel is surgically opened and sewn and/or patched after removal of the plaque.

Carpal tunnel syndrome: A medical condition in which the median nerve is compressed at the wrist, leading to parethesias, numbness, and muscle weakness in the hand.

Case-control study: An observational study of persons with the disease of interest (cases) and a suitable control group of persons without the disease to establish the extent of association between exposure(s) of interest and disease.

Cataplexy: A sudden loss of muscle control with retention of clear consciousness that follows a strong emotional stimulus (e.g., elation, surprise, or anger) and is a characteristic symptom of narcolepsy.

Cellulitis: An acute, infectious process that initially affects the epidermis and dermis and can subsequently spread within the superficial fascia.

Centrilobular: Affecting the central portion of the lobe.

Cerebral autoregulation: The process by which cerebral blood flow is maintained in a tight range over a wide range of peripheral blood pressures. It is accomplished by reactive dilation and constriction of cerebral arteries.

Cerebral blood flow (CBF): The volume of blood perfusing a given brain mass as a function of time.

Cerebral blood volume (CBV): The total volume of blood within the cerebral vasculature at a given point in time.

Cerebral microdialysis: A sampling method that allows continuous acquisition of a small volume of cerebral extracellular fluid specimens using a microdialysis probe inserted into the brain.

Cerebral oxygen consumption ($CMRO_2$): The cerebral metabolic rate for oxygen consumption calculated as the mean hemispheric CBF and the arteriovenous oxygen content difference ($AVDO_2$).

Cerebral oxygen delivery (CDO_2): The product of CBF and arterial oxygen content.

Cerebral perfusion pressure: A critical monitoring parameter in traumatic brain injury patients defined as the difference between the mean arterial pressure and the intracranial pressure.

Cerebrospinal fluid: The clear, colorless fluid that bathes and cushions the brain and spinal cord.

Cervical cap: A thimble-shaped latex rubber device that is held on the cervix by suction, thus acting as a barrier to reduce the risk of pregnancy.

Cervical effacement: During the first stage of labor, as the cervix is opening, it is also thinning. The thinning of the cervix is termed *effacement*.

Cervical ripening: Prior to inducing labor, the cervix must be favorable, approximately 2 cm dilated and 80% thinned out. If this is not the case, an agent must be used to induce histochemical changes to make the cervix more favorable.

Cervical stenosis: A cause for menstrual flow obstruction; often caused by surgical interventions for cervical dysplasia.

Cervicitis: Inflammation of the cervix.

Chancre: A sore or ulcer, the dermal lesion of primary syphilis.

Chancroid: A venereal dermal lesion caused by agents other than syphilis.

Cheilitis: Inflammation of the lips; can be related to retinoid use.

Children: Pediatric patients who are 1 to 11 years of age.

Cholelithiasis: A solid formation in the gallbladder or bile duct composed of cholesterol and bile salts. Also known as gallstone.

Cholestatic hepatitis: Rare form of hepatitis marked by stopped or suppressed flow of bile; characterized by pruritus, dark urine, light-colored stools, elevated alkaline phosphatase, and conjugated bilirubin.

Cholinesterase inhibitors: Class of medication that inhibits enzymatic activity of acetylcholinesterase, butyrylcholinesterase, or both to prevent the degradation of acetylcholine.

Chronic condition: An illness or impairment that cannot be cured.

Chronic kidney disease (CKD): Slow and progressive loss of kidney function that takes several years, often resulting in permanent kidney failure requiring dialysis or transplantation.

Chronic pain/persistent pain: Pain persisting for months to years.

Chronic pancreatitis: Chronic inflammation of the pancreas caused by the many sequelae of long-standing pancreatic injury leading to irreversible pancreatic damage.

Chvostek's sign: A facial twitch produced by tapping on the cheek over the branches of the facial nerve.

Circumstantial speech: Speech pattern whereby the expressed ideas are characterized by unnecessary detail. The speaker ultimately makes their point, but in a very roundabout manner.

Clearance: the volume of blood per unit of time (e.g. L/h, mL/min) completely cleared of a drug.

Clinical inertia: A clinical situation in which no therapeutic move was made to treat a medical condition in a patient that is not considered adequately treated, or at their treatment goal.

Clinical outcomes: Medical events that occur as a result of the condition or its treatment.

Clinical pharmacokinetics: The discipline that describes the absorption, distribution, metabolism, and elimination of drugs in patients.

Clinical proteinuria: Total protein in the urine in amounts greater than 300 mg/day.

Clinical resistance: Refers to failure of an antifungal agent in the treatment of a fungal infection that arises from factors other than microbial resistance, such as failure of the antifungal agent to reach the site of infection, or inability of a patient's immune system to eradicate a fungus whose growth is retarded by an antifungal agent.

Clinically isolated syndrome: The first attack of multiple sclerosis characterized by a neurologic syndrome such as optic neuritis and generally seen with silent or asymptomatic white matter lesions (seen on magnetic resonance imaging) suggestive of demyelination. Individuals that experience a clinically isolated syndrome are at high risk of developing definite multiple sclerosis.

Clotting cascade: A series of enzymatic reactions by clotting factors leading to the formation of a blood clot. The clotting cascade is initiated by several thrombogenic substances. Each reaction in the cascade is triggered by the preceding one, and the effect is amplified by positive feedback loops.

Clotting factor: Plasma proteins found in the blood that are essential to the formation of blood clots. Clotting factors circulate in inactive forms but are activated by their predecessor in the clotting cascade or a thrombogenic substance. Each clotting factor is designated by a Roman numeral (e.g., factor VII) and by the letter "a" when activated (e.g., factor VIIa).

Cluster headache: A primary headache disorder characterized by attacks of severe unilateral headache pain that occurs in series of weeks or months (cluster periods) separated by remission periods usually lasting months or years.

Cluster period: The time during which cluster-headache attacks occur regularly and at least once every other day.

Codon: A sequence of three consecutive nucleotides that specify an amino acid or amino acid chain termination.

Coelomic metaplasia: Transformation of normal cells into endometrial cells.

Cognitive behavioral therapy: A form of psychotherapy designed to replace distorted or inappropriate ways of thinking with healthy, more realistic thoughts to alter maladaptive moods and behavior. It is instructional in approach and is based on the theory that thoughts (not external influences such as people, situations, and events) cause feelings and behaviors. Patients learn to identify the thinking that causes the negative feelings and behaviors and then learn how to replace that thinking with thoughts that lead to more desirable feelings and behaviors.

Cogwheeling: A ratchet-like movement in the joints, characteristic of Parkinson disease.

Cohort study: Assembly of a group of persons without a disease(s) of interest at the onset of the study, determination of the exposure status of each person, and observation of the cohort over time to determine the development of disease in exposed and nonexposed persons.

Colectomy: Surgical removal of the colon.

Colonization resistance: Preservation of anaerobic flora by selective gut decontamination to prevent colonization by potentially pathogenic gram-negative organisms.

Colony-stimulating factors: Proteins that regulate the proliferation, maturation, and differentiation of stem cells to red blood cells, white blood cells, and platelets.

Coma: A state of unconsciousness whereby a patient is not opening his or her eyes, not obeying commands, and not uttering understandable words.

Comedo, comedones (pl.): Plug of sebum and keratinous material in a hair follicle; blackhead.

Comedogenicity: Product effect that causes follicular plugging resulting in comedones.

Comedolytic: Prevents shed keratinocytes from aggregating in follicle and clogging pores.

Communities: Organized groups of people with a shared identity or relationship that may be based on history, culture, context, or geography.

Comorbidity: A concomitant but unrelated pathologic or disease process.

Complementary and alternative medicine (CAM): Any practice for the prevention and treatment of disease that is not usual conventional medicine.

Complex partial seizure: A seizure beginning in one hemisphere of the brain. It is manifested by automatisms, periods of memory loss, or aberrations of behavior.

Compulsion: Repetitive ritualistic behavior such as ordering or hand washing or a mental act such as repeating words silently with the intent of preventing or reducing distress or some dreaded event or situation.

Conceptual model: The rationale for and description of the concepts that a measurement instrument is intended to assess and the interrelationships of those concepts.

Condom: A sheath, usually made of thin rubber, used to cover the penis during sexual intercourse to prevent conception or infection.

Confounding: A situation in which the effects of two processes are not separated. The distortion of the apparent effect of an exposure on risk brought about by the association of other factors that can influence the outcome.

Constrictive pericarditis: Constrictive pericarditis is a disorder caused by inflammation of the pericardium with subsequent thickening, scarring, and contracture of the pericardium. The pericardium cannot stretch during contraction, thereby preventing chamber filling.

Construct validity: The strength of the relationship between measures purporting to measure or reflect the same underlying theoretical construct.

Content validity: Refers to how adequately the questions/items capture the relevant aspects of the domain or concept being measured.

Continuation therapy: The second phase in drug therapy during which the goal is to eliminate any remaining symptoms and prevent a relapse.

Continuous-combined estrogen-progestogen therapy: Daily administration of both estrogen and a progestogen.

Continuous long-cycle estrogen-progestogen therapy: Estrogen is given daily and a progestogen is given six times a year (every other month for 12 to 14 days).

Convection: The movement of solutes, or metabolic waste products, by bulk flow in association with fluid removal. Convective clearance is not dependent on concentration gradients, and the magnitude of its contribution to total clearance is directly related to the ultrafiltration (fluid removal) rate.

Convulsion: Specific seizure type where the seizure is manifested by involuntary muscle contractions.

Cor pulmonale: Right-sided heart failure caused by lung disease.

Corneocytes: Flattened, dead, keratin-filled epidermal cells.

Coronary artery bypass graft surgery (CABGS): Thoracic surgery where parts of a saphenous vein from a leg or internal mammary artery from the arm are placed as conduits to restore blood flow between the aorta and one or more coronary arteries to *bypass* the coronary artery stenosis (occlusion).

Corpus cavernosum: Two chambers on the dorsal side of the penis. Chambers composed of sinusoidal tissue, which can fill with arterial blood to produce an erection.

Corpus luteum: The small yellow endocrine structure that develops within a ruptured ovarian follicle and secretes progesterone and estrogen.

Corpus spongiosum: One chamber on the ventral side of the penis. Chamber is composed of sinusoidal tissue, which can fill with arterial blood to produce an erection. The urethra passes through the corpus spongiosum.

Cortical necrosis: Acute renal failure secondary to ischemic necrosis of the renal cortex usually caused by significantly diminished renal arterial perfusion.

Corticotropin-releasing hormone (CRH): A trophic hormone released by the hypothalamus that stimulates release of adrenocorticotropic hormone (ACTH).

Cost-effectiveness ratio: The outcome of cost-effective analysis. The numerator of the ratio summarizes the costs and financial savings associated with the therapy, including the costs of the therapy itself, side effects, medical costs, and savings from avoided illness and disability. The denominator of the cost-effectiveness ratio reflects the health effect of the intervention. The year of life saved is probably the most commonly used measure of the health effect.

Cranial nerve palsy: Paralysis of one or more of the 12 cranial (brain) nerves.

Craniectomy (for stroke): Removal of part of the skull overlying an area of injury to relieve the pressure of cerebral edema.

C-reactive protein: An endogenous marker released by the body in response to inflammation.

Creatine kinase, creatine kinase MB: Creatine kinase (CK) enzymes are found in many isoforms, with varying concentrations depending on the type of tissue. Creatine kinase is a general term used to describe the nonspecific total release of all types of CK, including that found in skeletal muscle (MM), brain (BB), and heart (MB). Creatine kinase MB is released into the blood from necrotic myocytes in response to infarction and is a useful laboratory test for diagnosing myocardial infarction. If the total CK is elevated, then the relative index (RI), or fraction of the total that is composed of CK-MB, is calculated as follows:

$$RI = (\text{CK-MB}/\text{CK total}) \times 100$$

A RI greater than 2 is typically diagnostic of infarction.

Creatinine (serum): A protein metabolic by-product obtained from the diet or generated from muscles of the body. Creatinine is removed from blood by the kidneys; as kidney disease progresses, the level of creatinine in the blood increases.

Creatinine clearance: A test that measures how efficiently the kidneys filter creatinine and other waste products from the blood. Low creatinine clearance (<60 mL/min) usually indicates the presence of kidney damage.

Crepitus: A crinkly, crackling, or grating feeling or sound in the joints, skin, or lungs.

Cronbach α-coefficient: Commonly used statistical measure to quantify internal consistency reliability for multi-item scales or tests.

Crossmatch: A test to determine if a recipient has antibodies against donor antigens. A positive crossmatch indicates that the recipient has antibodies against the donor, and the two are incompatible. A negative crossmatch means the recipient does not have antibodies against the donor, and the two are considered compatible.

Crust: Dried exudate, secretion, or hemorrhage; scab.

Crypt abscess: Neutrophilic infiltration of the intestinal glands (Crypts of Lieberkuhn); a characteristic finding for patients with UC.

Cultural competency: The attitudes, knowledge, skills, and values that an individual and/or an organization acquires, develops, and uses to work effectively in a cross-cultural environment.

Culture: The acquired and shared attitudes, beliefs, knowledge, and values that individuals and/or groups use to influence their actions and behavior.

Culture negative endocarditis: Describes a patient in whom a clinical diagnosis of infective endocarditis is likely, but blood cultures do not yield a pathogen.

Cutaneous: Pertaining to the skin.

Cutis: Skin.

Cyanopsia: A condition when a patient sees a blue halo around objects, or objects appear to be blue-colored.

Cyanosis: Bluish tint to the skin or mucous membranes because of lack of oxygen.

Cyclic estrogen-progestogen therapy: Estrogen is taken continuously, with a progestogen added cyclically the last 10 to 14 days during each 28-day cycle.

Cyst: Sac or closed cavity containing fluid, semifluid, or solid material.

Cystitis: Inflammation of the bladder, usually caused by infection.

Cytokines: Protein molecules that are released by one cell (e.g., T-lymphocytes) that can have an influence on other cells. These proteins are important in numerous cell functions, such as regulating the immune response and cell-to-cell communication.

Dactylitis: Erythema and swollen hands, feet, fingers, and toes. Also known as *hand-and-foot syndrome*.

Deep vein thrombosis: A disorder of thrombus formation causing obstruction of a deep vein in the leg, pelvis, or abdomen.

Defibrillation: The therapeutic use of electric current in attempt to completely depolarize the myocardium and provide an opportunity for the natural pacemaker centers of the heart to resume normal activity.

Delayed cerebral ischemia: A worsening in neurologic function in a subarachnoid hemorrhage patient, occurring several days after the initial bleed, not due to another cause.

Delusion: Fixed, false beliefs that are not based in reality or consistent with the patient's religion or culture. Delusions can be classified as paranoid, somatic, or grandiose in nature. Delusions are often unshakable in spite of evidence to the contrary.

Dementia: A chronic progressive neurodegenerative syndrome characterized by a decline in memory and at least one other cognitive function.

Demyelination: Destruction of myelin in the spinal cord and brain leading to the formation of plaques that impair communication between neurons. Demyelination is classically found in the central nervous system of patients with multiple sclerosis and may be reversible.

Depersonalization: A change in an individual's self-awareness, during anxiety disorder, such that one feels detached from his or her own experiences, with the self, body, and mind seeming alien or distant. Persistent or recurrent experiences as if one is an outside observer of one's mental processes or body (e.g., feeling like one is in a dream).

Derealization: A feeling of estrangement or detachment from one's environment.

Dermatitis: Inflammation of the skin.

Dermatophyte: Fungal infection of the skin.

Dermis: The inner layer of skin between the epidermis and hypodermis.

Desensitization: Administration of increasing doses of drug to achieve patient tolerance and avoidance of hypersensitivity reactions.

Detoxification programs: A medically supervised treatment program for alcohol or drug addiction designed to purge the body of intoxicating or addictive substances. Such a program is used as a first step in overcoming physiologic or psychologic addiction.

Detumescence: Process by which an erect penis becomes flaccid.

Diagnostic overshadowing: Underestimating the significance of the emotional disturbances because of the presence of significant cognitive deficits.

Dialysate: The cleansing solution used in dialysis to remove excess fluids and waste products from the blood.

Dialysis: The process of removing toxic substances and fluid across a semipermeable membrane to maintain fluid, electrolyte, and acid–base balance.

Diaphragm: (1) A flexible ring covered with rubber or other plastic material, fitted over the cervix of the uterus to prevent pregnancy. (2) Muscular membrane separating the abdominal and thoracic cavities, used for respiration.

Diastolic blood pressure: The arterial BP that occurs after cardiac contraction when the cardiac chambers are filling.

Diastolic heart failure: A condition caused by increased resistance to the filling of one or both ventricles; this leads to symptoms of congestion from the inappropriate upward shift of the diastolic pressure-volume relation.

Diffuse idiopathic skeletal hyperostosis (DISH): A form of degenerative arthritis caused by calcification or a bony hardening of ligaments alongside the vertebrae of the spine. Also known as Forestier disease.

Diffuse idiopathic skeletal hyperostosis (DISH): Abnormal bone formation with calcifications and ossifications along the anterolateral aspect of vertebral bodies. A variant of Forestier disease.

Diffusion-weighted imaging: A type of magnetic resonance imaging (MRI) that can sensitively detect changes in water movement in tissue. It is particularly sensitive to the early changes seen during brain ischemia.

Digital clubbing: Rounded and swollen tip of finger usually associated with long-term pulmonary disease.

Dihydrotestosterone: The active androgen metabolite, which is formed inside various cells. In the case of benign prostatic hyperplasia (BPH), dihydrotestosterone is formed inside prostate cells by the action of 5-α-reductase, which converts testosterone to dihydrotestosterone. Dihydrotestosterone stimulates the glandular portion of the prostate to undergo hyperplasia.

Disinhibition: A physiologic effect that occurs during psychoactive substance use characterized by a loss of normal, executive functioning and normal behavior. An increase in behaviors with the propensity to harm the individual is common.

Dissociative amnesia: Inability to remember some important aspect of an event.

Diverticulitis: Inflammation of a diverticulum, especially of the small pockets in the wall of the colon that fill with stagnant fecal material and become inflamed; rarely, they can cause obstruction, perforation, or bleeding.

Dopamine: A monoamine neurotransmitter formed in the brain by the decarboxylation of dopa and essential to the normal functioning of the central nervous system.

Doppler imaging: With Doppler imaging, a probe generates sound waves typically at 2.5 MHz. When encountering an object, sound waves are scattered or reflected back toward the probe from the object's interface with adjacent structures; this is repeated in many times per second to build up a moving real-time image of the heart.

Drug abuse: A maladaptive pattern of substance use indicated by repeated adverse consequences related to the repeated use of the substance. Examples include failure to fulfill important obligations at work, school, or home; repeated use in situations in which it is physically dangerous, such as driving under the influence; legal problems; and social or interpersonal problems such as arguments and fights.

Drug addiction: A chronic disorder characterized by the compulsive use of a substance resulting in physical, psychologic, or social harm to the user and continued use despite that harm.

Dual diagnosis: A developmentally disabled person comorbid with a psychiatric disorder.

Dumping syndrome: A condition characterized by weakness, dizziness, flushing/warmth, nausea, and palpitation immediately or shortly after eating and produced by abnormally rapid emptying of the stomach, particularly in individuals who have had part of the stomach removed.

Dysentery: Diarrhea characterized by blood, mucus, and leukocytes in the stool with tenesmus and fever.

Dyskinesia: Choreiform abnormal involuntary movements involving usually the face, neck, trunk, and extremities.

Dysmenorrhea: Crampy pelvic pain occurring with or just prior to menses. *Primary* dysmenorrhea implies pain in the setting of normal pelvic anatomy, whereas *secondary* dysmenorrhea is secondary to underlying pelvic pathology.

Dyspareunia: Painful sexual intercourse.

Dyspepsia: Literally means "bad digestion" but refers to persistent or recurrent pain or discomfort centered in the upper abdomen. Symptoms may include epigastric pain, bloating, abdominal distention, postprandial fullness, early satiety, and nausea.

Dysphagia: Difficulty swallowing.

Dysphoria or dysphoric: A feeling of discomfort or an unpleasant mood, such as sadness, anxiety, or irritability.

Dyspnea: Dyspnea is referred to as shortness of breath or difficulty or distress in breathing.

Dystonia: Sustained muscular spasm or abnormal postures.

Early empirical therapy: The administration of systemic antifungal agents at the onset of fever and neutropenia.

Economic outcomes: The direct, indirect, and intangible costs compared with the consequences of a medical intervention.

Edema: Accumulation of fluid in tissues.

Effective renal plasma flow (ERPF): The flow of plasma through the kidneys; often measured by *p*-aminohippurate (PAH) clearance and expressed in volume per unit of time (mL/min). The ERPF is less than the true renal plasma flow (RPF) because plasma flow through renal connective and adipose tissue is not measured and the extraction of PAH, although high (>0.9), is not complete.

Ejaculatory dysfunction: This is a type of sexual dysfunction that can present as premature ejaculation (before orgasm has occurred), anejaculation (failure of emission), or retrograde ejaculation (when ejaculate moves backward into the bladder as opposed to forward and out of the body during orgasm). In some cases, ejaculatory dysfunction can decrease sexual enjoyment in the patient.

Ejection fraction: The ejection fraction is the percentage of blood ejected from the left ventricle with each heart beat.

Elation: An exaggerated feeling of well-being, euphoria, or elation.

Electroconvulsive therapy: A treatment for severe mental illness in which a precisely calculated electric stimulus is administered in a controlled medical setting to produce a generalized seizure.

Electroencephalograph (EEG): Used to evaluate brain electrical activity.

Electroencephalography: A test that measures electrical brain wave activity through the use of multiple scalp electrodes.

Electromyography: Test of muscle function because of either primary muscle disease or secondary to nerve injury.

Embolism: The sudden blockage of a vessel caused by a blood clot or foreign material that has been brought to the site by the flow of blood.

Embolization: The process by which a blood clot or foreign material dislodges from its site of origin, flows in the blood, and blocks a distant vessel.

Emergency contraception: Any method of contraception that acts after intercourse to prevent pregnancy.

Emesis: See *Vomiting*.

Empirical therapy: With systemic antifungal agents is administered to granulocytopenic patients with persistent or recurrent fever despite the administration of appropriate antimicrobial therapy.

Enanthem: Eruption on a mucous membrane (as the inside of the mouth) occurring as a symptom of a disease

Encephalitis: Inflammation of the brain tissue.

Encephalopathy: An altered brain state that may occur with altered brain structure. Many etiologies are associated with encephalopathy

(toxins, cancer, metabolic disorders, CNS infections, increased cranial pressure, radiation, alcohol, psychotropic drugs, trauma, inadequate nutrition, decreased brain oxygen, and CNS injury). Consciousness is impaired with patients having a decreased/altered mental state and diffuse slowing of the EEG.

Endobronchitis: Inflammation of the epithelial lining of the bronchi.

Endocarditis: An infection of the endocardial surface of the heart, which can include one or more heart valves, the mural endocardium, or a septal defect.

Endometriosis: Presence of endometrial tissue outside the uterus.

Enkephalins: Pentapeptide endorphins, found in many parts of the brain, that bind to specific receptor sites, some of which can be pain-related opiate receptors.

Enteric fever: Intestinal inflammation and ulceration with high fever and abdominal complaints caused by infection.

Enterocolitis: Inflammation of the small intestine and colon.

Enterotoxin: A cholera-like disease that produces secretory diarrhea.

Enuresis: Urinary incontinence, especially at night.

Enzymuria: Presence of enzymes in the urine.

Epidermis: The outer layer of skin.

Epigenetic: A change in the genome that is heritable and potentially reversible that does not alter the nucleotide sequence of DNA.

Epilepsy: Two or more unprovoked seizures; symptoms of disturbed electrical activity in the brain.

Epilepsy syndrome: The combination of seizure type with other components of the patient history such as age of onset, intellectual development, findings on neurologic examination, and results of neuroimaging.

Episodic: Recurring and remitting in a regular or irregular pattern.

Epistaxis: Nose bleed.

Epithelial cells: Cells that make up epithelium.

Epithelial tissue of the prostate: Also known as glandular tissue. This portion of the prostate is responsible for producing prostatic secretions, and this comprises only approximately 25% of the total volume of the enlarged prostate gland in patients with benign prostatic hyperplasia. Epithelial tissue is androgen dependent.

Epithelium: Layer of avascular cells covering body surfaces.

Erectile dysfunction: Also known as *impotence*. This is a failure of the penis to become rigid enough to allow for vaginal penetration of the sexual partner.

Erysipelas: Infection of the more superficial layers of the skin and cutaneous lymphatics.

Erythema: Redness.

Erythema multiforme: Symmetrical patches of raised, red skin.

Erythema nodosum: Raised, red, tender nodules on the skin that vary in size from 1 cm.

Erythroderma: Generalized redness of the skin.

Erythropoiesis: The production of erythrocytes (red blood cells) within the bone marrow.

Erythropoietic agents: Agents developed with recombinant DNA technology that have the same biologic activity as endogenous erythropoietin to stimulate red blood cell production. Available agents in the United States include epoetin alfa and darbepoetin alfa.

Erythropoietin: A hormone made by the kidneys that is required for red blood cell formation in the bone marrow. Lack of this hormone leads to anemia.

Eschar: Black, painless skin ulcer characteristic of cutaneous anthrax.

Esophageal: Involving the esophagus.

Esophageal stricture: A narrowing of the esophageal lumen because of acid reflux into the lower esophagus.

Esophagitis: Inflammation of the esophagus.

Essential hypertension: Persistently elevated BP that results from unknown pathophysiological etiology.

Essential or primary hypertension: Persistently elevated blood pressure that results from unknown pathophysiological etiology.

Estrogen therapy: Unopposed estrogen regimens administered to postmenopausal women following hysterectomy.

Euphoria: A mood state characterized by an exaggerated, superficial sense of well-being, characterized extreme happiness, sometimes more than is reasonable in a particular situation.

Euthymia or euthymic: A mood in a *normal* range without depression or mood elevation.

Evidence-based medicine (EBM): Evidence-based medicine emphasizes the consideration of results from clinical research as the basis for clinical decision making. Under this practice approach, unless individual patient-specific factors dictate otherwise, treatment should generally be guided by those approaches that have the best research evidence for efficacy, tolerability, and patient acceptance.

Evoked potentials: EEG-based technique involving measurement of brain-wave activity in response to stimuli, usually visual or auditory.

Exanthema: An eruption on the skin occurring as a symptom of a disease.

External beam radiotherapy: Treatment by radiation emitted from a source located at a distance from the body; also called beam therapy and external beam therapy.

Extrapyramidal: Regarding involuntary motor movement.

Extrapyramidal system: Neurotransmitter tracts in the midbrain with dopamine as the primary ascending neurotransmitter, with cell bodies in the substantial nigra and axons terminating in the basal ganglia (e.g., caudate nucleus, putamen). The extrapyramidal system is largely involved in the control of fine motor movements, and with some degree of emotional expression as well.

Fasciculations: The localized contractions of muscle groups, often visible through the skin, because of excessive neuronal discharge.

Fear: A direct, focused response to a specific event or object of which an individual is consciously aware.

Felty syndrome: Rheumatoid arthritis associated with splenomegaly and neutropenia.

Fibrin: An insoluble protein that is one of the principle ingredients of a blood clot. Fibrin strands bind to one another to form a fibrin mesh. The fibrin mesh often traps platelets and other blood cells.

Fibromyalgia: A syndrome characterized by chronic widespread pain, multiple tender points, abnormal pain, sleep disturbances, fatigue, and psychological distress.

Fibrosis: Formation of fibrous tissue as a reparative or reactive process.

First-generation (typical or traditional) antipsychotic: An antipsychotic medication with a mechanism of action thought to be primarily caused by the blockade of dopamine-2 (D_2) receptors. D_2-blockade is associated with hyperprolactinemia and extrapyramidal side effects.

Fistula: A communicating tube-like passage from one organ to another or from an organ to an external surface; often seen in severe cases of Crohn's disease.

Flight of ideas: An accelerated flow of speech with thoughts that change rapidly from one topic to another.

Focal seizures: Partial seizures.

Follicle-stimulating hormone (FSH): A polypeptide hormone secreted by the anterior pituitary gland that promotes ovarian follicle development and stimulates estradiol and progesterone.

Fragile X syndrome: A genetic disorder commonly associated with mental retardation in which the tip of the long arms of the X chromosome separates from the rest of the genetic material; most males and 30% of females with fragile X syndrome have mental retardation; males develop enlarged testicles, enlarged ears, and a prominent jaw.

Freezing: Intermittent immobility lasting a few seconds, particularly in walking, seen in Parkinsonism.

Fulminant hepatitis: Acute hepatic failure; rare complication of viral hepatitis, it can also result from hepatotoxins, or drug sensitivity and causes massive necrosis of the liver; marked by a high fatality rate.

Functional analysis: Evaluation performed by a psychologist qualified in applied behavioral analysis to determine if a behavior is caused by some environmental factor.

Functional pain: Pain due to abnormal operation of the nervous system.

Functional psychiatric disorder: A mental disorder that is primarily defined by a constellation of symptoms and behaviors and for which the pathophysiologic etiology is still largely unknown.

Fungemia: The presence of fungi in the blood.

Gastroesophageal reflux disease (GERD): Symptomatic clinical condition or histologic alteration that results from episodes of gastroesophageal reflux.

Gene: Series of codons that specify a particular protein.

Generalized anxiety disorder (GAD): Excessive anxiety and worry occurring more days than not for a period of at least 6 months.

Generalized convulsive status epilepticus (GCSE): Most common and dangerous type of status epilepticus. It consists of bilateral (both brain hemispheres) electrical seizure activity that manifests as tonic and/or clonic motor activity. The convulsions and/or brain discharges can be symmetrical or asymmetrical (i.e., parts of body and brain mirroring or not mirroring each other in activity). Consciousness is not maintained during the seizures episodes. The duration is sufficient enough in length to meet the definition of status epilepticus.

Generalized seizures: Seizures occurring in both hemispheres of the brain. They can be primary or secondarily generalized.

Generic/general measures: Instruments designed to be applicable across a wide variety of conditions/diseases, medical interventions, and populations.

Genotype: The genetic constitution of an individual.

Genu valgum: A deformity marked by lateral angulation of the leg in relation to the thigh.

Genu varum: A deformity marked by medial angulation of the leg in relation to the thigh; an outward bowing of the legs.

Gestation: Time from fertilization of egg until birth.

Gigantism: Excess secretion of growth hormone prior to epiphyseal closure in children.

Glasgow coma scale: The most widely used system to grade the arousal and functional capacity of the cerebral cortex consisting of eye opening, motor responses, and verbal responses.

Glaucoma: Any of a group of ocular disorders that lead to an optic neuropathy characterized by changes in the optic nerve head (optic disk) that is associated with loss of visual sensitivity and field. Open angle and closed angle are the two major types of glaucoma.

Glomerular filtration rate (GFR): The primary index of overall kidney function; the volume of plasma that is filtered by the glomerulus per unit of time; often reported in mL/min or mL/min/1.73 m^2.

Glomerulonephritis: Glomerular lesions characterized by inflammation of the capillary loops in the glomerulus caused by immunologic, vascular, and other idiopathic diseases (may be diffuse or membranoproliferative).

Glomerulosclerosis: Fibrosis of the glomeruli.

Glomerulus: A coiled capillary bed in the kidney that is responsible for filtering water and small molecular weight substances from the blood.

Gonadotropin: A sex hormone that promotes gonadal growth and functioning in both males and females.

Gonadotropin-releasing hormone (GnRH): A trophic hormone released by the hypothalamus that stimulates release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH).

Gout: A disease spectrum that includes hyperuricemia, recurrent attacks of acute arthritis associated with monosodium urate crystals in leukocytes found in synovial fluid, deposits of monosodium urate crystals in tissues (tophi), interstitial renal disease, and uric acid nephrolithiasis.

gp120: The glycoprotein structure on the surface of human immunodeficiency virus (HIV) that binds to CD4 on human cells.

Grandiosity: An inflated self-appraisal of one's status, power, or identity.

Granuloma inguinale: Granuloma lesions affecting the genital area.

Growth hormone (GH): A polypeptide hormone secreted by the anterior pituitary gland that stimulates insulinlike growth factor-1 (IGF-1) production and promotes growth of all body cells.

Growth hormone-releasing hormone (GHRH): A trophic hormone released by the hypothalamus that stimulates release of growth hormone.

Guillain-Barré's syndrome: A disorder characterized by progressive symmetrical paralysis and loss of reflexes, usually beginning in the legs. The paralysis typically involves more than one limb, is progressive, and usually proceeds from the end of an extremity toward the torso. Areflexia or hyporeflexia can occur in the limbs. It typically occurs after recovery from a viral infection.

Gumma: A granulomatous lesion found in organs or tissues as a result of syphilis.

Gynecomastia: Gynecomastia is the abnormal development of large breasts in men.

Half-life: The time required for serum concentrations to decrease by one-half after absorption and distribution are complete.

Hallucination: A sensory perception (e.g., auditory, gustatory, olfactory, somatic, tactile, visual) that occurs without external stimulation of the relevant sensory organ.

Haplotype: Set of polymorphisms that are inherited together.

Haptocorrin: A group of carrier proteins that bind with vitamin B_{12} in the blood and aid in its transport.

Haptoglobin: A group of α_2-globulins in human serum, so called because of their ability to combine with hemoglobin, preventing loss in the urine; levels are decreased in hemolytic disorders and increased in inflammatory conditions or with tissue damage.

Hay fever: See *Rhinitis*.

Health literacy: The degree to which individuals have the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions (as defined by the Institute of Medicine).

Health outcomes: The consequences or ends results of a disease and/or its treatment.

Health profiles: Generic instruments that provide an array of scores representing individual dimensions or domains of health-related quality of life (HRQOL) or health status.

Health-related quality of life (HRQOL): A person's perception of how health impacts his or her physical, social, and psychologic functioning and well-being.

Health state preference: The perceived relative desirability of a health state measured on a scale where 1.0 equals full health, and 0.0 equals dead.

Heart failure: A clinical syndrome that can result from any disorder that impairs the ability of the heart to fill with or eject blood. Although heart failure may be caused by numerous cardiac disorders, the primary clinical signs and symptoms of dyspnea, fatigue, and volume overload are similar regardless of the initial cause.

Heinz bodies: Intracellular inclusions usually attached to the red cell membrane composed of denatured hemoglobin.

Hemagglutinin: The major antigenic determinant of the influenza virus; a surface antigen that allows the influenza virus to enter host cells by attaching to sialic acid receptors.

Hematemesis: Vomiting up blood that can be bright red or similar to coffee grounds in appearance.

Hematochezia: The presence of visible bright red blood in the stool.

Hematopoiesis: The formation and maturation of blood cells and their derivatives.

Hematopoietic growth factors: See *Colony-stimulating factors*.

Hematopoietic stem cell: An immature cell capable of self-renewal and subsequent differentiation into mature blood cells.

Hematuria: Presence of red blood cells in the urine.

Hemetemesis: Vomiting up blood that may be bright red or appear like coffee grounds. The digestive action of acid and enzymes may cause blood in the stomach to darken and appear like coffee grounds in the vomitus.

Hemochromatosis: Hemochromatosis is a disorder that interferes with iron metabolism, which results in excess iron deposition throughout the body.

Hemodialysis: A dialysis procedure during which blood is pumped outside the body through a dialyzer that acts like an artificial kidney; the dialyzer removes extra fluids and wastes from the blood and returns the clean blood to the body.

Hemolytic uremic syndrome: A condition characterized by the breakup of red blood cells (hemolysis) and kidney failure. Platelets clump together within the kidney's small blood vessels resulting in ischemia leading to kidney failure.

Hemosiderin: A golden yellow or yellow-brown insoluble protein produced by phagocytic digestion of hematin; found in most tissues, especially in the liver, spleen, and bone marrow, in the form of granules much larger than ferritin molecules (of which they are believed to be aggregates) but with a higher content, as much as 37%, of iron.

Hepatosplenic candidiasis: Clinical presentation often manifested only as fever while a patient remains neutropenic (<1,000 white blood cells/mm^3). When the white blood cell (WBC) count increases to >1000 cells/mm^3, imaging studies can detect the presence of abscess or microabscesses in the liver and spleen, often found with acute suppurative and granulomatous reactions. Infection can persist for months and ultimately cause the patient's death despite aggressive systemic therapy with antifungal agents.

Heterozygous: Presence of different (alleles) genes at one location.

Hippocampal sclerosis: A condition in which there is histopathological changes in the hippocampus that have been associated with patients with a history of prolonged status epilepticus. There is an association with hippocampal sclerosis and temporal lobe epilepsy.

Hippocampus: A sea horse–shaped structure located within the brain that is an important part of the limbic system. The hippocampus is involved in some aspects of memory, in the control of the autonomic functions, and in emotional expression.

Hirsutism: Heavy, abnormal growth of hair on the face or body; excess body hair appearing on the lower abdomen, around the nipples, around the chin and upper lip, between the breasts, and on the lower back.

HLA (human leukocyte antigen): See *Human leukocyte antigen*.

Hollenhorst plaque: Cholesterol emboli that usually dislodges from the carotid arteries, or calcific fragments from a stenosed aortic valve that can be visualized on a retinal exam.

Homocysteine: A homolog of cysteine, produced by the demethylation of methionine, and an intermediate in the biosynthesis of 1-cysteine from 1-methionine through 1-cystathionine. Elevated levels of homocysteine have been associated with certain forms of heart disease.

Homozygous: Presence of identical genes (alleles) at one location.

Hormone therapy: Either estrogen-only therapy or combined estrogen and progestogen therapy.

Hot flashes/flushes: A sensation of warmth, frequently accompanied by skin flushing and perspiration.

Human leukocyte antigen (HLA): The *self antigens* are the histocompatibility antigens found on human leukocytes and tissues that enable the body to differentiate *self* from *foreign* cells. The HLA antigens are used in histocompatibility testing to determine the suitability of an organ for transplant.

Humanistic outcomes: Patient-reported outcomes such as patient satisfaction and health-related quality of life.

Hydrocephalus: An uncharacteristic increase in the amount of cerebrospinal fluid within the skull, causing dangerous expansion of the cerebral ventricles.

Hyperalgesia: Exaggerated painful response to normally noxious stimuli.

Hyperarousal: A state of elevated or increased alertness, awareness, or wakefulness.

Hypercapnia: Elevation of carbon dioxide gas in the blood.

Hypercoagulable state: A disorder or state of excessive or frequent thrombus formation; also known as *thrombophilia*.

Hypereosinophilic syndrome: Hypereosinophilic syndrome is a group of leukoproliferative disorders characterized by an overproduction of eosinophils resulting in organ damage.

Hyperkalemia: Serum potassium concentration above 5.5 mEq/L.

Hyperlinear palms: Increased number of skin creases on the palms.

Hypermagnesemia: Serum magnesium concentration above 1.8 mEq/L or 2.3 mg/dL.

Hyperpigmentation: Excess pigment in skin causing an area of darker color than surrounding skin.

Hyperprolactinemia: A state of persistent serum prolactin elevation characterized by prolactin concentrations greater than 20 mcg/L observed on multiple occasions.

Hyperresponsiveness: In the airways, the characteristic of an exaggerated response to stimuli.

Hypertensive crises: Clinical situations where BP values are very elevated, typically greater than 180/120 mm Hg. They are categorized as either a hypertensive emergency or hypertensive urgency depending on the clinical presentation.

Hypertensive emergency: A clinical situation in which a patient has extremely high BP values, typically greater than 180/120 mm Hg that is also accompanied by the presence of acute and/or progressing target-organ damage. Immediate but gradual reduction in BP using intravenous antihypertensive agents is needed to prevent acute morbidity and/or mortality.

Hypertensive urgency: A clinical situation in which a patient has extremely high BP values, typically >180/120 mmHg, that is not accompanied by acuter or progressing target-organ injury. These situations require oral antihypertensive therapy to reduce BP to Stage 1 values over a period of several hours to several days.

Hypertrichosis: Abnormal hair growth on the body in areas where hair does not usually grow.

Hypertrophic cardiomyopathy: Hypertrophic cardiomyopathy is a genetic disorder characterized by disproportionate hypertrophy of the left ventricle, and occasionally of the right ventricle.

Hypervigilance: An enhanced state of sensory sensitivity accompanied by an exaggerated intensity of behaviors whose purpose it is to detect threats.

Hypnagogic hallucinations: Dreamlike experiences on the threshold of sleep that intrude into wakefulness.

Hypnopompic hallucinations: Dreamlike experiences on the threshold of awakening that intrude into wakefulness.

Hypochlorhydria: Presence of an abnormally small amount of hydrochloric acid in the stomach.

Hypogonadism: Little or no hormone production by the testes (in men) or ovaries (in women).

Hypokalemia: Serum potassium concentration below 3.5 mEq/L.

Hypomagnesemia: Serum magnesium concentration below 1.4 mEq/L or 1.7 mg/dL.

Hypomania: An abnormally and persistently elevated, expansive, or irritable mood that lasts at least 4 days but does not cause marked impairment in functioning.

Hypomimia: Decreased facial expression often associated with decreased blink rate.

Hypophonia: Decreased volume of speech.

Hypothalamus: A small region at the base of the brain that controls the release of hormones from the anterior and posterior regions of the pituitary gland and regulates limbic functions, fluid balance, body temperature, cardiovascular function, respiratory function, and diurnal rhythms.

Hysterectomy: Excision of the uterus.

Hysteresis: A situation in which concentration-effect curves do not always follow the same pattern when serum concentrations increase as they do when serum concentrations decrease. This can result from tolerance to a drug (clockwise hysteresis) or accumulation of active metabolites (counterclockwise hysteresis).

Iatrogenesis or iatrogenic disease: A disease produced as a consequence of medical or surgical treatment.

Ichthyosis: Dry, rectangular scales on the skin.

Ictal: The period during a seizure.

Icteric: Relating to or marked by jaundice.

Idiopathic: Unknown etiology of status epilepticus, often considered a genetic etiology for the prolonged seizure.

Ileitis: Inflammation of the ileus.

Illusions: Visual perceptions that are misinterpreted but have a real sensory stimulus.

Immunocompromised host: A patient with defects in host defenses that predisposes him or her to infection (risk factors can include neutropenia, immune system defects from disease or immunosuppressive drug therapy, compromise of natural host defenses, environmental contamination, and changes in normal flora of the host).

Immunoglobulin: Structurally related glycoproteins that function as antibodies and are divided into classes on the basis of structure/biologic activity.

Impaction: An immovable packing; a lodgment of something in a strait or passage of the body; as, impaction of the fetal head in the strait of the pelvis; impaction of food or feces in the intestines of man or beast.

Impedance-pH monitoring: New technique used to detect reflux by measuring changes in intraluminal resistance determined by the presence of liquid or gas inside the esophagus. When combined with pH monitoring, it can differentiate between acid and nonacid reflux.

Impending status epilepticus: Any seizure that does not stop automatically within 5 minutes has been termed impending status epilepticus. This is a fairly new term that was created to recognize the importance of early treatment of status epilepticus. Pharmacologic and nonpharmacologic treatment of status epilepticus should be initiated for those seizures that do not spontaneously terminate within 5 minutes.

Impetigo: A superficial skin infection that is seen most commonly in children.

Implantable cardioverter-defibrillator (ICD): The ICD is a surgically implanted electronic device that monitors, detects, and treats potentially life-threatening ventricular tachycardia with rate-responsive ventricular pacing.

Inanition: Severe weakness and wasting as occurs from lack of food, defect in assimilation, or neoplastic disease.

Incubation period: The time between exposure of a biologic (i.e., pathogen), chemical, or radiologic substance and when symptoms first start to appear (also known as latency).

Induction: Administration of a highly intense level of immunosuppression in the perioperative period or use of antibody therapy to provide enough immunosuppression to delay administration of nephrotoxic calcineurin inhibitors.

Infant mortality: Deaths occurring in those younger than the age of 1 year per 1,000 live births.

Infants: Pediatric patients who are 1 month to 1 year of age.

Infection: Inflammatory response to invasion of host tissue by microorganisms.

Information bias: A flaw in measuring exposure or outcome data that results in systematic differences in the quality of information gathered for study and comparison groups. See also *Selection bias.*

Instrumental activities of daily living: Housekeeping chores, shopping, going outside, medication management. See also *Activities of daily living*.

Insulin-like growth factor-1: An anabolic peptide that acts as a direct stimulator of cell proliferation and growth in all body cells.

Integumentary system: Skin, subcutaneous tissue, and skin appendages.

Interleukin: A type of cytokine, usually influencing a white blood cell.

Intermittent-combined estrogen-progestogen therapy: A regimen that combines a daily estrogen with a progestogen administered intermittently in cycles of 3 days on and 3 days off (which is then repeated without interruption).

International normalized ratio (INR): A measure of coagulation calculated from the patient's prothrombin time (PT) measurement compared to the laboratory's mean normal control measurement and takes into account the sensitivity of the thromboplastin used to perform the test.

Interpersonal psychotherapy: A psychologic intervention that focuses on interpersonal relationships and psychosocial functioning.

Interpretability: The degree to which one can assign qualitative meaning to an instrument's quantitative scores.

Intertriginous areas: Body fold areas (e.g., between buttocks, beneath breasts, between toes, under arms).

Intertrigo: An inflammatory condition of skinfolds induced or aggravated by heat, moisture, maceration, friction, and lack of air circulation.

Intoxication: The development of a substance-specific syndrome after recent ingestion and presence in the body of a substance; associated with maladaptive behavior during the waking state caused by the effect of the substance on the central nervous system.

Intracavernosal injection: Injection into the corpus spongiosum.

Intracranial hypertension: Excessive pressure (>20 mm Hg) within the nondistensible intracranial cavity (i.e., skull) that can develop following traumatic brain injury.

Intracranial pressure: The pressure of the cerebral spinal fluid that is essentially the same as the pressure within the brain tissue (i.e., intraparenchymal pressure).

Intraperitoneal: Within the peritoneal cavity.

Intrauterine device: A device inserted in the uterus to prevent pregnancy, either through spermicidal action (copper device) or thickening cervical mucus to inhibit sperm penetration and migration (progesterone device).

Intrinsic resistance: See *Primary resistance.*

Intussusception: Invagination of one portion of the intestine into an adjacent part of the intestines.

Inulin: A fructose polysaccharide that is filtered by the glomerulus; its clearance is often used as an index of GFR.

Iothalamate: A nonradiolabeled or radiolabeled iodinated contrast agent that is filtered by the glomerulus; its clearance is often used as an index of GFR.

Irritable: Easily annoyed and provoked to anger.

Irritative voiding symptoms: Urinary urgency and frequency. This results from detrusor muscle decompensation that results from long-standing bladder outlet obstruction.

Isolated systolic hypertension: Patients with DBP values that are less than or equal to 90 mm Hg and SBP values that are greater than or equal to 140 mm Hg.

Janeway lesion: These lesions appear as flat, painless, red to bluish-red spots on the palms and soles of patients with acute bacterial endocarditis.

Jarisch-Herxheimer reaction: An increase in symptoms of spirochetal disease caused by the initiation of treatment.

J-curve phenomenon (in hypertension): A theoretical situation where lowering BP provides a reduced risk of cardiovascular events, but when BP is lowered too much, can paradoxically increase the risk of cardiovascular events.

Jugular venous oxygen saturation ($SjvO_2$): Oxygen hemoglobin saturation of blood in the jugular bulb, which is a key element in estimating $CMRO_2$.

Just Culture of Patient Safety: an approach to analysis and prevention of medication errors that relies on encouragement of internal risk transparency, coaching and consoling of employees, avoiding

negative retribution for errors, and gathering then using information to prevent error recurrence.

K complexes: Electronegative waves followed by electropositive waves seen on the EEG during sleep.

Karyotyping: Chromosomal analysis.

Keratinization: Keratin formation.

Keratinized: Skin that has developed thicker areas of keratin in the stratum corneum.

Keratinocyte: Cell of the epidermis that produces keratin.

Keratoconjunctivitis sicca: Dry, itchy eyes that result from atrophy of the lacrimal ducts, which can be seen in inflammatory arthritis.

Keratolytic: Agent that solubilizes intracellular cement of keratin cells in the stratum corneum.

Keratosis pilaris: Small, rough bumps, generally on the face, upper arms, and thighs.

Ketogenic diet: A special antiseizure diet that is high in fat and low in carbohydrates and protein.

Kleptomania: An impulse control disorder characterized by frequent and repeated theft.

Köbner phenomenon: De novo lesion psoriasis appearing at the site of cutaneous trauma.

Kt/V: A measurement of how much urea is being removed from the blood during dialysis. The measurement takes into account the efficiency of the dialyzer (clearance, K), the treatment time (t), and the volume of distribution of urea (V).

Kussmaul sign: Kussmaul sign is a rise in jugular venous pressure on inspiration. Kussmaul sign is seen in conditions in which there is right ventricular filling.

Lactation: Production and secretion of breast milk.

Lactogenesis II: Copious milk production that begins between 24 and 102 hours postpartum resulting from decreased maternal progesterone serum concentration.

Lanugo: Fine body hair normally found on a fetus. The hair develops in patients with anorexia nervosa when they are very underweight and malnourished.

Laparoscopic: Abdominal exploration or surgery employing a type of endoscope called laparoscope.

Laparotomy: Surgical opening of the abdominal cavity.

Laryngospasm: The spasmodic closure of the larynx because of a variety of causes such as allergic reactions, response to irritants, and pharmacologic actions.

Lavage: Washing out.

Laxative: A medication or agent used to produce a bowel movement.

Left ventricular ejection fraction: Also known simply as the ejection fraction, it is the fraction or percentage of the end diastolic blood volume ejected by the left ventricle during systole. It is a measurement of cardiac systolic function with a normal ejection being >60%. It can be determined noninvasively by an echocardiogram.

Left ventricular end diastolic volume: Left ventricular end diastolic volume refers to the volume of blood found in the left ventricular at the end of heart relaxation or diastole.

Left ventricular hypertrophy: Enlargement of the left ventricle, which is seen in heart failure and can give rise to arrhythmias.

Lentigines, PUVA: Brown to black macules resulting from long-term use of psoralens plus ultraviolet A light.

Leptospirosis: A bacterial disease that affects humans and animals caused by the genus Leptospira.

Lewy bodies: Pink-staining spheres found inside neuronal cells of the substantia nigra and other brain regions, considered to be a histopathologic marker for Parkinson's disease.

Lichenification: Thick, leathery skin, usually the result of constant scratching and rubbing.

Linear pharmacokinetics: The situation when changes in long-term daily doses of drugs result in proportional changes in steady-state serum drug concentrations. Most drugs follow this pattern.

Linguistic competency: The ability of individuals and organizations to communicate effectively with people from diverse language backgrounds.

Linkage disequilibrium: Two or more polymorphisms that are inherited together more frequently than would be expected based on chance.

Lipid peroxidation: A pathophysiologic process involving the iron-catalyzed attack of lipid membranes by reactive oxygen species.

Liposomes: Spherical amphiphilic vesicles capable of sustained release of water-soluble substances.

Locus ceruleus: A small area in the brainstem containing norepinephrine neurons that is considered to be a key brain center for anxiety and fear.

Low-glycemic-load diet: A low-glycemic-load diet emphasizes consuming carbohydrates with a low glycemic index. To eat a low-glycemic-load diet, avoid foods such as white bread, refined cereal, cookies, and sugary drinks. Emphasize fruits, vegetables, legumes, and minimally processed grains.

Low glycemic index: The term low glycemic index refers to the quality of carbohydrates and how fast they are absorbed. Foods with a low glycemic index are absorbed more slowly, thus keeping insulin levels more stable.

Lumbar puncture: The procedure used to withdraw cerebrospinal fluid through a needle inserted in the lumbar region of the spinal column.

Luteinizing hormone (LH): A polypeptide hormone secreted by the anterior pituitary gland that stimulates ovulation and maintains the corpus luteum.

Luteolysis: Death of the corpus luteum.

Lymphangitis: An inflammation involving the subcutaneous lymphatic channels.

Lymphocytosis: Increased blood concentration of lymphocytes ($>4 \times 10^9$ cells/mm^3) commonly observed in mononucleosis, pertussis, measles, chickenpox, or lymphoid malignancies.

Lymphedema: A lymphatic obstruction of localized fluid retention and tissue swelling caused by compromised lymphatic system.

Lymphogranuloma venereum: Inflammation of the lymph nodes caused by *Chlamydia trachomatis* resulting in destruction and scarring of tissue.

Macule: Flat, nonpalpable, variable-colored lesion.

Maculopapular: Skin eruption containing both macules and papules.

Magnetic resonance angiography (MRA): A noninvasive method to evaluate the patency of blood vessels using magnetic resonance imaging.

Magnetic resonance imaging (MRI): An imaging technique based on the magnetic properties of the hydrogen atom. It provides an accurate, computer-processed image that can be more sensitive than computed tomography.

Major depression: A psychiatric disorder in which the patient can present with symptoms of depressed mood, a lack of interest in usual activities or inability to experience pleasure, changes in sleep and eating habits, guilt, reduced energy, thoughts of self-harm, and a sense of helplessness or hopelessness.

Major histocompatibility complex (MHC): A set of genes responsible for most of the proteins on the surface of cells in the body that are responsible for recognition of *self*.

Mania: An abnormally and persistently elevated, expansive, or irritable mood that lasts at least 1 week and causes marked impairment in functioning.

Masked hypertension: Patients that have elevated BP measurements based on home measurements but have normal BP measurements when measured in a clinical setting. These patients have chronic hypertension but either may not be diagnosed or may have a diagnosis of hypertension that is undertreated.

Mass effect: Distortion or displacement of the brain anatomy because of an implied or apparent mass (such as stroke or tumor).

Mastalgia or mastodynia: Pain in the breast.

Mean arterial pressure: The mean arterial pressure is the product of the cardiac output and systemic vascular resistance. Since the cardiac output is pulsatile, rather than continuous, and since two thirds of the normal cardiac cycle is spent in diastole, the mean arterial pressure is not the arithmetic mean of the systolic and diastolic blood pressures. Mean arterial pressure = diastolic blood pressure + (1/3)(systolic blood pressure – diastolic blood pressure).

Measurement model: An instrument's scale and subscale structure and the procedures followed to create scale and subscale scores.

Meconium ileus: Intestinal obstruction caused by meconium.

Medication error: Any preventable event that may cause or lead to inappropriate medication use or patient harm while the medication is in the control of the healthcare professional, patient, or consumer (per the National Coordinating Council for Medication Error Reporting and Prevention).

Megakaryocytes: Precursors of platelets.

Melanin: Dark pigment that is part of determining skin color.

Melena: Dark-colored stools resulting from upper gastrointestinal bleed.

Membrane stripping: When the cervix is dilated, a practitioner can use a hand to separate the amniotic membranes from the uterus. This technique has been shown to reduce the need for labor induction.

Menarche: The time of the first menstrual period or flow.

Meningitis: Inflammation, usually infectious, of the meninges, a covering of the brain.

Menopause: The permanent cessation of menses following the loss of ovarian follicular activity.

Menorrhagia: Menstrual blood loss of greater than 80 mL per cycle; a more practical definition is heavy menstrual flow associated with problems of containment of flow, unpredictably heavy flow days, or other associated symptoms.

Menses: Periodic bloody discharge from the uterus.

Mental status examination: An objective patient evaluation conducted through a direct patient interview and used to make a diagnosis, assess the course of illness, or determine treatment response.

Meralgia parethetica: A disorder characterized by tingling, numbness, and burning pain in the outer side of the thigh. The disorder is caused by compression of the lateral femoral cutaneous nerve, a sensory nerve to the skin, as it exits the pelvis.

Mesolimbic pathway: A dopaminergic pathway in the brain that connects the ventral tegmental area in the midbrain to the nucleus accumbens in the striatum and is involved in motivation and reward.

Metabolic syndrome: A constellation of metabolic and cardiovascular changes consisting of at least three of the following: obesity, low high-density lipoprotein (HDL), elevated triglycerides, hypertension, and elevated fasting blood glucose.

Metastasis: Movement or spread of disease from one organ or part to new location not directly connected.

Methemoglobin: A form of hemoglobin that occurs when its iron is oxidized to the +3 state, which decreases oxygen binding.

Methionine: The 1-isomer is a nutritionally essential amino acid and the most important natural source of *active methyl* groups in the body, hence usually involved in methylations in vivo.

Michaelis–Menten kinetics: the situation in which changes in steady-state serum drug concentrations of drugs are disproportional to changes in long-term daily doses due to alterations in drug metabolism.

Microalbuminuria: A condition in which a small amount of albumin (30–300 mg/day) is present in the urine; often indicates an early stage of chronic kidney disease (CKD).

Microcephalic: Abnormally small head.

Microcomedo: Microscopic lesion formed from the combination of sloughed, clumping keratinocytes reacting with sebum and fatty acids from the sebaceous gland.

Micrographia: Handwriting that is small, trails off in size, or very slow.

Midsystolic: Middle of systole.

Migraine aura: Early symptom of an attack of migraine with aura, which is the manifestation of focal cerebral dysfunction. The aura typically precedes the headache.

Mild cognitive impairment: A syndrome characterized by cognitive impairment that is not of sufficient severity to warrant a diagnosis of dementia.

Milia: Small, white cysts containing keratin.

Mixed states: Rapidly alternating mood states (mania and major depressive episodes) that last at least 1 week, and cause marked impairment in functioning.

Molds: Fungal organisms that grow as multicellular branching, thread-like filaments (hyphae) that are either *septate* (divided by

transverse walls) or *coenocytic* (multinucleate without cross walls). On agar media, molds grow outward from the point of inoculation by extension of the tips of filaments, and then branch repeatedly, interweaving to form fuzzy, matted growths called *mycelium*. Germ tubes are the beginning of *hyphae*, which arise as perpendicular extensions from the yeast cell, with no constriction at their point of origin.

Molybdenum (Mo): A bioelement found in a number of proteins.

Monoamine neurotransmitters: Neurotransmitters that contain one amino group and are derived from amino acids such as tyrosine and tryptophan. Includes, among others, the catecholamines (dopamine and norepinephrine) and an indoleamine (serotonin).

Mood: A more pervasive and sustained emotional state that colors a person's perception of the world.

Morbilliform: Maculopapular lesions that become confluent on the face and body.

Mucolytic: The ability to break down mucus.

Mucositis: Inflammation of the mucosa.

Multiattribute health status classification systems: Preference-based HRQOL instruments for which health-state preferences have been derived from population studies. The instruments assess respondents' health status, and then population preferences are applied to produce the index score.

Multiparity: Condition of having given birth to multiple children.

Multiple-organ dysfunction syndrome (MODS): Presence of altered organ function requiring intervention to maintain homeostasis.

Multiple sclerosis (MS): A demyelinating disease, caused by inflammation, leading to neurologic deficits and often, disability.

Mutism: A state in which a person either has the inability or refuses to speak or vocalize sounds.

Mycotic: A fungal infection.

Myectomy: A surgical removal of the overgrown septal muscle to decrease the outflow tract obstruction.

Myocarditis: Inflammation of the cardiac muscle.

Myoclonic seizures: Brief shock-like muscular contractions of the face, trunk, and extremities. They usually begin in adolescence and are referred to as *juvenile myoclonic epilepsy* (JME).

Myoclonus: A sudden twitching of muscles or parts of muscles, without any rhythm or pattern.

Myositis: Inflammation of the muscle, characterized by pain, tenderness, and sometimes spasm in the affected area.

Narrowband UVB (NB-UVB): 311 nm ultraviolet B light.

National Kidney Foundation (NKF): A major voluntary health organization that seeks to prevent kidney and urinary tract diseases, improve the health and well-being of individuals and families affected by these diseases, and increase the availability of all organs for transplantation.

Nausea: An unpleasant sensation associated with an awareness of the urge to vomit.

Necrosis: Local death of cells or tissue.

Necrotizing fasciitis: A rare, but very severe infection of the subcutaneous tissue that can be caused by aerobic and/or anaerobic bacteria and results in progressive destruction of the superficial fascia and subcutaneous fat.

Negative symptoms: Those symptoms of schizophrenia that are largely associated with a deficit in psychosocial functioning, emotional expression, and interpersonal interactions. Examples include blunted affect, alogia, decreased interest and involvement in social and occupational activities, and decreased grooming and hygiene.

Neonatal: Within the first 4 weeks (28 days) of life.

Neonates: Newborns who are 1 day to 1 month of age.

Nephritis: Inflammation of the kidney.

Nephrolithiasis: Presence of one or more stones in the renal pelvis, collecting system, or ureters.

Nephron: The working unit of the kidney that is comprised of a glomerulus and tubule. Each kidney is made up of approximately 1 million nephrons, which collectively remove drugs, toxins, and fluid from the blood.

Nephropathy: Refers to a pathologic alteration of the kidney.

Nephrotic range proteinuria: Proteinuria >3 g/day associated with glomerular disease and nephrotic syndrome.

Nephrotoxicity: Toxic insult to the kidney.

Nerve conduction studies: Measurement of the speed of electrical conduction through a nerve.

Neuraminidase: The second major antigenic determinant of the influenza virus; a surface antigen that allows the release of new viral particles from host cells by catalyzing the cleavage of linkages to sialic acid.

Neuritic plaques: Hallmark pathologic marker of Alzheimer's disease comprised of β-amyloid protein and masses of broken neurites.

Neurofibrillary tangles: Hallmark pathologic marker of Alzheimer's disease derived from abnormal phosphorylation of τ-protein filaments.

Neuropathic pain: Pain due to nervous system damage.

Neutropenia: An abnormally reduced number of neutrophils circulating in peripheral blood; although exact definitions of neutropenia often vary, an absolute neutrophil count of <1000 cells/mm^3 indicates a reduction sufficient to predispose patients to infection.

New York Heart Association classification: The New York Heart Association classification provides a simple way of classifying the extent of heart failure. It places patients in one of four categories based on how much they are limited during physical activity.

***N*-methyl-D-aspartate antagonists:** Class of medications that decreases the activity of synaptic glutamate, thus decreasing the likelihood of cell death.

***N*-methyl-D-aspartate (NMDA) receptors:** One of three types of ionotropic postsynaptic glutamate receptors. Upon binding glutamate, these receptors permit the influx of Ca^{+2} ions and results in brain excitation. These are one of the two primary receptors for excitatory neurotransmission in the brain.

Nociceptive pain: Pain due to physiologic processes that involve stimulation, transmission, perception, and modulation.

Nocturia: Frequent nighttime urination (>2 micturitions per night).

Nodule: Elevated, palpable, solid, round or oval lesion more than 0.5 cm in diameter.

Nonalcoholic fatty liver disease (NAFLD): Refers to a wide spectrum of liver disease ranging from simple fatty liver (steatosis), to nonalcoholic steatohepatitis (NASH), to cirrhosis (irreversible, advanced scarring of the liver). All of the stages of NAFLD have in common the accumulation of fatty infiltration in the liver cells.

Nonarteritic, anterior, ischemic optic neuropathy: A disorder caused by an acute decrease of blood flow to the optic nerve, which results in sudden vision loss. If persistent, it can lead to permanent vision loss.

Nonconvulsive status epilepticus (NCSE): Believed to be less common and have a better prognosis than GCSE. The most common two types are absence status epilepticus and complex partial status epilepticus. Both are associated with an impairment in consciousness. For the more common of the two, absence status, the patient appears in a twilight state to lethargy, there is no return to consciousness as occurs in complex partial status epilepticus. For complex partial status epilepticus partial return to consciousness can occur. It may or may not be associated with motor activity or automatisms. The duration is sufficient enough in length to meet the definition of status epilepticus.

Nonoliguria: Production of >450 mL urine/day.

Nonpolyposis: Absence of polyps.

Nonulcer dyspepsia: Ulcer-like dyspepsia that has been investigated, but endoscopic findings yield no evidence of mucosal injury (ulcer).

Norepinephrine (NE): A hormone secreted by the adrenal medulla and also released at synapses.

Nosocomial infection: An infection acquired in a healthcare facility.

NSAID: Nonsteroidal antiinflammatory drug.

***N*-terminal proBNP:** The biologically inactive fragment of B-type natriuretic peptide (BNP). Compared to BNP, *N*-terminal proBNP circulates at higher plasma concentrations and has a longer half-life.

Nulliparity: Condition of not having given birth to a child.

Obesity–hypoventilation syndrome: Also known as Pickwickian syndrome.

Oblique lie: The fetus is at an angle to the cervix. The head is not the presenting part, and often the patient will need to be delivered by cesarean section.

Obsession: Recurrent and persistent thoughts, images, or impulses experienced as intrusive and distressing.

Obsessive–compulsive disorder (OCD): An anxiety disorder characterized by obsessions and/or compulsions that are time-consuming and interfere significantly with normal routine, social or occupational functioning, or relationships.

Obstructive voiding symptoms: Decreased force of the urinary stream, hesitancy, incomplete bladder emptying, urinary dribbling. This results from bladder outlet obstruction as could be caused by benign prostatic hyperplasia.

Odynophagia: Painful swallowing.

Oligoanovulation: The condition of having few to no ovulatory menstrual cycles.

Oligomenorrhea: Reduced frequency of menses with a time interval between periods greater than 40 days but less than 6 months.

Oliguria: Diminished volume of urine output (volume <400 to 500 mL/day).

Omentumectomy: Excision of the double fold of peritoneum attached to the stomach and connecting it with abdominal viscera (omentum).

Onychomycosis: Fungal infection of the nail apparatus.

Open prostatectomy: In this surgical procedure, an enlarged prostate is removed in its entirety. Access to the prostate can be achieved by cutting through the bladder and reaching down to the prostate, or by cutting through the perineum (between the legs).

Ophthalmia neonatorum: Inflammation of the conjunctiva resulting from acquisition of gonococcal infection at birth.

Opioid addiction: A behavioral pattern manifesting as loss of control over opioid use, compulsive use, and continued use despite harm.

Opioid dependence: State that occurs subsequent to extended exposure to an opioid and manifests as withdrawal symptoms after abrupt dose reduction, discontinuation or after the administration of an opioid antagonist.

Opioid tolerance: Decreased effectiveness of opioid over time due to opioid exposure.

Opportunistic infection (OI): Infection with microorganism that occurs because of altered physiologic state of the patient.

Orchiectomy: The surgical removal of the testicles.

Organic erectile dysfunction: Term used to refer to erectile dysfunction that is caused by vascular, neurologic, and/or hormonal causes.

Orthopnea: Difficulty breathing after lying down.

Orthostatic hypotension: A significant drop in BP, defined as a SBP decrease of greater than 20 mm Hg or a DBP decrease of greater than 10 mm Hg, that occurs when changing from a supine to a standing position.

Osler nodes: Osler nodes are red, raised tender nodules usually 5 mm in diameter on the pulps of toes or fingers. Seen in patients with endocarditis, they are thought to be caused by the deposition of immune complexes.

Osteogenesis imperfecta: Genetic disorder characterized by low trabecular and cortical bone density.

Osteomalacia: Abnormal bone mineralization, referred to as rickets in children.

Osteomyelitis: Infection involving the bone.

Osteopenia: Low bone density, dual-energy x-ray absorptiometry (DXA) T-score of –1 to –2.5.

Osteophyte: A bony outgrowth or protuberance.

Osteoporosis: Very low bone density, DXA T-score less than –2.5, with or without a low trauma fracture. National Osteoporosis Foundation definition: "A chronic, progressive disease characterized by low bone mass, microarchitectural deterioration and decreased bone strength, bone fragility and a consequent increase in fracture risk."

Osteotomy: The surgical cutting of a bone.

Otitis media: Inflammation of the middle ear.

Ovulation: Periodic ripening and rupture of mature follicle and the discharge of ovum from the cortex of the ovary.

Oxytocin: A polypeptide hormone secreted by the posterior pituitary gland that stimulates uterine contraction.

Paget's disease: Disorder of bone remodeling in discrete sections of bone.

PAH: *p*-aminohippurate, a small molecule that is completely secreted from the tubules into urine, so that blood leaving the kidney is virtually free of PAH; a marker that is often used to measure renal plasma flow (RPF).

Pain: An unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage.

Palpation: Touching the skin to feel the outline of an organ.

Pan- or holosystolic: Throughout the end time of systole.

Pancolitis: Inflammation that involves the majority of the colon for patients with inflammatory bowel disease.

Pancreatitis: An acute or chronic inflammation of the pancreas with variable involvement of local tissues and remote organs.

Panel reactive antibody (PRA): The percentage of cells from a panel of donors with which a potential recipient's bloodstream reacts. The more antibodies in the recipient's bloodstream, the higher the PRA. The higher the PRA, the higher the risk for a positive crossmatch.

Panhypopituitarism: A condition of complete or partial loss of anterior and posterior pituitary function resulting in a complex disorder characterized by multiple pituitary-hormone deficiencies.

Panic attack: A discrete period in which there is the sudden onset of intense apprehension, fearfulness, or terror, often associated with feelings of impending doom.

Panic disorder: The presence of recurrent, unexpected panic attacks followed by at least 1 month of persistent concern about having another panic attack, worry about the possible implications or consequences of the panic attacks, or a significant behavioral change related to the attacks.

Panlobular: Affecting the entire lobe.

Papillary: Upper layer of the dermis.

Papilledema: Swelling around the optic nerve, usually caused by pressure on the nerve by a tumor or stroke.

Papule: Solid, elevated, lesion more than 0.5 cm in diameter.

Papules: Small raised bumps that may open when scratched and become crusty and infected.

Papulosquamous: Raised plaque or papule with scaling.

***p*-Aminohippurate (PAH):** A small molecule that is completely secreted from the tubules into urine, so that blood leaving the kidney is virtually free of PAH; a marker that is often used to measure renal plasma flow (RPF).

Paranoia: Ideation involving suspiciousness or the belief that one is being harassed, persecuted, or unfairly treated.

Parenchyma: Specific cells or tissue of an organ.

Paresthesia: An abnormal sensation, such as of burning, pricking, tickling, or tingling.

Parkinsonism: A constellation of symptoms with atypical features such that a diagnosis of idiopathic Parkinson disease cannot be made.

Parous: Having borne one or more children.

Paroxysmal nocturnal dyspnea: Onset of difficulty breathing after lying down for several hours.

Partial agonist: A drug with high binding affinity to a receptor and that elicits a weaker response than the endogenous neurotransmitter. At least theoretically, this causes an agonist effect in states of decreased endogenous neurotransmitter tone and an antagonist effect in the endogenous state of heightened neurotransmitter activity.

Partial seizure: A seizure that begins in one hemisphere of the brain. It can be simple, complex, or secondarily generalized.

Patch: Large macule (more than 2 cm in diameter).

Patient-reported outcomes: The consequences of the disease and/or its treatment as perceived and reported by the patient.

Pelvic inflammatory disease (PID): Infection of the lining of the uterus, the fallopian tubes, or the ovaries.

Penumbra (ischemic): The area of brain tissue around the core of the infarct that has decreased function but remains viable. It is proposed that reperfusion of this tissue will allow survival of the affected neurons and other brain cells.

Peptic ulcer: Cellular distribution of the gastrointestinal mucosa, submucosa, and muscular layer. Chronic peptic ulcers usually occur as a "single hole" and are found most often in the stomach and duodenum.

Percussion: Tapping on a structure to elicit a sound.

Percussion and postural drainage: Tapping on the thorax to physically loosen pulmonary secretions and posturing the body to facilitate expectoration.

Percutaneous coronary intervention (PCI): A minimally invasive procedure whereby access to the coronary arteries is obtained through the femoral artery up the aorta to the coronary os. Contrast media is used to visualize the coronary artery stenosis using a coronary angiogram. A guidewire is used to cross the stenosis and small balloon is inflated and/or stent is deployed to break up atherosclerotic plaque and restore coronary artery blood flow. The stent is left in place to prevent restenosis of the coronary artery.

Pericarditis: Inflammation of the pericardium, which is the fibroserous sac enclosing the heart.

Perimenopause: The period immediately prior to the menopause and the first year after menopause. Reflects the transition to menopause (with irregular menstrual cycles) and includes the 3 to 5 years before and 1 year after the cessation of menstrual flow.

Perinatal: Time shortly before and after birth.

Periodontitis: A serious gum infection caused by inflammation and infection of the ligaments that support the teeth.

Perioral dermatitis: Rash around the mouth. In patients with anorexia nervosa or bulimia nervosa, the rash is secondary to repeated vomiting that creates skin irritation from exposure to the gastric contents.

Peripheral arterial disease (PAD): Atherosclerotic occlusive disease of the extremities, usually diagnosed by symptoms (claudication) or assessment of the blood flow to an extremity.

Peripheral blood progenitor cells: Immature blood cells, which are capable of producing white blood cells, platelets, and red blood cells.

Peritoneal dialysis (PD): A dialysis procedure performed in the peritoneal cavity in which the peritoneum acts as the semipermeable membrane.

Peritonitis: The acute, inflammatory response of the peritoneal lining to microorganisms, chemicals, irradiation, or foreign body injury.

Periungual pyogenic granulomas: Benign vascular lesion around the fingernails or toenails; can relate to acitretin use.

Perseveration: Persistent repetition of the same verbal or motor response despite differing stimuli.

Pervasive developmental disorder: A group of disorders characterized by severe and pervasive impairments in the development of socialization and communication skills, as well as behavioral repertoire, with a typical diagnosis younger than age 3 years; includes autistic disorder, Rett syndrome, pervasive development disorder not otherwise specified, childhood disintegrative disorder, and Asperger disorder.

Petechiae: Pinpoint, flat, round, red spots under the skin caused by intradermal hemorrhage.

Peyronie's disease: Disease of the penis associated with fibrous tissue scarring along the inside of the penile shaft resulting in significant and abnormal curvature of the erect penis. Associated with penile pain; deformity makes sexual intercourse difficult or impossible.

P-glycoprotein: An adenosine triphosphatase (ATPase)-dependent membrane transporter efflux pump coded for by the multidrug-resistance gene 1 (MDR1 or ABCB1 or PGY1) found in the human blood-brain barrier and intestine as well as other tissues; lipophilic molecules are good substrates for the ABCB1 efflux transport system at the blood–brain barrier.

Pharmacodynamics: The study of the relationship between the concentration of a drug and the response obtained in a patient.

Pharmacoepidemiology: The study of the use of and the effects of drugs in large numbers of people with the purpose of supporting safe and effective drug therapies. This type of observational research is useful when more rigorous, experimental designs are not feasible.

Pharmacogenetics: Genetic basis for interindividual differences in drug response.

Pharmacovigilance: The science and activities relating to the detection, assessment, understanding, and prevention of adverse effects or any other drug-related problems.

Pharyngitis: An acute infection of the oropharynx or nasopharynx.

Phase I reactions: Metabolic changes by the body that generally make the drug molecule more polar and water soluble so that it is prone to elimination by the kidney, such as oxidation, hydrolysis, and reduction.

Phase II reactions: Metabolic changes by the body that generally make the drug molecule more prone to elimination by the kidney, such as conjugation to form glucuronides, acetates, or sulfates.

Phenotype: Outward expression of the genotype.

Phenotypes: How a gene is expressed (e.g., eye color, height, drug metabolism capacity). The expression of genetic alleles (genotype) as an observable physical or biochemical trait.

Phobia: A persistent, abnormal, and irrational fear of a specific thing or situation that compels one to avoid it, despite the awareness and reassurance that it is not dangerous.

Phonophobia: Hypersensitivity to sound, usually causing avoidance.

Photic stimulation: Stimulation of the visual cortex through visual stimulation with bright and alternating light.

Photoallergy: Photosensitivity disorder of skin (light and photoallergic agent).

Photophobia: Hypersensitivity to light, usually causing avoidance.

Phototoxicity: Photosensitivity disorder of skin (light and phototoxic agent).

Physical dependence: A state of adaptation that is manifested by a drug class–specific withdrawal syndrome that can be produced by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, and/or administration of an antagonist.

Pickwickian syndrome: Excess load of excess body fat on the chest tissues resulting in a constellation of syndromes that include excessive daytime sleepiness, shortness of breath due to elevated blood carbon dioxide pressure, disturbed sleep at night, and flushed face.

Pilonidal: Hair-containing cyst.

Pilosebaceous: Sebaceous gland and adjacent hair follicle.

Placenta accreta: Attachment of placental villi to the muscle of the uterine wall causing abnormally firm placental adherence. Complications include intractable postpartum hemorrhage.

Placenta previa: Placental implantation at or near the opening of the cervix. Severe maternal hemorrhage can occur because the placenta precedes the infant during birth.

Plantar fasciitis: A condition that causes heel and arch pain as a result of irritation and inflammation of the plantar fascia, the connective tissues that form the arch of the foot.

Plaque: Raised, flat lesion (more than 2 cm in diameter).

Pneumonitis: Inflammation of lung tissue.

Poikilocytosis: The presence of irregularly shaped red blood cells in the peripheral blood.

Poikilothermia: Inability to maintain normal body temperature.

Polyarteritis nodosa: A systemic necrotizing vasculitis of small and medium-sized arteries.

Polycystic ovarian syndrome: An endocrine disorder with a constellation of symptoms with excessive androgen activity, including irregular or no menstrual periods, acne, excessive hair growth, and infertility.

Polycythemia: An increase in the number of red cells present in the blood.

Polymorphism: Genetic variations occurring at a frequency of at least one percent in the human population.

Porphyria: A group of disorders involving heme biosynthesis, characterized by excessive excretion of porphyrins or their precursors; can be inherited or can be acquired, as from the effects of certain chemical agents.

Porphyrins: Pigments widely distributed throughout nature (e.g., heme, bile pigments, cytochromes) consisting of four pyrroles joined in a ring (porphin) structure.

Positive symptoms: Those symptoms of schizophrenia, largely based on perceptual and thought disturbances, that are typically associated with psychosis. Examples are suspiciousness, paranoia, delusions, hallucinations, and disorganized thought processes.

Positron emission tomography (PET): Specialized nuclear scanning technique that allows the measurement of regional blood flow and glucose metabolism. With radiolabeled ligands, also allows for the measurement of the binding of drugs to receptors.

Posterior fossa: The cavity in the back part of the skull that contains the cerebellum, brainstem, and cranial nerves 5–12.

Postexposure prophylaxis: Dispensing or administering a medication (including a vaccine) to start immediately after exposure to a disease or organism, to prevent the disease from developing or spreading.

Postictal: The recovery period after a seizure, when a patient can be lethargic or confused. Duration can be variable.

Posttraumatic seizures: Seizure event(s) that can occur following a traumatic brain injury within the first 7 days postinjury (early) or beyond 7 days postinjury (late).

Postrenal acute renal failure (ARF): Acute renal failure with an anatomical cause that is in the urinary tract.

Posttraumatic stress disorder: An anxiety disorder in which exposure to an exceptional mental or physical stressor is followed by persistent reexperiencing of the event, avoidance of reminders of the event, and arousal symptoms.

Postvoid residual urine volume: Urine left in the bladder after the patient has been asked to completely empty urine out of the bladder. Normally the postvoid residual urine volume should be zero. A high postvoid residual urine volume is associated with recurrent urinary tract infection.

PRA (panel reactive antibody): The percentage of cells from a panel of donors with which a potential recipient's bloodstream reacts. The more antibodies in the recipient's bloodstream, the higher the PRA. The higher the PRA, the higher the risk for a positive crossmatch.

Preexposure vaccination: Administration of a protective vaccine to the public, military troops, or high-risk individuals prior to the potential exposure to an infectious disease.

Preference-based measures: Measures that provide an overall HRQOL index score based on a scale anchored by 1.0 (full health) and 0.0 (dead).

Prefrontal cortex: Part of the brain that integrates thought, emotion, and motivation.

Preload: Along with afterload, it is an important determinant of cardiac output. It is the degree of stretch of the myocardial fibers (sarcomeres) at the end of diastole. As the sarcomeres are stretched, the force of contraction increases. Preload is approximated by the left ventricular end diastolic volume or pressure.

Premature infants: Those born before 37 weeks of gestational age.

Premature ovarian failure: Amenorrhea, sex-steroid deficiency, and infertility in women younger than 40 years of age.

Premenstrual dysphoric disorder (PMDD): Severe psychiatric mood disorder with marked affective symptoms causing significant interference in work or relationships temporally associated with the luteal phase and not caused by an underlying psychiatric disturbance; a severe form of premenstrual syndrome and is listed in the appendix of the *Diagnostic and Statistical Manual of Mental Disorders*, *Fourth Edition Revised*. The diagnostic criteria require prospective documentation of symptoms, a specific constellation of symptoms, and functional impairment.

Premenstrual molimina: Includes premenstrual symptoms such as breast tenderness, pelvic heaviness or bloating, and food cravings that are not distressing and do not interfere with daily functioning.

Premenstrual syndrome (PMS): A constellation of symptoms including mild mood disturbance and physical symptoms that occur prior to the menses and resolve with initiation of menses.

Premonitory migraine symptoms: Symptoms preceding and forewarning of a migraine attack by 2 to 48 hours, occurring before the aura in migraine with aura and before the onset of pain in migraine without aura.

Prerenal ARF: Acute renal failure caused by a reduction of renal blood flow. Often associated with volume depletion or poor cardiac function.

Presbycusis: Progressive bilateral loss of hearing that occurs in the aged.

Pressured speech: More and faster speech that is difficult or impossible to interrupt.

Preterm: Before 37 weeks of gestation.

Priapism: Painful prolonged erection.

Primary amenorrhea: Absence of menses by age 16 years in the presence of normal secondary sexual development or absence of menses by age 14 years in the absence of normal secondary sexual development.

Primary hypertension: Same as essential hypertension; persistently elevated BP that results from unknown pathophysiological etiology.

Primary hypogonadism: Failure of the testes to produce an adequate supply of testosterone to meet physiologic needs.

Primary lesion: Basic skin lesion that appears at the beginning of skin disorder.

Primary resistance: Refers to resistance recorded prior to drug exposure in vitro or in vivo, as determined by in-vitro susceptibility testing using standardized methodology.

Proctitis: Inflammation confined to the rectum for patients with inflammatory bowel disease.

Prodrome: Early symptom indicating that disease or further symptoms are imminent.

Progestogen: A term referring to progesterone and the synthetic progestational compounds (sometimes referred to as *progestins*).

Progressive multifocal leukoencephalopathy (PML): Rapidly progressive neuromuscular disease caused by opportunistic infection of brain cells by the JC virus.

Prolactin: A polypeptide hormone secreted by the anterior pituitary gland that stimulates lactation.

Proprioception: A sense or perception, usually at a subconscious level, of the movements and position of the body and especially its limbs, independent of vision; this sense is gained primarily from input from sensory nerve terminals in muscles and tendons and the fibrous capsule of joints combined with input from the vestibular apparatus.

Prostate-specific antigen (PSA): A clinical laboratory test; PSA is a tumor marker that is used to screen for, monitor response to treatment

of, and determine degree of spread of prostate cancer. Normally, PSA blood levels should be low as PSA is passed out of the body in the ejaculate.

Prostatectomy: Removal of all or part of the prostate gland. There are two main types: (1) transurethral resection of the prostate (TURP)—removes part of the tissue surrounding the urethra that can be blocking the flow of urine; and (2) radical prostatectomy, which removes all of the prostate and the seminal vesicles.

Protease: An enzyme in HIV that cleaves large precursor polypeptides into functional proteins that are necessary to produce a complete virus.

Proteinuria: A condition in which the urine contains large amounts of protein (>150 mg/day); often a sign of glomerular or tubular damage in the kidney.

Proteolytic: The ability to break down protein.

Prothrombin: A clotting factor that is converted to thrombin; also known as factor II.

Prothrombin time (PT): A measure of coagulation representing the amount of time required to form a blood clot after the addition of thromboplastin to the blood sample; also known as Quick's test.

Pruritus: Itching.

Pseudoaddiction: A behavior pattern reflective of seeking relief of pain and resembling that of addictive behavior.

Pseudoallergic: Adverse reactions that appear like allergic reactions but do not have an immunologic mechanism.

Pseudocyst: Collection of pancreatic juice and tissue debris enclosed by a wall of fibrous or granulation tissue.

Pseudohypertension: A falsely elevated BP measurement that is usually because of rigid, calcified brachial arteries; this can be seen in patients who are elderly, have longstanding diabetes, or have chronic kidney disease.

Pseudomembranous colitis: Inflammation of the colon caused by the toxin of *Clostridium difficile* and resulting in bloody diarrhea.

Pseudopolyps: An area of hypertrophied gastrointestinal mucosa that resembles a polyp and contains nonmalignant cells.

Pseudotumor cerebri: Increased intracranial pressure caused by decreased venous drainage from the brain as a result of increased intraabdominal pressure. Symptoms usually include severe headache, bilateral pulsatile auditory tinnitus, and visual field cuts. Also known as idiopathic intracranial hypertension.

Pseudoxanthoma elasticum: Pseudoxanthoma elasticum is a chronic degenerative disease of connection tissues of the skin, eyes, and cardiovascular system resulting from fragmentation and calcification of elastic fibers.

Psoriasis: A chronic, noncontagious autoimmune disease that affects the skin in the form of thick, red, scaly patches.

Psychoeducation: Education geared toward patients becoming more informed about their mental illness and treatment. Additional goals include self-monitoring, efforts to improve treatment adherence, interactions between patient and clinicians, and empowerment.

Psychogenic erectile dysfunction: Erectile dysfunction because of failure of central nervous system to perceive or process sexually stimulating information.

Psychometrics: The measurement of psychologic constructs, such as quality of life.

Psychomotor: Movement or muscular activity related to mental processes.

Psychomotor retardation: A slowing or limitation of motor functioning or muscular movements.

Psychosocial functioning: A person's level of functioning on a daily basis that encompasses all the domains of life experience (e.g., interpersonal relationships, work, school, recreation).

Psychosocial rehabilitation programs: Care programs oriented toward improving patient's daily adaptive functioning. Includes such interventions as basic living skills, social skills training, basic education, work programs, and supported housing.

Psychosocial stressor: Any significant life event or change that can be associated with the onset, occurrence, or exacerbation of a mental disorder.

Psychotherapy: A general term used to describe a form of treatment based on talking with a therapist. Psychotherapy aims to relieve distress by discussing and expressing feelings, to help the patient to change attitudes, behavior, and habits and to develop better ways of coping.

Pulmonary artery occlusion pressure: It is usually determined by a balloon-tipped Swan-Ganz catheter that is advanced into a distal branch of the pulmonary artery. Inflation of the balloon at the catheter tip occludes the pulmonary artery and allows measurement of the left atrial pressure that reflects the left ventricular diastolic pressure. Therefore, it is a measure of the left ventricular preload.

Pulmonary aspiration: The inhalation of fluids and gastric contents into the lungs that can cause aspiration pneumonitis.

Pulmonary capillary wedge pressure: It is usually determined by a balloon-tipped Swan-Ganz catheter that is advanced into a distal branch of the pulmonary artery. Inflation of the balloon at the catheter tip occludes the pulmonary artery and allows measurement of the left atrial pressure, which reflects the left ventricular diastolic pressure. Therefore, it is a measure of the left ventricular preload.

Pulmonary embolism: A disorder of thrombus formation causing obstruction of a pulmonary artery or one of its branches and results in pulmonary infarction.

Pulsating: Throbbing or beating with a rhythm.

Pulseless electrical activity: The absence of a detectable pulse and the presence of some type of electrical activity other than VF or PVT.

Purgatives: An agent used for purging the bowels.

Purpura: Discoloration of skin because of a hemorrhagic spot more than 0.5 cm in diameter.

Pustule: Small, raised lesion containing pus or exudates.

Pyelonephritis: An infection involving the kidneys and representing upper tract infection.

Pyoderma: Purulent skin disease.

Pyoderma gangrenosum: Skin ulceration with necrotic edges.

Pyuria: Presence of pus or white blood cells in the urine.

Quality-adjusted life-years (QALY): A health outcome summary measure in which quantity of life is adjusted for its quality. A year in

full health is equivalent to 1.0 QALY. A year in a health state considered worse than full health, such as 0.5, would equal 0.5 QALY, which is equivalent to living half a year in full health.

Radionuclide ventriculography: Radionuclide ventriculography, also known as contrast ventriculography, provides imaging of a ventricle of the heart after the injection of a radioactive contrast medium. The technique is less invasive than cardiac catheterization and is used to assess ventricular function.

Rales: The clicking, rattling, or crackling noises heard on auscultation of the lungs during inhalation.

Rating scales: Tools used to objectively describe, assess, and measure subjective findings common in psychiatric illnesses. Rating scales are also used to diagnose specific psychiatric conditions.

Rational polytherapy: The concurrent use of two or more drugs for patients not responding to monotherapy. The combination of drugs is based on a consideration of mechanism of action, clinical pharmacokinetics, adverse reactions, and drug interactions.

Rebound insomnia: Sleep that is worsened compared with patient's baseline sleep for a few days after discontinuation of a sedative hypnotic medication.

Rebound vasodilation or congestion: See *Rhinitis medicamentosa*.

Refractory status epilepticus: Status epilepticus is considered refractory when adequate doses of a benzodiazepine, hydantoin, or barbiturate have failed to terminate the seizures, that is, a patient must have failed two first line therapies to be considered refractory.

Rejection: The response of the immune system, usually involving T- or B-lymphocytes, to the recognition of foreign antigens in transplanted tissue, which destroys the cells in the transplanted organ and ultimately leads to organ failure, if not treated successfully.

Relapse: New or old multiple sclerosis symptoms lasting 24 hours or longer often associated with demyelination or inflammation in the brain or spinal cord. Relapses are also referred to as an attack, exacerbation, or flare-up of multiple sclerosis.

Relapsing-remitting multiple sclerosis: The most common form of multiple sclerosis at the time of diagnosis. It is characterized by attacks usually with full or partial recovery and no disease progression between attacks.

Relative risk reduction: The amount of risk reduced when compared to a control. When one sees a 5% event rate in the control group and a 4% event rate in the treatment group, the relative risk reduction is 20%. The absolute risk reduction is 1%.

Reliability: The extent to which measures give consistent or accurate results.

Remote symptomatic: When the cause of the status epilepticus is from a previous neurological injury or anatomical malformation, e.g., a patient with a prior stroke, head trauma or brain tumor.

Renal osteodystrophy (ROD): The condition resulting from sustained metabolic changes that occur with chronic kidney disease including secondary hyperparathyroidism, hyperphosphatemia, hypocalcemia, and vitamin D deficiency. The skeletal complications associated with ROD include osteitis fibrosa cystica (high bone turnover disease), osteomalacia (low bone turnover disease), adynamic bone disease, and mixed bone disorders.

Renal replacement therapy: Any form of dialysis or hemofiltration used to support patients without adequate kidney function. Goals of renal replacement therapy are to remove excess fluid; remove waste products and toxins; and control electrolyte concentrations.

Renal: General term referring to the kidneys.

Renin-angiotensin-aldosterone system: A complex endogenous humoral mediated system that is involved with most of the regulatory components involved with arterial BP.

Renovascular: Pertaining to blood vessels located within the kidney, such as the afferent and efferent arterioles, and renal arteries.

Resistant hypertension: Patients with hypertension that have not achieved their goal BP value despite treatment with three or more antihypertensive drugs.

Respiratory disturbance index: A summary measure that quantifies the number of apneas, hypopneas, and respiratory effort-related arousals per hour of sleep.

Respondent burden: The time, energy, and other demands placed on those to whom the instrument is administered.

Responsiveness: The ability or power of a measure to detect clinically important change when it occurs.

Resting tremor: Tremor that occurs or exacerbates when the affected body part is at rest; it decreases or disappears with active motions.

Restrictive cardiomyopathy: Restrictive cardiomyopathy is characterized by nondilated ventricles with impaired ventricular filling. Hypertrophy is typically absent, although the infiltrative and storage diseases can cause a left ventricular wall thickness elevation.

Retching: Contractions of the diaphragm, thoracic, and abdominal muscles without expulsion of gastric contents.

Retinitis: Inflammation of the retina, often caused by infection with cytomegalovirus.

Retinoid dermatitis: Erythematous scaly patches with superficial skin fissuring.

Retrograde pyelography: A procedure where radiocontrast dye is injected into the ureter to produce detailed radiographs of the ureter and kidneys.

Rett's syndrome: A type of pervasive developmental disorder typically associated with severe to profound mental retardation, seen in females only, with the development of significant multiple progressively worsening deficits following a period of normal development (microcephaly, loss of purposeful hand motor skills, and acquisition of stereotyped hand movements, diminished social interests, and appearance of poorly coordinated gait or trunk movements).

Reverse transcriptase: The enzyme in HIV that synthesizes a complementary strand of DNA.

Reversible posterior leukoencephalopathy syndrome (RPLS): Rare, life-threatening condition affecting the brain. Symptoms include headaches, seizures, confusion, and vision problems. Prognosis good with early identification and treatment.

Reye's syndrome: Acute encephalopathy characterized by fever, vomiting, fatty infiltration of the liver, disorientation, and coma, occurring mainly in children and usually following a viral infection, such as chicken pox or influenza.

Rhabdomyolysis: The breakdown of muscle tissue and release of myoglobin and intracellular electrolytes into the circulation because of a variety of causes such as crush injuries, drug-induced

immobilization, and status epilepticus. It often leads to acute renal failure.

Rheumatoid arthritis: A systemic, symmetric autoimmune disease with swelling, pain, and inflammation of joints as a key finding.

Rhinitis: Inflammation of the nasal mucous membrane. Can be seasonal (*hay fever*) or perennial (increasingly called *intermittent* or *persistent*).

Rhinitis medicamentosa: Nasal congestion associated with tolerance to and resulting overuse of topical decongestants. Also known as *rebound vasodilation* or *rebound congestion*.

Rickets: See *Osteomalacia*.

Rigidity: Increased resistance detectable with the passive movement of a limb.

Roth spots: A hemorrhage in the retina with a white center. Roth spots are often associated with bacterial endocarditis.

Russell sign: Callus on dorsum of the hand secondary to self-induced vomiting.

S_4 gallop: An S_4 gallop is a presystolic atrial sound that immediately precedes the first heart sound (S_1). This finding on auscultation of the heart can be indicative of myocardial disease.

Salicylism: Poisoning by salicylic acid or any of its compounds.

Salpingo-oophorectomy: Surgical removal of the ovaries and fallopian tubes.

Sarcoidosis: Sarcoidosis is a multisystem granulomatous disorder of unknown etiology characterized histologically by noncaseating epithelioid granulomas involving various organs or tissues, with symptoms dependent on the site and degree of involvement.

Scale: Flake of stratum corneum.

Scar: Fibrous tissue formed during healing of injury to skin.

Schizophrenia: A chronic disorder of thought and affect encompassing different constellations of symptoms (i.e., positive symptoms, negative symptoms, cognitive dysfunction), with the individual having a significant disturbance in interpersonal relationships and ability to function in society on a daily basis.

Scleritis: Inflammation of the white portion of the eyeball, which can be superficial (episcleritis) or involve deeper layers of the eye.

Scleroderma: Scleroderma is a diffuse connective tissue disease characterized by changes in the skin, blood vessels, skeletal muscles, and internal organs.

Sebaceous gland: Gland that secretes sebum.

Sebosuppressive: Decreasing amount of sebum produced by the sebaceous gland.

Sebum: Oil produced by the sebaceous gland.

Second-generation antipsychotic (atypical antipsychotic): An antipsychotic medication that has pharmacodynamic and clinical properties different than the first generation (typical or traditional) antipsychotics that act primarily by having high levels of binding to dopamine-2 (D_2) receptors. Although definitions of atypicality vary, all second-generation antipsychotics share the property of causing a much lower incidence of extrapyramidal side effects.

Secondary amenorrhea: Cessation of menses in a woman previously menstruating for 6 months or more.

Secondary brain injury: A complex sequence of pathophysiologic events precipitated by the initial or primary brain injury that disrupts the normal central nervous system balance between oxygen supply and demand resulting in a worsened patient outcome.

Secondary hypertension: Persistently elevated BP that results from a known pathophysiological etiology or drug-induced cause.

Secondary hypogonadism: Failure of hypothalamus or pituitary gland to produce adequate amount of luteinizing hormone-releasing hormone (LHRH) or luteinizing hormone (LH). Thus, testicular production of testosterone is reduced.

Secondary prophylaxis (or suppressive therapy): Refers to administration of systemic antifungal agents (generally prior to and throughout the period of granulocytopenia) to prevent relapse of a documented invasive fungal infection that was treated during a previous episode of granulocytopenia.

Secondary resistance: Develops on exposure to an antifungal agent and can be either reversible, because of transient adaptation, or acquired as a result of one or more genetic alterations.

Secondary-progressive multiple sclerosis: Often follows relapsing-remitting multiple sclerosis whereby attacks become continuously progressive over time. It is sometimes accompanied by acute relapses.

Seizure: Paroxysmal disorder of central nervous system, characterized by abnormal neuronal discharges with or without loss of consciousness. They vary in cause, presentation, consequences, duration, and management.

Selection bias: Systematic differences in characteristics between those selected for study and those who are not. See also *Information bias*.

Sepsis: The systemic inflammatory response syndrome (SIRS) secondary to infection. See also *Systemic inflammatory response syndrome*.

Septic arthritis: Infection involving a joint.

Septic shock: Sepsis with persistent hypotension despite fluid resuscitation, along with the presence of perfusion abnormalities. Patients who are on inotropic or vasopressor agents might not be hypotensive at the time perfusion abnormalities are measured.

Serotonin (5-hydroxytryptamine [5-HT]): An inhibitory neurotransmitter present in the raphe nucleus of the brainstem, platelets, carcinoid tumors, and other tissues. It is a vasoconstrictor and neurochemical involved in mood and sleep.

Serum urea nitrogen (SUN): See *Blood urea nitrogen*.

Severe sepsis: Sepsis associated with organ dysfunction, hypoperfusion, or hypotension. Hypoperfusion and perfusion abnormalities can include, but are not limited to, lactic acidosis, oliguria, or acute alteration in mental status.

Short stature: A broad term describing a condition commonly defined by a physical height that is more than two standard deviations below the population mean and lower than the third percentile for height in a specific age group.

Sickle cell disease: A group of inherited red blood cell (RBC) disorder in which sickle cell hemoglobin (HbS) is present. Hemolytic anemia and painful vasoocclusion are the main features.

Simple partial seizure: A seizure beginning in one hemisphere of the brain. It is manifested by alterations in motor functions, sensory or somatosensory symptoms without loss of consciousness. It can progress to a complex partial seizure or to a secondarily generalized seizure with loss of consciousness.

Single-nephron GFR (SNGFR): The rate of filtration through a single glomerulus of a nephron; often reported in nL/min.

Sinus ostia: The pathways that drain the sinuses.

Sinusitis: An inflammation and/or infection of the paranasal sinus mucosa.

Sjögren's syndrome: An inflammatory process affecting the mucous membranes. Can cause dry mouth with difficulty swallowing. Can occur secondary to autoimmune diseases such as rheumatoid arthritis or systemic lupus erythematosus.

Sleep latency: The amount of time it takes to fall asleep.

Sleep spindles: Brief burst of electrical activity seen on the EEG, 12 to 14 Hz.

Slipped capital femoral epiphysis (SCFE): Increased width of the femoral plate observed during GH treatment resulting in hip or knee pain.

Social anxiety disorder (SAD): A disorder characterized by clinically significant anxiety provoked by exposure to certain types of social or performance situations, often leading to avoidance behavior.

Social phobia: See *Social anxiety disorder*.

Somatic pain: Pain arising from skin, bone, joint, muscle, or connective tissue.

Specific measures: Instruments intended to provide greater detail concerning particular outcomes, in terms of functioning and well-being, uniquely associated with a condition and/or its treatment.

Specific phobia: A phobia characterized by clinically significant anxiety provoked by exposure to a specific feared object or situation, often leading to avoidance behavior.

Spermicide: A substance (nonoxynol-9 in the United States) placed in the vagina to inhibit the activity of sperm, thus reducing the risk of pregnancy; available as vaginal creams, films, foams, gels, suppositories, sponges, and tablets.

Spirochete: The class of microorganism that is the agent of syphilis (*Treponema pallidum*).

Standard gamble: An approach to health-state preference elicitation in which the respondent is offered a choice between two alternatives: choice A—living in health state *i* (a health state between full health and death) with certainty, or choice B—taking a gamble on a new treatment for which the outcome is uncertain.

Status epilepticus: Defined as any recurrent or continuous seizure activity lasting longer than 30 minutes in which the patient does not regain baseline mental status. The two most common types are generalized convulsive status epilepticus and nonconvulsive status epilepticus.

Steatorrhea: Excessive fat in stool.

Stereotypy: Persistent repetition of senseless acts or words.

Stevens–Johnson syndrome: A serious dermatologic reaction characterized by blistering of the mucous membranes (mouth, eyes, vagina) with patchy rashes that can cover most of the body. Patients can also experience fever, headache, and cough.

Stress-related mucosal damage: Superficial gastritis-like lesions associated with critical illness in hospitalized patients.

Striae: Linear, atrophic, pink, purple, or white lesions of skin secondary to changes in connective tissue.

Stricture: An area of narrowing or constriction in the gastrointestinal tract due to buildup of fibrotic tissue; often a result of longstanding inflammation.

Stroke: A sudden onset, focal neurologic deficit, of presumed vascular origin, lasting longer than 24 hours.

Stroke volume: The volume of blood ejected from the heart during systole.

Stromal tissue of the prostate: This portion of the prostate is composed of smooth muscle tissue, which is embedded with α-adrenergic receptors. When stimulated, the muscle contracts around the urethra. This comprises approximately 75% of the total volume of the enlarged prostate gland in patients with benign prostatic hyperplasia.

Subarachnoid hemorrhage: Accumulation of blood in the space (subarachnoid space) surrounding the brain that usually contains the cerebrospinal fluid. It is usually caused by rupture of an intracranial aneurysm or trauma. It is a type of hemorrhagic stroke and can cause focal neurologic deficits.

Substance abuse: A maladaptive pattern of substance use indicated by repeated adverse consequences related to the repeated use of the substance. Examples include failure to fulfill important obligations at work, school, or home; repeated use in situations in which it is physically dangerous, such as driving under the influence; legal problems; and social or interpersonal problems such as arguments and fights.

Substance dependence: The continued use of the substance despite adverse substance-related problems. The criteria for substance dependence are the same for each of the drugs or drug classes, varying only to fit the unique pharmacologic properties of each drug.

Substantia nigra: Area of the brain (basal ganglia) where cells produce dopamine; characterized by neuromelanin deposits.

Subtle status epilepticus: For patients with prolonged refractory status epilepticus. The electrographical seizures persist; however, the motor manifestations of the seizures may not be apparent. In such cases the patient is considered in subtle status epilepticus.

Sudden death: Also known as sudden cardiac death; an unexpected death because of cardiac causes occurring in a short time period (generally within 1 hour of symptom onset) in a person with known or unknown cardiac disease in whom no previously diagnosed fatal condition is apparent. Most cases are related to cardiac arrhythmias, particularly ventricular fibrillation.

SUN (serum urea nitrogen): See *Blood urea nitrogen*.

Suppressive therapy: See *Secondary prophylaxis*.

Surge capacity: A term that refers to a healthcare system's ability to handle a large influx of patients in the event of an epidemic or disaster.

SV2A: A presynaptic vesicle protein found in the hippocampus as well as other areas of the brain believed to be important in the mechanism of action of levetiracetam.

Swan–Ganz catheter: A catheter (tube) inserted into the heart to measure pressure and cardiac output.

Symptomatic intracerebral hemorrhage: Collection of blood in the brain, usually after an ischemic stroke, that is associated with neurologic worsening.

Symptomatic status epilepticus: Status epilepticus occurring during the time of an acute neurological injury. This etiology is associated with a poorer prognosis.

Systemic vascular resistance: The resistance to blood flow that is primarily determined by the vascular tone of the arteriolar blood vessels.

Symptomatic: SE occurring during the time of an acute neurological injury. This etiology is associated with a poorer prognosis.

Syncope: Fainting.

Synechiae: A *creeping* angle closure that sometimes occurs in patients between attacks of closed-angle glaucoma.

Synergism: The combination of two drugs (such as antibiotics) that produces an effect greater than the sum of the two drugs if used alone.

Synesthesias: The overflow of one sensory modality to another. For example, colors are heard, sounds are seen.

Synovitis: Inflammation of the synovial lining of the joint.

Synovium: Synovial membrane, the inner of the two layers of the articular capsule of a synovial joint, composed of loose connective tissue and having a free smooth surface that lines the joint cavity. It secretes the synovial fluid.

Systemic inflammatory response syndrome (SIRS): Systemic inflammatory response to a variety of clinical insults, which can be of infectious or noninfectious etiology.

Systemic vascular resistance (SVR): The resistance to blood flow that is primarily determined by the vascular tone of the arteriolar blood vessels.

Systolic blood pressure: The arterial BP that occurs during cardiac contraction.

Systolic heart failure: Systolic heart failure is a condition characterized by a decrease in myocardial contractility, which results in a reduction in the cardiac output and left ventricular ejection fraction.

Tachy-brady syndrome: Tachy-brady syndrome, also known as sick sinus syndrome, is a condition in which the sinoatrial node is unable to perform as the pacemaker of the heart.

Tangential speech: Speech pattern whereby the connections between expressed ideas are unrelated or have little relationship to each other.

Taper: To gradually decrease the dosage of a drug over a period of time.

Tardive: A modifier used to describe movement disorders secondary to chronic antipsychotic treatment (duration of treatment must be greater than 3 months). The disorder must persist for greater than 4 weeks and exhibit masking and unmasking characteristics. Tardive dyskinesia, tardive chorea, tardive dystonia, and tardive akathisia are examples of tardive movement disorders.

Telangiectases: Spidery red skin lesions caused by dilated blood vessels.

Tendonitis: Inflammation of tendons.

Tenesmus: Difficulty with bowel evacuation despite the urgency to defecate.

Teratogenicity: Ability of an agent to cause a defect or malformation in a fetus.

TEWL (transepidermal water loss): The rate of water loss by evaporation from the skin.

Thalassemia: Any of a group of inherited disorders of hemoglobin metabolism in which there is impaired synthesis of one or more of the polypeptide chains of globin.

Third-spacing: The shift of fluid and protein into the peritoneal cavity and bowel wall lumen that occurs as a result of peritonitis.

Thought blocking: Interruption of a train of thought whereby the person stops speaking suddenly and without warning, even in the middle of a sentence. Person may report that the thoughts were taken out of his or her head.

Thought broadcasting: Belief that one's thoughts are audible to others.

Thrombin: The enzyme formed from prothrombin that converts fibrinogen to fibrin. It is the principle driving force in the clotting cascade.

Thrombogenesis: The process of forming a blood clot.

Thrombolysis: The process of enzymatically dissolving or breaking apart a blood clot.

Thrombolytic: An enzyme that dissolves or breaks apart blood clots.

Thromboplastin: A substance that triggers the coagulation cascade. Tissue factor is a naturally occurring thromboplastin and used in the prothrombin time (PT) test.

Thrombopoiesis: The process of platelet production from immature cells.

Thrombosis: The process of forming a thrombus.

Thrombotic thrombocytopenic purpura: A life-threatening disease involving embolism and thrombosis of the small blood vessels in the brain and kidney.

Thrombus: An aggregation of fibrin and platelets within a blood vessel. A thrombus often causes vessel obstruction, inflammation, and injury.

Thrush: Fungal infection of the oral mucosa.

Thyroid-stimulating hormone (TSH): A polypeptide hormone secreted by the anterior pituitary gland that stimulates iodine uptake and thyroid hormone synthesis.

Thyrotropin-releasing hormone (TRH): A trophic hormone released by the hypothalamus that stimulates release of thyroid-stimulating hormone (TSH).

Time trade-off: An approach to health-state preference elicitation in which the respondent is asked to trade off years of life in less than full health for a shorter number of years in full health.

Tinea barbae: Fungal infection of the hair follicles of the beard or mustache.

Tinea capitis: Fungal infection of the scalp, hair follicles, or adjacent skin.

Tinea corporis: Fungal infection of the glabrous skin of the trunk and extremities.

Tinea cruris: Fungal infection of the proximal thighs and buttocks.

Tinea manuum: Fungal infection of the palmar surface of the hands.

Tinea pedis: Fungal infection of the feet.

Tinnitus: A noise in the ears, as ringing, buzzing, roaring, clicking, etc. Such sounds can at times be heard by those other than the patient.

Tocolytic: Agent that stops labor contractions.

Tolerance: (1) A state of adaptation in which exposure to a drug induces changes that result in a diminution of one or more of the

drug's effects over time. (2) The ability of the immune system to accept a transplanted allograft as part of *self*.

Tonic-clonic seizures: Sharp tonic contraction of muscles followed by a period of rigidity and clonic movement.

Tophi: Urate deposits.

Toxic epidermal necrolysis: A syndrome similar to Stevens-Johnson syndrome characterized by blistering of skin and mucous membranes in response to administration of a drug. Large areas of skin may peel off.

Toxic megacolon: A segmental or total colonic distension of >6 cm with acute colitis and signs of systemic toxicity.

Toxic shock syndrome: Sudden onset of fever, muscle ache, vomiting and diarrhea, accompanied by a peeling rash and followed by low body temperature and shock; caused by staphylococcal endotoxin, especially from infection of the vagina associated with tampon use.

Toxoplasmosis: Clinical infection with *Toxoplasma gondii.*

Transmural: Across the wall of an organ or structure; in the case of CD, inflammation may extend through all four layers of the intestinal wall.

Transurethral incision of the prostate: In this surgical procedure, the bladder neck opening is widened by making incisions at various locations around the bladder neck with a resectoscope, which is inserted into the penis. Excess prostate tissue is not removed.

Transurethral prostatectomy: In this surgical procedure, an enlarged prostate core is removed from the inside out. That is, a resectoscope is inserted into the penis. A cutting blade at the end shaves out excess prostate tissue.

Transverse lie: The fetus is perpendicular to the mother. Usually the shoulder is the presenting part. Fetuses in this position must be delivered by cesarean section.

Transverse myelitis: Inflammation of the full width of the spinal cord that disrupts communication to the muscles, resulting in pain, weakness, and muscle paralysis.

Traveler's diarrhea: Diarrhea caused by contaminated food or water and usually attributed to enterotoxigenic *Escherichia coli* (ETEC), *Shigella*, *Campylobacter*, *Salmonella* species, or viruses.

Troponin: A protein found predominately in cardiac, but not skeletal, muscle, which regulates calcium-mediated interaction of actin and myosin. Troponin I and T are released into the blood from the myocytes at the time of myocardial cell necrosis secondary to infarction. These biochemical markers become elevated and are used in the diagnosis of myocardial infarction. Troponin I and T are more sensitive and specific for infarction than creatinine kinase, which is found in both skeletal and myocardial cells. The exact value of troponin I or T, which is diagnostic of infarction, differs based on assay.

Trousseau's sign: A hand spasm produced by placing a blood pressure cuff over the forearm and inflating the pressure above the systolic pressure for 3 minutes.

Tubule: Section of the nephron that is responsible for secretion and reabsorption of water, electrolytes, and drugs.

Tumor: Elevated, solid lesion.

Tumor necrosis factor-α (TNF-α): A proinflammatory cytokine.

Type I reaction: An immediate, immunoglobulin E (IgE)-mediated allergic reaction.

Ulcer: Loss of epidermis and dermis caused by sloughing of necrotic tissue.

Ultradian sleep–wake rhythm: Is a cycle of sleep and wake that repeats in less than 24 hours. Babies have an ultradian sleep–wake rhythm with multiple sleep and wake periods in a 24-hour period.

Ultrafiltration: The process of removing water from the blood during dialysis.

Ultraviolet A light: 315–400 nm ultraviolet A light.

Ultraviolet A light 1: 340–400 nm ultraviolet A light.

Ultraviolet B light, broadband: 280–315 nm ultraviolet B light.

Ultraviolet B light, narrow band: 311 nm ultraviolet B light.

Umbilication: Slight, navel-like depression, or dimpling, of the center of a rounded body.

Unilateral: On either the right or left side, not crossing the midline. When used for defining sensory or motor disturbances of migraine aura, it includes complete or partial hemi-distribution.

Upper respiratory tract infection: Otitis media, sinusitis, pharyngitis, laryngitis (croup), rhinitis, or epiglottitis.

Urea: A waste product found in the blood and caused by the normal breakdown of protein in the body.

Uremia: An array of symptoms associated with accumulation of metabolic by-products and endogenous toxins in the blood due to impaired kidney function. Symptoms include nausea, vomiting, loss of appetite, weakness, and mental confusion.

Urethritis: Inflammation of the urethra.

Urinalysis: The diagnostic analysis of urine and its components; can be microscopic or macroscopic in nature.

Urinary incontinence: Involuntary leakage of urine; can result from urethral underactivity (stress urinary incontinence), urethral overactivity (overflow incontinence), or mixed pathophysiologic mechanisms.

Urine: Fluid waste resulting from filtration of blood by the kidneys; transferred to the bladder by ureters and expelled from the body through the urethra by the act of voiding or urinating.

Urticaria: Hives (red, raised bumps) that may occur after exposure to an allergen.

Vacuum erection device: Medical device used to manually induce an erection.

Vagal nerve stimulator (VNS): A medical device that is surgically implanted in patients with refractory epilepsy.

Validity: An estimation of the extent to which an instrument is measuring what it is purported to be measuring.

Valsalva maneuver: The Valsalva maneuver is the expiratory effort against a closed glottis, which increases thoracic cavity pressure, which impedes venous return to the heart. This maneuver results in blood pressure and heart rate changes and is used to diagnose treat various cardiac conditions.

Vasculitis: Inflammation of blood vessels.

Vasopressin: A posterior pituitary hormone that controls fluid balance by acting on the renal collecting ducts to prevent water loss.

Vector: Carrier (person, animal, or insect) of disease.

Vegetation: Bacterial growth on heart valves.

Ventricular remodeling: Alterations in myocardial cells and the extracellular matrix that result in changes in the size, shape, structure, and function of the heart. The remodeling process leads to reductions in myocardial systolic and/or diastolic function that, in turn, leads to further myocardial injury, perpetuating the remodeling process and the decline in ventricular dysfunction and progression of heart failure.

Vesicle: Clear blister (<0.5 cm in diameter) filled with fluid.

Visceral pain: Pain arising from internal organs such as the large intestine or pancreas.

Visual analog scale: A response scale that is a line with the end points well defined (e.g., 0 = worst imaginable health state, and 100 = best imaginable health state).

Volume of distribution: A proportionality constant that relates the amount of drug in the body to its serum concentration.

Vomiting: Contraction of the abdominal muscles, descent of the diaphragm, and opening of the gastric cardia resulting in expulsion of stomach contents from the mouth.

Vulgaris: Ordinary, common.

Wearing-off phenomena: Also known as end-of-dose wearing-off or motor fluctuations. The waning of the effects of a dose of levodopa prior to the scheduled time for the next dose, resulting in return of parkinsonian features, such as, tremor, slowness, and rigidity.

White coat hypertension: Patients have normal BP measurements based on home measurements but have elevated BP measurements when measured in a clinical setting.

Withdrawal: The development of a substance-specific syndrome after cessation of or reduction in intake of a substance that was used regularly by the individual to induce a state of intoxication. Withdrawal causes significant distress to the individual and is associated with impairment in social, occupational, or other areas of functioning. Withdrawal is usually associated with substance dependence. Withdrawal generally is also associated with a craving to readminister the drug to relieve the symptoms.

Withdrawal bleeding: The predictable bleeding that results from cessation of a progestogen.

Withdrawal syndrome: The onset of a predictable constellation of signs and symptoms involving alerted activity of the central nervous system after the abrupt discontinuation of, or rapid decrease in, dosage of a drug.

Xerosis: Dry skin.

Xerostomia: Dry mouth caused by decreased salivary production.

Yeasts: Oval or spherically shaped unicellular forms that generally produce pasty or mucoid colonies on agar media, similar to those observed with bacterial cultures. Yeasts have rigid cell walls that reproduce by budding, a process in which daughter cells arise from pinching off a portion of the parent cell.

Zeitgeber: Environmental cue.

Zollinger–Ellison syndrome: Gastric acid hypersecretory disease caused by a gastrin-secreting tumor and leading to multiple, severe duodenal ulcers.

Filgrastim (G-CSF), 1163, 1787, 2248, 2340, 2395, 2458, 2465
  colony-stimulating factors, recommendations for use, 2118*t*
  use of, 2124
Finasteride, 1461, 1776, 2321
  antisebum agents, 1686
  5 α -reductase inhibitors, 1462
  benign prostatic hyperplasia, medical treatment options for, 1459*t*
  chemoprevention, 2320
  hirsutism, 1340
  pharmacologic therapy, 1459
  prostate cancer, hormonal manipulations in, 2323
First heart sound (S_1), 56, 57*f*
First pass effect, 708
Fixed-dose combination products, 129, 130*t*
Flecainide, 274, 278, 292, 293, 295
  additive drug combinations, 278
  as antiarrhythmic drugs, classification of, 278*t*
  cardiac arrhythmia suppression trial (CAST), life table curves, 295*f*
  causing tachycardia, 300
  class Ic AADs, 278
  drug—drug and drug—food interactions, 809
  evidence-based pharmacologic treatment recommendations for, 285*t*
  heritable polymorphic ventricular tachycardia, 297*t*
  negative inotropic effect, 145*t*
  oral doses, 282*t*
  pharmacokinetics of, 281*t*
  selection guidelines for, 287–290, 289*t*
  side effects of, 280*t*
Flexible sigmoidoscopy, 545
Flolan (epoprostenol)
  drug class information, 505*t*
  specific pharmacologic therapy, 502
Flomax (tamsulosin)
  benign prostatic hyperplasia, medical treatment options for, 1459*t*
  dosing schedule of, 1461*t*
Floppy baby syndrome, 1370
Floppy iris syndrome, 1461
Fluconazole, 2081, 2085, 2088, 2094
  for coccidioidomycosis, 2183*t*
  for cryptococcal meningitis, 1838, 2183*t*
  for invasive candidiasis, 2048, 2061, 2065
  for mucosal candidiasis, 2038
  for vulvovaginal candidiasis, 2057, 2058
Flucytosine, 2099
  acute *C neoformans* meningitis, 1837
  dosing of, 1832
  treatment of HIV-associated cryptococcal meningitis, 1838
Fludarabine
  based therapy, 2410
  for chronic lymphocytic leukemia, 2410, 2410*t*, 2411
  in conditioning for hematopoietic stem cell transplantation, 2461
  dose modification of, in renal impairment, 2204*t*
Fludarabine monophosphate, 2204
  purines and purine antimetabolites, 2204
Fludarabine phosphate
  purine analogs, 2349
Fluid, 2486
  distribution and major indications, 427
Flumazenil, 1124
  availability of, 544
  effect on neurotransmission, 653
  portosystemic encephalopathy, 652*t*
  substance intoxication, pharmacologic treatment of, 1123*t*
  as systemic antidotes available in, 33*t*
  used to, 44
Flunisolide, 463
  availability of, 462*t*
  corticosteroids, pharmacodynamic/pharmacokinetic comparison of, 457*t*
  nasal steroids, dosage of, 1657*t*
Flunitrazepam, 1116
  as date rape drug, 1117
  sedative-hypnotics, dependence on, 1116*t*
  use of, 1116
Fluorescence in situ hybridization (FISH), 2240
Fluoropyrimidines, 2308, 2309, 2311, 2312
  Adjuvant based chemotherapy, 2287, 2299
  algorithm for treatment, 2310*f*
  capecitabine, 2308
  chemotherapy and endocrine agents, 2202, 2304
  metastatic colorectal cancer, trials in, 2306*t*
  preoperative (neoadjuvant) therapy, 2303
Fluoroquinolones, 676, 2115, 2119
  antibiotics, 2497
  prophylaxis with, 2119
Fluorouracil/leucovorin, 2246, 2301–2303, 2305, 2307, 2313
  adjuvant chemotherapy, 2301
  agents in development, 2313
  based regimens, 2304, 2305*t*
  benefit of, 2299
  biologic therapy, 2308
  for breast cancer, 2247
  capecitabine, 2302, 2308
  chemotherapy regimens for, 2301*t*, 2304
  colon cancer, treatment of, 2299, 2301
  compatibility of medication, 2500
  cytotoxic drugs, 2246
  hepatic artery infusion, 2309
  initial metastatic regimen, approach to selection, 2310
  investigational approaches, 2302
  irinotecan's activity, 2305–2307, 2311
  for metastatic colorectal cancer, 2305, 2306*t*
  oxaliplatin, 2307, 2311
  for rectal cancer, 2303
  systemic chemotherapy, 2310
Fluorouracil plus oxaliplatin, for oncologic disorders, 2302
Fluoxetine (Prozac), 1070, 1092, 1096, 1106, 1204, 1214, 1405
  adult dosages for, 1178*t*
  alcohol dependence treatment, pharmacologic agents used in, 1135*t*
  algorithm and guidelines for, 1197*t*
  alternative drug treatments, 1234
  antidepressant therapy, 1232, 1232*t*
  clopidogrel and prasugrel, pharmacokinetics of, 254*t*
  cytochrome (CYP) P450 enzyme inhibitory potential, 1185*t*
  dementia, noncognitive symptoms, use for, 957*t*
  dose of, 711*t*
  efficacy, 1223
  fatigue, 975
  fraction of, 862*t*
  in hepatic and renal disease, 1236
  hepatocellular injury, 659
  interactions of, 1184*t*
  interactions with antipsychotic medications, 1165*t*–1166*t*
  maintenance phase and discontinuation, 1221
  mechanism of action, 1216
  in narcolepsy treatment, 1248*t*
  nonpharmacologic therapy, 1106, 1107
  norepinephrine and serotonin reuptake blockade, potencies of, 1179*t*
  panic disorder treatment, 1219*t*
  pediatric patients, 1185
  pharmacokinetics, 1236
  properties of, 1182*t*
  pharmacologic therapy, 1219, 1246
  prophylactic migraine therapies, 1067*t*
  selected menstrual disorders, therapeutic agents for, 1396*t*
  as selective serotonin reuptake inhibitors (SSRIs), 1156, 1164
  serotonergic antidepressants, 1236
  serotonin reuptake inhibitors, dosing of, 1237*t*
  serotonin selective reuptake inhibitors, 1180
  used to, 45
  warfarin drug interactions, 329*t*
Fluoxymesterone
  erectile dysfunction, selected drug treatments for
  dosing regimens for, 1442*t*
  metastatic breast cancer, endocrine therapies used for, 2255*t*
  pharmacokinetics, 1448
Fluphenazine (Prolixin), 1095, 1160, 1162, 1204
  doses and dosage forms, 1153*t*
  long-acting injectable antipsychotics, 1155
  pharmacokinetic parameters of, 1158*t*
  pharmacokinetics, 1157
  side-effect incidence of, 1158*t*
Flurandrenolide
  corticosteroid potency chart, 1697*t*
  corticosteroids, 1696
Flurazepam (Dalmane)
  benzodiazepine therapy, 1216
  pharmacokinetics of, 1244*t*
Flutamide, 2328
  as antiandrogens, 2327*t*
  antisebum agents, 1486
  benign prostatic hyperplasia, medical treatment options for, 1459*t*
  hormonal therapy, comparative costs of, 2330*t*
  prostate cancer, hormonal manipulations in, 2323*t*
Fluticasone, 486, 487, 491
  dosage of nasal steroids, 1657*t*
  inhalation devices, characteristics of, 449*t*
Fluticasone propionate, 463
  inhaled corticosteroid products, 462*t*
  pharmacodynamic/pharmacokinetic comparison, 457*t*
  topical corticosteroid potency chart, 1697*t*
Fluvastatin, 381, 851, 2186
  drug–drug interactions, 1944*t*
  drug-induced lupus, medications implicated in, 1513*t*

Fluvastatin (*continued*)
drug therapy effects on lipids and lipoproteins, 375*t*
hyperlipidemia, 842
statins, pharmacokinetics of, 376*t*
Fluvoxamine (Luvox), 1070, 1156, 1186, 1203
adult dosages for, 1178*t*
anxiety disorders, drug choices for, 1213*t*
clopidogrel and prasugrel, pharmacokinetics of, 254*t*
cytochrome (CYP) P450 enzyme inhibitory potential, 1185*t*
dosage adjustment, 711*t*
drug class information, 506*t*
drug interactions of, 1184*t*, 1218
panic disorder, treatment of, 1219*t*, 1222–1224
pharmacokinetic properties of, 1182*t*
potential drug interactions with antipsychotic medications, 1165*t*–1167*t*
side-effect profile, 1179*t*
warfarin drug interactions, 329*t*
Focal segmental glomerulosclerosis (FSGS), 845
clinical presentation, 846
etiology and epidemiology, 845
pathophysiology, 845–846

Common Laboratory Tests

Laboratory	Conventional Units	Conversion Factor	SI Units
Acid phosphatase			
Male	2–12 units/L	16.7	33–200 nkat/L
Female	0.3–9.2 units/L	16.7	5–154 nkat/L
Activated partial thromboplatin time (aPTT)	25–40 s		
Adrenocorticotropic hormone (ACTH)	15–80 pg/mL or ng/L	0.2202	3.3–17.6 pmol/L
Alanine aminotransferase (ALT, SGPT)	7–53 IU/L	0.01667	0.12–0.88 μkat/L
Albumin	3.5–5.0 g/dL	10	35–50 g/L
Albumin:creatinine ratio (urine)			
Normal	Less than 30 mg/g creatinine		
Microalbuminuria	30–300 mg/g creatinine		
Proteinuria	Greater than 300 mg/g creatinine		
or	*or*		
Normal			
Male	Less than 2.0 mg/mmol creatinine		
Female	Less than 2.8 mg/mmol creatinine		
Microalbuminuria			
Male	2.0–20 mg/mmol creatinine		
Female	2.8–28 mg/mmol creatinine		
Proteinuria			
Male	Greater than 20 mg/mmol creatinine		
Female	Greater than 28 mg/mmol creatinine		
Aldosterone			
Supine	Less than 16 ng/dL	27.7	Less than 444 pmol/L
Upright	Less than 31 ng/dL	27.7	Less than 860 pmol/L
Alkaline phosphatase			
10–15 years	130–550 IU/L	0.01667	2.17–9.17 μkat/L
16–20 years	70–260 IU/L	0.01667	1.17–4.33 μkat/L
Greater than 20 years	38–126 IU/L	0.01667	0.13–2.10 μkat/L
Alpha-fetoprotein (AFP)	Less than 15 ng/mL	1	Less than 15 mcg/L
$Alpha_1$-antitrypsin	80–200 mg/dL	0.01	0.8–2.0 g/L
Amikacin, therapeutic	15–30 mg/L peak	1.71	25.6–51.3 μmol/L peak
	Less than or equal to 8 mg/L trough		Less than or equal to 13.7 μmol/L trough
Amitriptyline	80–200 ng/ml or mcg/L	3.4	272–680 nmol/L
Ammonia (plasma)	15.33–56.20 mcg NH_3/dL	0.5872	9–33 μmol NH_3/L
Amylase	25–115 IU/L	0.01667	0.42–1.92 μkat/L
Androstenedione	50–250 ng/dL	0.0349	1.7–8.7 nmol/L
Angiotensin-converting enzyme	15–70 units/L	16.67	250–1167 nkat/L
Anion gap	7–16 mEq/L	1	7–16 mmol/L
Anti–double-stranded DNA (anti-ds DNA)	Negative		
Anti-HAV	Negative		
Anti-HBc	Negative		
Anti-HBs	Negative		
Anti-HCV	Negative		
Anti–Sm antibody	Negative		
Antinuclear antibody (ANA)	Negative		
Apolipoprotein A-1			
Male	95–175 mg/dL	0.01	0.95–1.75 g/L
Female	100–200 mg/dL	0.01	1.0–2.0 g/L
Apolipoprotein B			
Male	50–110 mg/dL	0.01	0.5–1.10 g/L
Female	50–105 mg/dL	0.01	0.5–1.05 g/L
Aspartate aminotransferase (AST, SGOT)	11–47 IU/L	0.01667	0.18–0.78 μkat/L
$Beta_2$-microglobulin	Less than 0.2 mg/dL	10	2 mg/L
Bicarbonate	22–26 mEq/L	1	22–26 mmol/L
Bilirubin			
Total	0.3–1.1 mg/dL	17.1	5.13–18.80 μmol/L
Direct	0–0.3 mg/dL	17.1	0–5.1 μmol/L
Indirect	0.1–1.0 mg/dL	17.1	1.71–17.1 μmol/L
Bleeding time	3–7 minutes		
Blood gases (arterial)			
pH	7.35–7.45	1	7.35–7.45
PO_2	80–105 mm Hg	0.133	10.6–14.0 kPa
PCO_2	35–45 mm Hg	0.133	4.7–6.0 kPa
HCO_3	22–26 mEq/L	1	22–26 mmol/L
O_2 saturation	Greater than or equal to 95%	0.01	0.95
Blood urea nitrogen	8–25 mg/dL	0.357	2.9–8.9 mmol/L
B-type natriuretic peptide (BNP)	0–99 pg/mL	1	0–99 ng/L
BUN-to-creatinine ratio	10:1 to 20:1		
C-peptide	0.51–2.70 ng/mL	330	170–900 pmol/L or
		0.33	0.172–0.900 nmol/L
C-reactive protein	Less than 0.8 mg/dL	10	Less than 8 mg/L
CA-125	Less than 35 units/mL	1	Less than 35 kilounits/L
CA 15-3	Less than 30 units/mL	1	Less than 30 kilounits/L
CA 19-9	Less than 37 units/mL	1	Less than 37 kilounits/L
CA 27-29	Less than 38 units/mL	1	Less than 38 kilounits/L
Calcium			
Total	8.6–10.3 mg/dL	0.25	2.15–2.58 mmol/L
	4.3–5.16 mEq/L	0.50	2.15–2.58 mmol/L
Ionized	4.5–5.1 mg/dL	0.25	1.13–1.28 mmol/L
	2.26–2.56 mEq/L	0.50	1.13–1.28 mmol/L
Carbamazepine, therapeutic	4–12 mg/L	4.23	17–51 μmol/L
Carboxyhemoglobin (nonsmoker)	Less than 2%	0.01	Less than 0.02
Carcinoembryonic antigen (CEA)			
Nonsmoker	Less than 2.5 ng/mL	1	Less than 2.5 mcg/L
Smoker	Less than 5 ng/mL		Less than 5 mcg/L
Cardiac troponin I (see troponin I)	Variable ng/mL	1	Variable mcg/L
CD4 lymphocyte count	31–61% of total lymphocytes		

(continued)

Laboratory	Conventional Units	Conversion Factor	SI Units
CD8 lymphocyte count	18–39% of total lymphocytes		
Cerebrospinal fluid (CSF)			
Pressure	75–175 mm H_2O		
Glucose	40–70 mg/dL	0.0555	2.2–3.9 mmol/L
Protein	15–45 mg/dL	0.01	0.15–0.45 g/L
WBC	Less than 10/mm^3		
Ceruloplasmin	18–45 mg/dL	10	180–450 mg/L
		0.063	1.1–2.8 μmol/L
Chloride	97–110 mEq/L	1	97–110 mmol/L
Cholesterol			
Desirable	Less than 200 mg/dL	0.0259	Less than 5.18 mmol/L
Borderline high	200–239 mg/dL	0.0259	5.18–6.19 mmol/L
High	Greater than or equal to 240 mg/dL	0.0259	Greater than or equal to 6.2 mmol/L
Chorionic gonadotropin (β-hCG)	Less than 5 milliunits/mL	1	Less than 5 units/L
Clozapine	Minimum trough 300–350 ng/mL or mcg/L	3.06	918–1071 nmol/L
CO_2 content	22–30 mEq/L	1	22–30 mmol/L
Complement component 3 (C3)	70–160 mg/dL	0.01	0.7–1.6 g/L
Complement component 4 (C4)	20–40 mg/dL	0.01	0.2–0.4 g/L
Copper	70–150 mcg/dL	0.157	11–24 μmol/L
Cortisol (fasting, morning)	5–25 mcg/dL	27.6	138–690 nmol/L
Cortisol (free, urinary)	10–100 mcg/day	2.76	28–276 nmol/day
Creatine kinase			
Male	30–200 IU/L	0.01667	0.50–3.33 μkat/L
Female	20–170 IU/L	0.01667	0.33–2.83 μkat/L
MB fraction	0–7 IU/L	0.01667	0.0–0.12 μkat/L
Creatinine clearance (CrCl) (urine)	85–135 mL/minute/1.73 m^2	0.00963	0.82–1.3 mL/s/m^2
Creatinine			
Male 4–20 years	0.2–1.0 mg/dL	88.4	18–88 μmol/L
Female 4–20 years	0.2–1.0 mg/dL	88.4	18–88 μmol/L
Male (adults)	0.7–1.3 mg/dL	88.4	62–115 μmol/L
Female (adults)	0.6–1.1 mg/dL	88.4	53–97 μmol/L
Cyclosporin			
Renal transplant	100–300 ng/mL or mcg/L	0.832	83–250 nmol/L
Cardiac, liver, or pancreatic transplant	200–350 ng/mL or mcg/L	0.832	166–291 nmol/L
Cryptococcal antigen	Negative		
D-dimers	Less than 250 ng/mL	1	Less than 250 mcg/L
Desipramine	75–300 ng/mL or mcg/L	3.75	281–1125 mmol/L
Dexamethasone suppression test (DST) (overnight)	8:00 am cortisol less than 5 mcg/dL	0.0276	Less than 0.14 μmol/L
DHEAS			
Male	170–670 mcg/dL	0.0271	4.6–18.2 μmol/L
Female			
Premenopausal	50–540 mcg/dL	0.0271	1.4–14.7 μmol/L
Postmenopausal	30–260 mcg/dL	0.0271	0.8–7.1 μmol/L
Digoxin, therapeutic	0.5–1.0 ng/mL or mcg/L	1.28	0.6–1.3 nmol/L
Erythrocyte count (blood) See under Red blood cell count			
Erythrocyte sedimentation rate (ESR)			
Westergren			
Male	0–20 mm/hour		
Female	0–30 mm/hour		
Wintrobe			
Male	0–9 mm/hour		
Female	0–15 mm/hour		
Erythropoietin	2–25 mIU/mL	1	2–25 IU/L
Estradiol			
Male	10–36 pg/mL	3.67	37–132 pmol/L
Female	34–170 pg/mL	3.67	125–624 pmol/L
Ethanol, legal intoxication	Greater than or equal to 50–100 mg/dL	0.217	10.9–21.7 mmol/L
	Greater than or equal to 0.05–0.1%	217	
Ethosuccimide, therapeutic	40–100 mg/L or mcg/mL	7.08	283–708 μmol/L
Factor VIII or factor IX			
Severe hemophilia	Less than 1 IU/dL	0.01	Less than 0.01 units/mL
Moderate hemophilia	1–5 IU/dL	0.01	0.01–0.05 units/mL
Mild hemophilia	Greater than 5 IU/dL	0.01	Greater than 0.05 units/mL
Usual adult levels	60–140 IU/dL	0.01	0.60–1.40 units/mL
Ferritin			
Male	20–250 ng/mL	1	20–250 mcg/L
Female	10–150 ng/mL	1	10–150 mcg/L
Fibrin degradation products (FDP)	2–10 mg/L		
Fibrinogen	200–400 mg/dL	0.01	2.0–4.0 g/L
Folate (plasma)	3.1–12.4 ng/mL	2.266	7.0–28.1 nmol/L
Folic acid (RBC)	125–600 ng/mL	2.266	283–1360 nmol/L
Follicle-stimulating hormone (FSH)			
Male	1–7 mIU/mL	1	1–7 IU/L
Female			
Follicular phase	1–9 mIU/mL	1	1–9 IU/L
Midcycle	6–26 mIU/mL	1	6–26 IU/L
Luteal phase	1–9 mIU/mL	1	1–9 IU/L
Postmenopausal	30–118 mIU/mL	1	30–118 IU/L
Free thyroxine index (FT_4I)	6.5–12.5		
Gamma glutamyl transferase (GGT)	0–30 IU/L	0.01667	0–0.5 μkat/L
Gastrin (fasting)	0–130 pg/mL	1	0–130 ng/L
Gentamicin, therapeutic	4–10 mg/L peak	2.09	8.4–21 μmol/L peak
	Less than or equal to 2 mg/L trough		Less than or equal to 4.2 μmol/L trough
Globulin	2.3–3.5 g/dL	10	23–35 g/L
Glucose (fasting, plasma)	65–109 mg/dL	0.0555	3.6–6.00 mmol/L
Glucose, two hour postprandial blood (PPBG)	Less than 140 mg/dL	0.0555	Less than 7.8 mmol/L
Granulocyte count	1.8–6.6 $\times$ $10^3/\mu$L	10^6	1.8–6.6 $\times$ 10^9/L
Growth hormone (fasting)			
Male	Less than 5 ng/mL	1	Less than 5 mcg/L
Female	Less than 10 ng/mL	1	Less than 10 mcg/L

(continued on back inside cover)

Laboratory	Conventional Units	Conversion Factor	SI Units
Haptoglobin	60–270 mg/dL	0.01	0.6–2.7 g/L
HBeAg	Negative		
HbsAg	Negative		
HBV DNA	Negative		
Hematocrit			
Male	40.7–50.3%	0.01	0.407–0.503
Female	36.1–44.3%	0.01	0.361–0.443
Hemoglobin (blood)			
Male	13.8–17.2 g/dL	10	138–172 g/L
		Alternate SI: 0.62	8.56–10.67 mmol/L
Female	12.1–15.1 g/dL	10	121–151 g/L
		Alternate SI: 0.62	7.5–9.36 mmol/L
Hemoglobin A1c	4.0–6.0%	0.01	0.04–0.06
Heparin			
Via protamine titration method	0.2–0.4 mcg/mL		
Via anti-factor Xa assay	0.3–0.7 mcg/mL		
High-density lipoprotein (HDL) cholesterol	Greater than 35 mg/dL	0.0259	Greater than 0.91 mmol/L
Homocysteine	3.3–10.4 μmol/L		
Ibuprofen			
Therapeutic	10–50 mcg/mL	4.85	49–243 μmol/L
Toxic	100–700 mcg/mL or more	4.85	485–3395 μmol/L or more
Imipramine, therapeutic	100–300 ng/mL or mcg/L	3.57	357–1071 nmol/L
Immunoglobulin A (IgA)	85–385 mg/dL	0.01	0.85–3.85 g/L
Immunoglobulin G (IgG)	565–1765 mg/dL	0.01	5.65–17.65 g/L
Immunoglobulin M (IgM)	53–375 mg/dL	0.01	0.53–3.75 g/L
Insulin (fasting)	2–20 microunits/mL or milliunits/L	7.175	14.35–143.5 pmol/L
International normalized ratio (INR), therapeutic	2.0–3.0 (2.5–3.5 for some indications)		
Iron			
Male	45–160 mcg/dL	0.179	8.1–31.3 μmol/L
Female	30–160 mcg/dL	0.179	5.4–31.3 μmol/L
Iron binding capacity (total)	220–420 mcg/dL	0.179	39.4–75.2 μmol/L
Iron saturation	15–50%	0.01	0.15–0.50
Lactate (plasma)	0.7–2.1 mEq/L	1	0.7–2.1 mmol/L
	6.3–18.9 mg/dL	0.111	
Lactate dehydrogenase	100–250 IU/L	0.01667	1.67–4.17 μkat/L
Lead	Less than 25 mcg/dL	0.0483	Less than 1.21 μmol/L
Leukocyte count	$3.8–9.8 \times 10^3/\mu L$	10^6	$3.8–9.8 \times 10^9$/L
Lidocaine, therapeutic	1.5–6.0 mcg/mL or mg/L	4.27	6.4–25.6 μmol/L
Lipase	Less than 100 IU/L	0.01667	1.7 μkat/L
Lithium, therapeutic	0.5–1.25 mEq/L	1	0.5–1.25 mmol/L
Low-density lipoprotein (LDL) cholesterol			
Desirable	Less than 130 mg/dL	0.0259	Less than 3.36 mmol/L
Borderline high risk	130–159 mg/dL	0.0259	3.36–4.11 mmol/L
High risk	Greater than or equal to 160 mg/dL	0.0259	Greater than or equal to 4.13 mmol/L
Luteinizing hormone (LH)			
Male	1–8 milliunits/mL	1	1–8 units/L
Female			
Follicular phase	1–12 milliunits/mL	1	1–12 units/L
Midcycle	16–104 milliunits/mL	1	16–104 units/L
Luteal phase	1–12 milliunits/mL	1	1–12 units/L
Postmenopausal	16–66 milliunits/mL	1	16–66 units/L
Lymphocyte count	$1.2–3.3 \times 10^3/\mu L$	10^6	$1.2–3.3 \times 10^9$/L
Magnesium	1.3–2.2 mEq/L	0.5	0.65–1.10 mmol/L
	1.58–2.68 mg/dL	0.411	0.65–1.10 mmol/L
Mean corpuscular volume	80.0–97.6 μm^3	1	80.0–97.6 fL
Mononuclear cell count	$0.2–0.7 \times 10^3/\mu L$	10^6	$0.2–0.7 \times 10^9$/L
Nortriptyline, therapeutic	50–150 ng/mL or mcg/L	3.8	190–570 nmol/L
NT-ProBNP (see Pro-BNP)			
Osmolality (serum)	275–300 mOsm/kg	1	275–300 mmol/kg
Osmolality (urine)	250–900 mOsm/kg	1	250–900 mmol/kg
Parathyroid hormone (PTH), intact	10–60 pg/mL or ng/L	0.107	1.1–6.4 pmol/L
Parathyroid hormone (PTH), N-terminal	8–24 pg/mL or ng/L		
Parathyroid hormone (PTH), C-terminal	50–330 pg/mL or ng/L		
Phenobarbital, therapeutic	15–40 mcg/mL or mg/L	4.31	65–172 μmol/L
Phenytoin, therapeutic	10–20 mcg/mL or mg/L	3.96	40–79 μmol/L
Phosphate	2.5–4.5 mg/dL	0.323	0.81–1.45 mmol/L
Platelet count	$140–440 \times 10^3/\mu L$	10^6	$140–440 \times 10^9$/L
Potassium (plasma)	3.3–4.9 mEq/L	1	3.3–4.9 mmol/L
Prealbumin (adult)	19.5–35.8 mg/dL	10	195–358 mg/dL
Primidone, therapeutic	5–12 mcg/mL or mg/L	4.58	23–55 μmol/L
ProBNP	Less than 125 pg/mL or ng/L	0.118	Less than 14.75 pmol/L
Procainamide, therapeutic	4–10 mcg/mL or mg/L	4.23	17–42 μmol/L
Progesterone			
Male	13–97 ng/dL	0.0318	0.4–3.1 nmol/L
Female			
Follicular phase	15–70 ng/dL		0.5–2.2 nmol/L
Luteal phase	200–2500 ng/dL		6.4–79.5 nmol/L
Prolactin	Less than 20 ng/mL	1	Less than 20 mcg/L
Prostate-specific antigen (PSA)	Less than 4 ng/mL	1	Less than 4 mcg/L
Protein, total	6.0–8.0 g/dL	10	60–80 g/L
Prothrombin time (PT)	10–12 seconds		
Quinidine, therapeutic	2–5 mcg/mL or mg/L	3.08	6.2–15.4 μmol/L
Radioactive iodine uptake (RAIU)	Less than 6% in 2 hours		
Red blood cell (RBC) count (blood)			
Male	$4–6.2 \times 10^6/\mu L$	10^6	$4–6.2 \times 10^{12}$/L
Female	$4–6.2 \times 10^6/\mu L$	10^6	$4–6.2 \times 10^{12}$/L
Pregnant			
Trimester 1	$4–5 \times 10^6/\mu L$	10^6	$4–5 \times 10^{12}$/L
Trimester 2	$3.2–4.5 \times 10^6/\mu L$	10^6	$3.2–4.5 \times 10^{12}$/L
Trimester 3	$3–4.9 \times 10^6/\mu L$	10^6	$3–4.9 \times 10^{12}$/L
Post partum	$3.2–5 \times 10^6/\mu L$	10^6	$3.2–5 \times 10^6$/L

(continued)

Laboratory	Conventional Units	Conversion Factor	SI Units
Red blood cell distribution width (RDW)	11.5–14.5%	0.01	0.115–0.145
Reticulocyte count			
Male	0.5–1.5% of total RBC count	0.01	0.005–0.015
Female	0.5–2.5% of total RBC count	0.01	0.005–0.025
Retinol-binding protein (RBP)	2.7–7.6 mg/dL	10	27–76 mg/L
Rheumatoid factor (RF) titer	Negative		
Salicylate, therapeutic	150–300 mcg/mL or mg/L	0.00724	1.09–2.17 mmol/L
	15–30 mg/dL	0.0724	
Sodium	135–145 mEq/L	1	135–145 mmol/L
Tacrolimus			
Renal transplant	6–12 ng/mL or mcg/L		
Liver transplant	4–10 ng/mL or mcg/L		
Pancreatic transplant	10–18 ng/mL or mcg/L		
Bone marrow transplant	10–20 ng/mL or mcg/L		
Testosterone (total)			
Men	300–950 ng/dL	0.0347	10.4–33.0 nmol/L
Women	20–80 ng/dL		0.7–2.8 nmol/L
Testosterone (free)			
Men	9–30 ng/dL	0.0347	0.31–1.04 nmol/L
Women	0.3–1.9 ng/dL		0.01–0.07 nmol/L
Theophylline			
Therapeutic	5–15 mcg/mL or mg/L	5.55	28–83 μmol/L
Toxic	20 or more mcg/mL or mg/L	5.55	111 or more μmol/L
Thrombin time	20–24 seconds		
Thyroglobulin	Less than 42 ng/mL	1	Less than 42 mcg/L
Thyroglobulin antibodies	Negative		
Thyroxine-binding globulin (TBG)	1.2–2.5 mg/dL	10	12–25 mcg/L
Thyroid-stimulating hormone (TSH)	0.35–6.20 microunits/ml	1	0.35–6.20 milliunits/L
TSH receptor antibodies (TSH Rab)	0–1 unit/mL		
Thyroxine (T_4)			
Total	4.5–12.0 mcg/dL	12.87	58–155 nmol/L
Free	0.7–1.9 ng/dL	12.87	9.0–24.5 pmol/L
Thyroxine index, free (FT_4I)	6.5–12.5		
TIBC (See Iron-binding capacity [total])			
Tobramycin, therapeutic	4–10 mcg/mL or mg/L peak	2.14	8.6–21.4 μmol/L
	Less than or equal to 2 mcg/mL mg/L trough	2.14	Less than or equal to 4.28 μmol/L
Transferrin	200–430 mg/dL	0.01	2.0–4.3 g/L
Transferrin saturation	30–50%	0.01	0.30–0.50
Triglycerides (fasting)	Less than 160 mg/dL	0.0113	Less than 1.8 mmol/L
Triiodothyronine (T_3)	45–132 ng/dL	0.0154	0.91–2.70 nmol/L
Triiodothyronine (T_3) resin uptake	25–35%		
Troponin I	Less than 0.6 ng/mL	1	Less than 0.6 μg/L
Uric acid	3–8 mg/dL	59.48	179–476 μmol/L
Urinalysis (urine)			
pH	4.8–8.0		
Specific gravity	1.005–1.030		
Protein	Negative		
Glucose	Negative		
Ketones	Negative		
RBC	1–2 per low-power field		
WBC	3–4 per low-power field		
Valproic acid, therapeutic	50–100 mcg/mL or mg/L	6.93	346–693 μmol/L
Vancomycin, therapeutic trough for CNS infections	20–40 mcg/mL or mg/L peak	0.690	14–28 μmol/L peak
	5–20 mcg/mL or mg/L trough	0.690	3–14 μmol/L trough
	15–20 mcg/mL or mg/L trough	0.690	10–14 μmol/L trough
Vitamin A (retinol)	30–95 mcg/dL	0.0349	1.05–3.32 μmol/L
Vitamin B_{12}	180–1000 pg/mL	0.738	133–738 pmol/L
Vitamin D_3, 1, 25-dihydroxy	20–76 pg/m	2.4	48–182 pmol/L
Vitamin D_3, 25-hydroxy	10–50 ng/mL	2.496	25–125 nmol/L
Vitamin E (alpha tocopherol)	0.5–2.0 mg/dL	23.22	12–46 μmol/L
WBC count	$4–10 \times 10^3/\mu L$ or $4–10 \times 10^3/mm^3$	10^6	$4–10 \times 10^9$/L
WBC differential (peripheral blood)			
Polymorphonuclear neutrophils (PMNs)	50–65%		
Bands	0–5%		
Eosinophils	0–3%		
Basophils	1–3%		
Lymphocytes	25–35%		
Monocytes	2–6%		
WBC differential (bone marrow)			
Polymorphonuclear neutrophils (PMNs)	3–11%		
Bands	9–15%		
Metamyelocytes	9–25%		
Myelocytes	8–16%		
Promyelocytes	1–8%		
Myeloblasts	0–5%		
Eosinophils	1–5%		
Basophils	0–1%		
Lymphocytes	11–23%		
Monocytes	0–1%		
Zinc	60–150 mcg/dL	0.153	9.2–23.0 μmol/L

This table is a modification of the Medical Algorithms Project (Chapter 40), unit conversions of the following Excel worksheets: Conversion of Conventional to SI units: Blood Chemistries; Conversion of Conventional to SI units: Urine Chemistries; Conversion of Conventional to SI units: Hematology and Coagulation; and Conversion of Conventional to SI units: Therapeutic Drug Monitoring.
